The change of slope exhibited by the δ phase resistivity–temperature and susceptibility–temperature graphs at 560°K is probably a direct consequence of the increased rate of expansion of the lattice also observed above 560°K (Knapton 1959, private communication). The increased lattice constants modify the volume of the Brillouin zones and could increase the number of effectively free electrons, thus leading to the observed resistivity behaviour. Alternatively, the expansion could change the average mean free path of the current carriers. One expects, on general grounds, an expansion of the lattice to produce as well an increase in the density of states at the Fermi surface, and this could account for the increased slope in the susceptibility–temperature curve.

Finally it may be mentioned that the susceptibility–temperature behaviour of the δ and γ phases could be connected with the presence of antiferromagnetic order in these alloys with high Néel points, although no such order is found in the pure elements uranium or zirconium. Neutron diffraction measurements with these abnormal alloys would probably be very helpful.

ACKNOWLEDGMENTS

The author is indebted to Professor L. F. Bates for valuable discussion and for supervision of the work, to Dr. A. Knapton of Associated Electrical Industries, Aldermaston, for the thermal expansion data and to Dr. W. E. Gardner of the Atomic Energy Research Establishment, Harwell, for the provision of the alloys and much helpful discussion. Thanks are also due to the Director of the Atomic Energy Research Establishment, Harwell, for permission to publish the results.

Magnetostriction in Antiferromagnetic Nickel Oxide

By L. ALBERTS† and E. W. LEE
Department of Physics, The University, Sheffield

MS. received 1*st May* 1961

Abstract. Measurements of magnetostriction on a single crystal of antiferromagnetic nickel oxide were made in fields up to 21 kilo-oersteds. The order of magnitude of the magnetostriction is the same as that for ferromagnetic materials, viz. about -20×10^{-6} and a square law relation, with field, is obeyed up to several thousand oersteds before a gradual saturation tends to set in. The dependence of strain on field and measuring directions is described with respect to axes that constitute cylindrical symmetry.

§ 1. Introduction

Nickel oxide, NiO, is an antiferromagnetic substance with a Néel temperature of 523°K (La Blanchetais 1951). Above 523°K it has a cubic structure of the NaCl type. In the antiferromagnetic state below this temperature the spins are ordered in such a way that within a given (111) plane the spins are all parallel, but are antiparallel to those in adjacent (111) planes. This ordering results in a slight contraction of the [111] axis which is normal to the planes containing the spins (Slack 1960, Roth 1960). The unit cell can then be regarded as rhombohedral with a rhombohedral angle of 90°4′ at room temperature. As a result of this distortion a crystal having spins in different sets of octahedral planes will be twinned. These twin boundaries can normally be permanently removed by application of mechanical stresses or large fields (Slack 1960, Roth 1960), thereby reducing the crystal to one with all the spins in a single set of parallel octahedral planes. Indeed, it appears from Slack's and Roth's work that it requires rather careful heat treatment and subsequent handling to produce and maintain these twin boundaries in single crystals of NiO.

There appears to be no, or at least very small, inherent anisotropy with the (111) planes containing the spins (Roth and Slack 1960) and the antiferromagnetic domain orientation must be essentially determined by internal stresses, lattice imperfections etc. In the presence of a magnetic field the lowest energy state is one in which the spin-alignment axis is perpendicular to the field and consequently the domains can be aligned in moderate fields without significantly affecting the antiparallel ordering within the domains themselves. Exceedingly large magnetic forces will be required to rotate the spins appreciably out of the octahedral planes.

If a spontaneous magnetostriction exists within the domains, alignment of the latter will result in an overall strain of the crystal. Because the spin directions are confined to a plane the longitudinal and transverse strains within this plane will be equal and opposite provided that there is a random distribution of domains and that the volume magnetostriction is negligible. Since this is the case in ferromagnetic substances where the nature of the spin interaction is similar such an assumption seems quite reasonable.

---

† On leave from Department of Physics, University of the Orange Free State, South Africa.

Magnetostriction in polycrystalline NiO has been reported by Belov and and Levitin (1959). The strains they observed were very much smaller than those reported here in comparable field strengths and this might be responsible for the fact that they observed an effect only when a certain threshold field had been exceeded. Measurements on CoO crystals by Nakamichi and Yamamoto (1961) show that the magnetostriction increases steadily as the applied field is increased from zero. They also reported a variation of magnetostriction, in single crystals of NiO, with field direction, similar to that found here.

§ 2. EXPERIMENTAL PROCEDURE AND RESULTS

The crystal was kindly supplied by Dr. K. Hoselitz of Mullard Research Laboratories. It was approximately 6 mm square and 1 mm thick. X-ray analysis showed that the two parallel flat surfaces lay in a (227) plane. This is the plane ABC in Fig. 1 with $OA = OB$ and $\theta = 22°$ (where OB is perpendicular to AB).

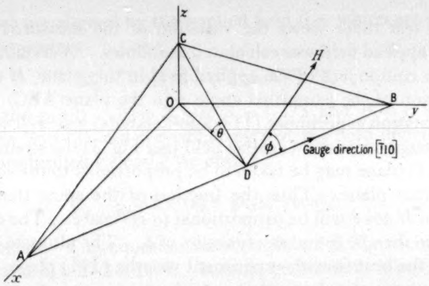

Fig. 1

The magnetostriction was determined by the usual strain gauge technique. The sensitivity and stability of the arrangement was such that the strain of 10^{-7} could be measured. A small strain gauge (Tinsley, Type 20A, Special) was fixed along the direction AB, i.e. in the $[\bar{1}10]$ direction. The crystal was mounted with the plane ABC horizontal so that the magnetic field, when the electromagnet was turned about a vertical axis, also rotated in this plane.

The experimental results are shown in Figs 3 and 4 and will be discussed separately.

§ 3. THEORETICAL CONSIDERATIONS

The observation of a strain in a NiO crystal on application of a magnetic field could, in principle, be due to (*a*) movement of twin boundaries, (*b*) the alignment of antiferromagnetic domains within the octahedral planes and (*c*) rotation of the spins out of the octahedral planes. Of these (*a*) can be ruled out immediately since it would give rise to a magnetostrictive strain which would be (1) negative, (2) irreversible and (3) would commence only in fields greater than about 5 kilo-oersteds (Slack 1960). However, preliminary x-ray analysis showed the crystal used here to be untwinned and a subsequent investigation using the high resolution afforded by Kössel lines due to fluorescence from the nickel atoms confirmed this. (These X-ray determinations were kindly carried out by Dr. P. Gaunt.) With regard to (*c*), bearing in mind that the transverse susceptibility of NiO is certainly not greater than 10^{-4}, an elementary calculation shows that the corresponding strain would be smaller than that actually observed by several orders of magnitude. The magnetostriction which we observed was positive, completely reversible and increased continuously as the field was increased from zero. These facts, coupled with the absence of twin boundaries lead to the conclusion that the observed magnetostriction must be due to movement of antiferromagnetic domains in which the spins are confined within the octahedral planes. Since the inherent crystal anisotropy in an octahedral plane is very small and the local 'easy directions' are presumably determined by internal stresses the type of domain movement which we envisage is different from that which occurs in a single crystal of, say, iron and is more akin to the situation in cold-worked nickel where the local easy directions are determined by local internal stresses and magnetization is believed to occur by coherent rotation of quite large groups of spins.

In order to test these views the variation of the measured strain with the direction of the applied field was calculated as follows. A certain (111) plane was selected and the component of the applied field in this plane, $H \cos \xi$, was calculated as a function of the azimuthal angle ϕ in the plane ABC. Since the field applied in the rotation experiment (11·6 kilo-oersteds) was well within the square law relation of magnetostriction against field (see Fig. 3) the strain in any direction in the given (111) plane may be taken to be proportional to the square of the field component in that plane. Thus the fraction of the spins that set themselves perpendicular to $H \cos \xi$ will be proportional to $H^2 \cos^2 \xi$. The direction cosines of these spins can then be found as a function of ϕ. The ultimate octahedral plane selected to give the best fit with experiment was the $(\bar{1}1\bar{1})$ plane.

By geometry it may be shown that

$$\cos^2 \xi = \frac{\frac{1}{3}\lambda^2 + \frac{2}{3}\tan^2\theta + (\sqrt{\frac{2}{3}})\lambda \tan\theta + 1}{\lambda^2 + \tan^2\theta + 1} \qquad \ldots\ldots (1)$$

where

$$\lambda = \left(\frac{2 + \tan^2\theta}{1 + \cos^2\theta}\right)^{1/2} \cot\phi$$

and $\theta = 22°$ as determined by X-rays. The direction cosines of the aligned spins (perpendicular to $H \cos \xi$) are

$$(1 - \lambda - \sqrt{2}\tan\theta)s, \quad -(\lambda + 1 + \sqrt{2}\tan\theta)s, \quad -2s, \qquad \ldots\ldots (2)$$

where $s = \{6 + 2(\lambda + \sqrt{2}\tan\theta)^2\}^{-1/2}$. These equations neglect the very small rhombohedral distortion as may be readily justified. The spins are parallel to the $(\bar{1}1\bar{1})$ plane and this may be taken as the base of a cylinder with the $[\bar{1}1\bar{1}]$ direction as axis. The strain in such a case is given by (Carr 1959)

$$\begin{aligned} \frac{dl}{l} &= k_0 + k_1\beta_3^2 + (k_2 + k_3\beta_3^2)\alpha_3^2 + k_4(\alpha_1\beta_1 + \alpha_2\beta_2)^2 \\ &\quad + k_5(\alpha_1\beta_1 + \alpha_2\beta_2)\alpha_3\beta_3 \qquad \ldots\ldots (3) \end{aligned}$$

where the α's and β's are the direction cosines of the spins and the measuring direction with respect to a set of orthogonal axes such that $\alpha_3 = 1$ corresponds to the cylinder axis and the k's are constants. If now the $[1\bar{1}\bar{2}]$ direction in the $(\bar{1}1\bar{1})$ plane is taken as the direction $\alpha_2 = 1$ (see Fig. 2), then it may be shown that

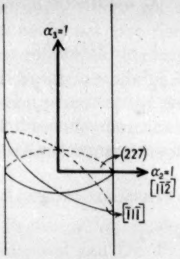

Fig. 2

those spins which are aligned by the applied field (i.e. which are perpendicular to it) have direction cosines

$$\alpha_2 = \{1 + \tfrac{1}{3}(\lambda + \sqrt{2}\tan\theta)^2\}^{-1/2},$$

$\alpha_1 = (1 - \alpha_2{}^2)^{1/2}$ and $\alpha_3 = 0$. Also $\beta_1 = 0$, $\beta_2 = 1/\sqrt{3}$ and $\beta_3 = \sqrt{\tfrac{2}{3}}$. Substituting these values into Eqn (3) and remembering that the field dependent part of the strain must be multiplied by $\cos^2 \xi$ we obtain

$$\frac{dl}{l} = k + (k_0 + \tfrac{1}{3}k_4\alpha_2{}^2)\cos^2\xi \qquad \ldots\ldots (4)$$

where k is a constant. This equation has been plotted in Fig. 4 with $k = 4{\cdot}55 \times 10^{-6}$, $k_0 = 1{\cdot}4 \times 10^{-6}$ and $k_4 = 27{\cdot}3 \times 10^{-6}$. It must be borne in mind that these values are applicable only for a particular field.

§ 4. DISCUSSION AND CONCLUSIONS

The agreement between Eqn (4) and the experimental values shown in Fig. 4 is satisfactory and would seem to confirm the basic premise that the observed magnetostriction is solely due to rotation of the spins within a set of (111) planes.

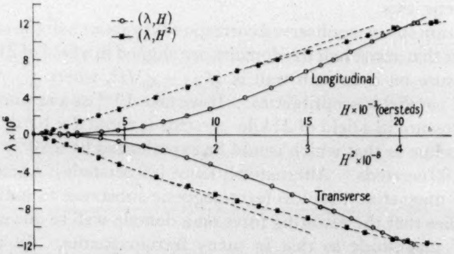

Fig. 3. Variation of longitudinal and transverse magnetostriction with field.

Fig. 3 shows that the longitudinal magnetostriction λ_L is proportional to H^2 up to 15 kilo-oersteds. For the transverse measurement λ_T the departure from the square law relation sets in about 12 kilo-oersteds. Within the square law region one may write

$$\lambda_{\mathrm{L}} = aH^2 \cos^2 \xi_{\mathrm{L}}$$

and

$$\lambda_{\mathrm{T}} = aH^2 \cos^2 \xi_{\mathrm{T}}$$

where a is a constant and cos ξ_{L} and cos ξ_{T} are to be obtained from Eqn (1). For a given value of H, therefore, $\lambda_{\mathrm{L}}/\lambda_{\mathrm{T}} = \cos^2 \xi_{\mathrm{L}}/\cos^2 \xi_{\mathrm{T}}$, which for the crystal used here is equal to 0·302. The measured value of 0·90 can be accounted for by the presence of a preferred domain orientation similar to that frequently observed in ferromagnetic materials.

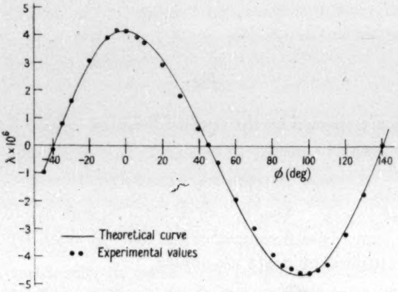

Fig. 4. Variation of magnetostriction with azimuthal angle ϕ in the plane of the crystal: magnetic field 11·6 kilo-oersteds.

As Fig. 2 shows, the magnetostriction shows a tendency towards saturation in the highest fields that were attainable.

An attempt to deduce the saturation value by fitting the high-field end of the longitudinal magnetostriction curve to the equation $\lambda = \lambda_s - c/H$ yielded the value $\lambda_s = 26 \times 10^{-6}$ but this is necessarily uncertain since an equation of this form is usually valid only in the region very close to saturation. Visual inspection of the curve leads to a value $\lambda_s \sim 20 \times 10^{-6}$. This means that there is a spontaneous magnetostriction in NiO which is roughly -20×10^{-6} in the direction of the antiferromagnetic axis.

The maximum strain we observed corresponds to about half the saturation value and this implies that about half the domains are aligned in a field of 21 kilo-oersteds. Now the pressure on a domain wall is $\frac{1}{2}(\chi_{\perp} - \chi_{\parallel})H^2$, where $\chi_{\perp}$ and $\chi_{\parallel}$ are the transverse and parallel susceptibilities. If we take 10^{-5} as a reasonable figure for $\chi_{\perp} - \chi_{\parallel}$, the pressure in a field of 21 kilo-oersteds is about 2×10^5 dyn cm^{-2}, which is roughly the same as that which would be experienced by a 90° wall in iron in a field of about 100 oersteds. Alternatively since 100 oersteds is a field which would be required to magnetize a typical ferromagnetic substance to half its saturation value this implies that the restoring force on a domain wall in our crystal is of the same order of magnitude as that in many ferromagnetics. In polycrystalline NiO, on the other hand, the observed magnetostriction is smaller by an order of magnitude (Belov and Levitin 1959) which implies that the restoring force on the domains walls are greater by a similar factor. Thus although movement of antiferromagnetic domain walls will give rise to a change in Young's modulus at the

Néel temperature as observed, for example, by Street and Lewis (1951) in polycrystalline NiO, it is very difficult to account for the magnitude of the changes they observed (a factor of about two) in terms of the same domain wall movement that is responsible for the magnetostriction which we observe. Our measurements suggest that such a mechanism could not give rise to an effect in NiO which is significantly greater than that observed in ferromagnetics. A more likely explanation is that the change in Young's modulus (which in NiO is a maximum at the Néel point whereas in nickel it occurs at the temperature of minimum anisotropy) is a consequence of the discontinuous changes in the thermal expansion coefficient and specific heat which accompany a second-order phase transition.

ACKNOWLEDGMENTS

It is a pleasure to thank Professor W. Sucksmith for putting all possible departmental facilities at our disposal and Dr. P. Gaunt for generous help and useful discussions in connection with the x-ray determinations.

The Electric Breakdown of Sodium Chloride

By R. COOPER and W. A. SMITH
Electrical Engineering Laboratories, University of Manchester

MS. received 25*th November* 1960, *in revised form* 30*th May* 1961

Abstract. Experiments are described which establish that the electric strength of sodium chloride decreases slowly with increase in specimen thickness. Flat topped impulses were used and the time lag to breakdown of each specimen was measured. The mean statistical time lag depended on the nature of the cathode, and it rapidly decreased with increase in the size of voltage increment. The characteristics of breakdown are similar to those predicted by the single avalanche theory of Seitz according to which disruption results from the passage of an electron avalanche exceeding a critical size.

§ 1. Introduction

Current theories of intrinsic electric breakdown in solid dielectrics have been comprehensively reviewed by Stratton (1961), who concluded that the collective electron mechanism of Fröhlich and Paranjape (1956) and not the single avalanche mechanism (Seitz 1949) is applicable to the alkali halides.

In collective breakdown it is assumed that the initial density of free electrons is sufficiently great for the inter-electron collisions to determine the electron energy distribution. This is Maxwellian but the electron temperature exceeds the lattice temperature by an amount that increases with the applied field. No steady state is possible if the field exceeds a critical value and the material is rapidly destroyed. The critical field is the intrinsic electric strength of the material and it is independent of the specimen size.

In avalanche breakdown, destruction of the material results from the passage of an electron avalanche exceeding a certain size. This avalanche grows from a single electron injected at the cathode. The critical size is determined by considering the energy balance in the cylindrical volume containing the avalanche, and estimating the electron density required to melt the material at the head of the avalanche near to the anode. The criterion of breakdown is similar to that of the streamer theory of gas breakdown (Loeb and Meek 1940) and as in gas breakdown statistical time lags are predicted with the distribution $N_t = N_0 \exp(-t/T)$. Here N_t is the number of time lags in excess of t, N_0 the total number of time lags and T is the mean statistical time lag. This is equal to the reciprocal of the product of the probability P_1 of electron injection and the probability P_2 of the electron growing into an avalanche in excess of the critical size. The mean statistical time lag depends on the cathode and decreases rapidly when the field increases beyond a certain value. A further prediction of the single avalanche theory is that the electric strength decreases with increase in specimen thickness. This distinguishes the avalanche theory from the collective electron theory because in the latter case a chance fluctuation may give rise to the necessary high density of free electrons and therefore the observation alone of statistical time lags (Cooper and Grossart 1956) is indecisive.

The predicted thickness effect is small in the range generally found convenient for intrinsic strength investigations using alkali halide crystals. It has not yet been detected but it could be obscured by the spread often observed in comparable values of electric strength (Cooper and Wallace 1956). Stratton (1961) drew his conclusion from a comparison of results obtained by Calderwood and Cooper (1953) and by Kawamura and Ryu (1954) but the validity of this comparison is questionable. There is a dearth of experimental evidence both about statistical time lags and about the influence of thickness on the breakdown of alkali halide crystals and the question of the operative mechanism is still open.

§ 2. METHOD

The specimens were of the plane-recessed type, prepared from (100) plates by the method of Calderwood, Cooper and Wallace (1953). The ranges of specimen thickness extended from about 0·01 cm to about 0·07 cm. This was determined by the necessity of using economically the available parent crystals. Specimens thinner than about 0·01 cm are easily cracked and specimens thicker than about 0·1 cm require much material to provide adequate flashover distances. The surfaces of the specimens were highly polished with a commercially available plastic polish, and then they were annealed at about 10 deg c below the melting point for several hours. This treatment makes the group more homogeneous by removing strains produced in preparing the specimens. It also renders a previously polished surface translucent (Smith 1956). Therefore, upon completion of annealing, the surfaces of each specimen were repolished so that it could be examined with transmitted light in a polarizing microscope. The minimum thickness of each specimen was measured to within ±3%. A dial gauge micrometer calibrated in divisions of 10^{-4} in. was used and the method was such that no spring pressure was applied to the specimen during the measurement.

The electric strength of each specimen was determined by applying a series of 0·8 : 8000 μsec voltage impulses. The amplitude of each impulse exceeded that of the preceding one by the same percentage and the wave was displayed on a cathode-ray oscilloscope and photographed. The time lag from the peak of the wave to the collapse of voltage at breakdown was measured from an enlargement of the oscillogram, and it was the sum of the formative time and the statistical time lag. The former is believed to be less than 10^{-7} sec (Whitehead 1951) and this estimation is confirmed by the present investigation (see § 3). The estimated error in time lag measurement was 0·2 μsec.

The impulses were obtained from a single-stage impulse generator and the amplitude of each impulse was determined by multiplying the charging voltage by the efficiency of the generator. The charging voltage was stabilized and the ripple was less than 0·02% of the mean voltage. An irradiated 6·25 cm diameter sphere gap was used for standardization purposes. The estimated error in voltage measurement was within ±4%. The electrode system was similar to that described by Calderwood, Cooper and Wallace (1953) and the ambient was silicone oil.

§ 3. Time Lags

The results illustrated in Fig. 1 show that the time lag distribution is influenced by the nature of the cathode. Curves *a* and *b* were obtained from specimens whose surfaces had been polished, and the cathode material was deposited on to the residue of this operation. In the former case the cathode material was soduim, deposited after baking the specimens in a vacuum for two days at 150°c, and backed by an evaporated layer of base metal to give protection against oxidation. The cathodes used in the experiment of curve *b* were colloidal graphite. Curve *c* was also obtained by using specimens with colloidal graphite cathodes but they were deposited on to the translucent crystal surfaces produced by the annealing treatment, i.e. the second polishing of the crystal surfaces was omitted.

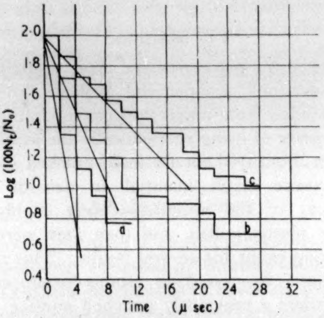

Fig. 1. Effect of cathode on time lag distribution. *a*, 67 specimens with sodium cathodes applied to polished surfaces. $T_{av}=1$ μsec, $S=1{\cdot}5$ μsec; *b*, 100 specimens with graphite cathodes applied to polished surfaces. $T_{av}=3{\cdot}2$ μsec, $S=4{\cdot}5$ μsec; *c*, 66 annealed specimens with graphite cathodes applied to unpolished surfaces. $T_{av}=11$ μsec, $S=17$ μsec.

The average time lag T_{av} and the standard deviation S are quoted in Fig. 1 for each group. Lags exceeding ten times the quoted average value were neglected in the calculation and consequently the values of T_{av} and S are not influenced by the few exceptional results. The size of the groups determined the sensitivity of the investigation. This was limited by the work involved in preparing specimens. A reasonable criterion of significance is that the difference between sample means should be greater than three times the standard error of the difference. With random sampling, this is likely to happen by chance in less than 1% of the trials. The differences between the average time lags quoted in Fig. 1 are significant, according to this standard.

Experiments were also performed with specimens possessing cathodes of evaporated gold, and silver, deposited on to polished crystal surfaces. The time lag distributions were similar to that illustrated in Fig. 1, curve *b*, and in both cases T_{av} was about 3 μsec.

In order to determine if T_{av} was influenced by the initial state of strain, the specimens used to obtain Fig. 1, curve *b*, were divided into two sub-groups. One sub-group consisted of 65 specimens and with these the annealing treatment was omitted. The difference between T_{av} for the two sub-groups was less than 0·5 μsec and this is not significant. Values of electric strength are quoted in §4. The small differences in the sizes of comparable groups in Tables 3 and 4 are due to occasional recording omissions.

Table 1. Influence of Voltage Increment on Mean Time Lag

(1)	(2)	(3)	(4)	(5)
Graphite applied to polished surface	1	29	14·5	17
Graphite applied to polished surface	4	95	3·2	4·5
Graphite applied to unpolished surface	4	63	11·0	17
Graphite applied to unpolished surface	12	42	2·2	4·1

(1) Cathode; (2) voltage increment (%); (3) number; (4) T_{av} (μ sec); (5) standard deviation S.

The influence of the voltage increment on T_{av} is illustrated by the results quoted in Table 1. Appreciable error is possible in the measurement of time lags less than 1 μsec and therefore the scale of the distribution for 12% voltage increments was extended by using specimens with their surfaces left unpolished after annealing. The results illustrated in Fig. 1, curves *b* and *c*, together with the measured value of 2·2 μsec for T_{av} suggest about 0·8 μsec is appropriate for specimens with polished surfaces, when they are broken down using 12% voltage increments. This estimation is supported by the fact that wavetail breakdown was not observed when a single 0·5 : 500 μsec impulse of peak voltage sufficient to produce a stress of 1·5 MV cm^{-1} was applied to polished specimens of NaCl. It is evident that T_{av} diminishes with increase in the voltage increment.

With respect to the formative time lag in the breakdown of alkali halide crystals, the result illustrated in Fig. 2 (Plate) is of interest. This is a photograph of the discharge damage caused during the intrinsic breakdown of an annealed specimen of KCl. A single impulse, producing a peak electric stress of 1·5 MV cm^{-1}, was applied to the specimen. The voltage wave increased approximately linearly, and reached the peak value in about 0·03 μsec. The voltage across the specimen collapsed after another 0·03 μsec from the peak of the wave, when it had decayed to about 95% of the peak value. A value about 1·0 MV cm^{-1} may be assumed for the electric strength of the specimen, measured with 1 : 5000 μsec waves (Cooper, Grossart and Wallace 1956) and therefore the stress applied to the above specimen exceeded this value for about 0·04 μsec. Referring to Fig. 2, a partly completed discharge track can be seen to the left of the main discharge channel. It extends from the anode into the body of the specimen and terminates half way to the cathode. This is a suppressed discharge (Meek and Craggs 1953) and its presence indicates the formative time to be less than 0·04 μsec. Experiments have shown (Cooper, Higgin and Smith 1960) that the behaviour of KCl with respect to time lags is similar to that of NaCl. The formative time lag is a negligible fraction of the measured time.

§ 4. Electric Strength

Average, maximum, and minimum values of electric strength, obtained from the groups of specimens used in the time lag studies, are compared in Table 2 and the significant minimum values, for annealed specimens, are constant to within ±6% of 0·74 MV cm^{-1}. The electric strength of sodium chloride is independent of the cathode material. Apart from the cathode, the 240 specimens used to obtain the information stated in rows (1) to (5) of Table 2 were similar, and they were broken down in the same way. The range of specimen thickness extended from 0·01 cm to 0·06 cm and the result of dividing, according to thickness, the above group into seven sub-groups is stated in Table 3. Comparable values of electric strength decrease as the thickness of the specimens in the sub-groups increases. The effect is smallest for the minimum values of electric strength. The product moment correlation coefficient obtained from these values of electric

strength (column (2), Table 3) and the corresponding specimen thickness (column (7), Table 3) is $-0{\cdot}94$ and Student's '*t*' test shows that the probability of this value occurring by chance is less than 1% and nearly 0·1%. Evidence is thus provided of a decrease in the electric strength of NaCl with increase in specimen thickness.

The field distribution in a plane-recessed specimen depends upon the ratio of cavity radius R to specimen thickness t. Assuming breakdown occurs when the maximum stress (at the surface of the recess) becomes equal to a thickness-independent intrinsic electric strength, the effect of decreasing the ratio R/t on the measured electric strength (i.e. mean stress at breakdown) can be estimated (Loeb and Meek 1940). The effect is very small in the range of R/t used in this investigation. This is confirmed by comparing the values of electric strengths quoted in rows (7) and (8) of Table 3. The thickness effect cannot be accounted for by changes in the field distribution due to varying the specimen thickness t and not keeping the ratio R/t constant.

Corroboration of the thickness effect is provided by the behaviour of the variances, stated in column (5) of Table 3, which become small when the average electric strength of the group decreases below about 0·9 MV cm^{-1}. This can be explained by considering the interaction of the mechanical and electrical phenomena, which may occur in measuring the electric strength of alkali halide crystals (Cooper and Wallace 1956). If the electric field applied to annealed NaCl exceeds about 0·9 MV cm^{-1}, the Coulomb force between the electrodes is sufficient to cause plastic deformation of the crystals. The electric strength ultimately achieved is determined by the work hardening characteristic, which is not the same for apparently similar annealed specimens. This is the cause of the large spread in values of electric strength (Table 2). The above value is independent of specimen thickness between 0·012 cm and 0·045 cm, where observations have been made. If the electric strength of the specimens falls below 0·9 MV cm^{-1} the spread in comparable values should approach that expected from known experimental errors and this is the case. In the final group, row (8), of Table 3 only one specimen possessed electric strength exceeding 0·9 MV cm^{-1} and the spread about the average of the remainder was less than ± 10%.

§ 5. SECONDARY FACTORS

An apparent decrease of electric strength with increase in specimen thickness is observed when breakdown results from damage caused by ambient discharges (Whitehead 1932). Also in this circumstance, the apparent electric strength depends on the time of application of voltage because the breakdown results from cumulative damage and the longer the application of voltage the lower is the apparent electric strength. In the experiments described previously about ten 0·8 : 8000 μsec impulses were applied, on average, to each specimen and the application of twenty impulses was rare. The absence of injurious discharges is established if it can be shown that the electrode system yields values of electric strength independent of the number of impulses applied. The experiment was carried out as follows.

The impulse generator was charged from a constant voltage source and it was tripped automatically every 30 seconds, the total number of impulses being recorded with an electromechanical counter. The specimens were provided with graphite electrodes. The electrode system was similar to that used in the experiments previously described and it was immersed in silicone oil. The initial voltage applied to each specimen was adjusted to produce not less than 0·70 MV cm^{-1} in the region of minimum thickness. One thousand impulses of the same amplitude were applied, and then the amplitude was increased by 4%, and another 1000 impulses of fixed amplitude were applied, and so on until the specimen broke down. A resistance of about 100 ohms was connected in series with the specimen to provide some protection against damage and to produce, upon breakdown, a voltage to operate a relay and switch off the generator. Fifteen specimens in the thickness range 0·038 cm to 0·050 cm were broken down. Five failed due to discharge damage at the edges of the colloidal graphite electrode. The minimum apparent electric strength in this group was 0·75 MV cm^{-1} and the specimen withstood 1177 impulses. The maximum apparent electric strength was 0·89 MV cm^{-1} and the specimen withstood 5613 impulses. The average number of impulses for this sub-group was 2957 and the average electric strength was 0·83 MV cm^{-1}. The puncture in the remaining ten specimens was at the bottom of the recess and the values of electric strength ranged from 0·75 MV cm^{-1} to 1·1 MV cm^{-1}. The numbers of impulses applied to these two extreme cases were respectively 2100 and 11 107. The range of electric strengths obtained in this experiment is similar to that stated in Table 3 for specimens of comparable thickness, and obtained by applying on average about ten impulses. Therefore, there is no reason to believe that ambient discharges had influenced the measurements described previously.

The apparent electric strength may decrease with specimen thickness if space charges occur, because the applied voltage is dropped over relatively thin layers of crystal near to the electrodes. There has been speculation in the past about the effect of ionic migration upon the measurement of the electric strength of the alkali halides. These materials conduct by the transport only of positive ions at the temperatures generally used in the study of electric breakdown and the possibility must be considered of both thermal and space charge effects. The influence of ionic conductivity upon the electric strength of NaCl measured at room temperature, using 1 : 8000 μsec impulses, and specimens similar to the ones used in the present investigation, has recently been determined by Cooper, Higgin and Smith (1960). The ionic conductivity was controlled by the addition of small amounts of $CdCl_2$ and it was found that the electric strength of NaCl at 20°C was not changed by increasing the ionic conductivity up to sixty-fold. Previous investigators have claimed (e.g. Caspari 1955) that the electric strength of alkali halide crystals depends upon the cathode material. The effect has been attributed to electronic space charges created by field emission, the rate of which was assumed dependent on the cathode material. The present experiments provide no evidence of this since there is no correlation between corresponding values of average time lag and average electric strength. When a cathode effect has been claimed, the evidence usually consists of apparent differences between the average electric strengths of very small groups of unannealed specimens and may be doubted for statistical reasons.

§ 6. DISCUSSION

The characteristics of electric breakdown established for sodium chloride are similar to those predicted by the single avalanche theory. The deviation (see

Fig. 1) from the theoretical time lag distribution law $N_t = N_0 \exp(-t/T)$ follows from the manner of performing the experiments. This law is based on the assumption that the probability of a suitable avalanche remains constant but this was not the case throughout each experiment. Using solids, the minimum peak voltage required to cause breakdown in the time permitted by the form of the voltage wave cannot be determined, as a preliminary to the experiment, because of the destructive nature of this test. Fixed voltage increments were applied to each specimen but the overvoltage at breakdown measured relative to the above voltage was not known and it was most unlikely to be the same for all of the specimens in each group. A number of excessively long time lags are to be expected from those specimens in a group that break down with relatively small overvoltages and the effect is to raise the tail of the distribution above the theoretical curve in the way illustrated by Fig. 1. The form of the voltage wave also contributed to this effect since the probability of a suitable avalanche decreased as the voltage decreased from the peak value.

The initiating electrons in avalanche breakdown are assumed to be provided by field emission at the cathode. The rate of emission for the various cathodes cannot be determined because the average time lag depends also on the probability of an electron growing into a suitable avalanche. It is evident however that several electrons per microsecond must have been provided in the active region of the specimen, which probably was a cylinder of diameter 0·1 cm and length equal to the specimen thickness. With these assumptions, the emission must have amounted to about 10^{-11} A cm^2 or greater. Little appears to be known about the cold emission of electrons into solid dielectrics but Geller (1956) has obtained currents exceeding 10^{-10} A cm^2 in crystals of KBr. This material is similar to NaCl in its behaviour with respect to time lags. Geller found the rate of emission was not very sensitive to the metal used as cathode but it was effected by the treatment applied to the crystal surface. These results are not inconsistent with the ones obtained in the present investigation. The difference between the average time lags of 3·2 μsec and 11 μsec, obtained respectively from specimens with polished and unpolished crystal surfaces and using graphite cathodes in both cases, is attributed to a difference in the composition of the contaminated surface layers of the crystals.

There are various difficulties in the calculation of electric strength, according to the avalanche theory and these have been discussed by Stratton. The predicted effect of thickness for sodium chloride in the range of 0·02 to 0·06 cm amounts to a decrease in electric strength of from about 1·0 to about 0·85 MV cm^{-1}. The observed decrease was from 0·8 to 0·7 MV cm^{-1}. The critical avalanche according to Seitz's criterion will cause melting of the material in the region of maximum electron density and the processes causing propagation of the molten channel back from the anode to the cathode are speculative.

ACKNOWLEDGMENTS

We wish to acknowledge the kindness of Dr. R. Stratton who provided a copy of his review paper before its publication and the help of Dr. D. T. Grossart in making preliminary measurements using a specimen with sodium cathodes. The photograph of Fig. 2 was obtained in this laboratory by Dr. A. Fernandez.

APPENDIX

The electric strength of annealed KBr is low, and the mechanical force between the electrodes is insufficient to deform plastically the crystal before electrical breakdown occurs. The spread in values of electric strength obtained from comparable annealed specimens of KBr is mainly determined therefore by the random errors of measurement, although some variation must still arise from relatively small structural differences which remain after annealing. Fewer specimens than in the case of NaCl are required to establish the thickness effect in the breakdown of KBr. The result of this experiment is stated in Table 4.

Table 4. Influence of Thickness on Electric Strength of KBr

(1)	(2)	(3)	(4)	(5)	(6)
0·018–0·030	0·50	0·58	0·69	0·0033	14
0·053–0·061	0·44	0·48	0·55	0·0014	12

(1) Thickness range (cm); (2)–(4) electric strength (MV cm^{-1}): (2) minimum, (3) average, (4) maximum; (5) variance; (6) number.

The method was similar to that used for NaCl and the electrodes were colloidal graphite applied to polished crystal surfaces. In the absence of large spread due to mechanical work hardening, average values of electric strength provide a better comparison than do minimum values. Student's '*t*' test indicates that the difference between the average values stated in Table 4 is significant at the 0·1% level. Similar values of electric strength were obtained from specimens of KBr using voltages that increased approximately linearly at the rate of 2 kv sec^{-1} (approx).

Photofluorescence Decay Times of Organic Phosphors

By T. D. S. HAMILTON†
Department of Physics, Rhodes University, Grahamstown, South Africa

MS. received 15*th March* 1961

Abstract. An accurate and convenient method for measuring photofluorescence decay times in the nanosecond region is described. Results are given for a number of organic compounds and reasons for differences with previous results are discussed. For anthracene, a value of 24·2 nsec has been measured for a 1 cm cube crystal. Some previous results for quantum efficiencies are corrected on the basis of these measurements and apparent inconsistences examined with regard to the mean free path of excitons in very thin crystals.

§ 1. Introduction

Photofluorescence decay times of organic phosphors have been measured by a number of workers (Hanle *et al.* 1951, Liebson 1952, Birks and Little 1953), but a comparison of the results (Table 1) shows large differences. To measure these decay times, which fall in the range 10^{-7} to 10^{-9} sec, a number of methods have been used, as detailed in the references above. The methods depend in general on the measurement of phase differences at high frequencies (of the order tens of Mc/s). This necessitates the calibration of a phase changer at these frequencies which is difficult to do with great accuracy. The method to be

described in the present paper depends on the calibration of a d.c. galvanometer which can be carried out much more easily and accurately.

§ 2. OUTLINE OF METHOD

The present method is based on that originally suggested by Tumerman (1941) and the development of this by Bailey and Rollefson (1953). If we consider the excitation of a phosphor by light modulated at a high frequency, then, due to the finite decay time, there will be a phase difference between the exciting and fluorescent light. Tumerman showed that the phase difference ϕ was related to the decay time τ by the equation

$$\tan\phi = \omega\tau \qquad \ldots\ldots(1)$$

where ω is the angular frequency of modulation of the exciting light. This equation is the basis of the methods previously used. It may be shown (§ 3) that there is also a relation between the relative degree of modulation of the exciting and fluorescent light and the decay time. This forms the basis of the present method. The degree of modulation is the ratio of the varying to the steady component of the signal. In measuring the relative modulation of the two signals the varying components are made equal, by adjusting the intensity of the incident light, so that any non-linearity in the r.f. detector is eliminated. The relative modulation is then just the ratio of the two steady components.

§ 3. THEORY OF THE METHOD

Consider a phosphor excited by light, the intensity of which will be represented by a Fourier series to allow for harmonic components. The basic assumption made in all measurements of photofluorescence decay times is that the decay is exponential. This is to be expected theoretically for a monomolecular process, but it does not necessarily hold when there is re-absorption in the phosphor. This case is discussed in § 4. Following Bailey and Rollefson, the differential equation relating the fluorescence intensity I to the exciting intensity $J(t)$ is

$$\frac{dI}{dt} = -k_1 I + k_2 J(t) \qquad \ldots\ldots(2)$$

where k_1 and k_2 are constants and the decay time $\tau = 1/k_1$. The intensity of the exciting light will be represented by

$$J(t) = \tfrac{1}{2}a_0 + \sum_n \left[a_n \cos(n\omega t) + b_n \sin(n\omega t)\right] \qquad \ldots\ldots(3)$$

where $n = 1, 2, 3 \ldots$, a_n and b_n are constants depending on n and $\tfrac{1}{2}a_0$ is the average intensity of the exciting light. The equation obtained by substituting (3) in (2) is easily solved to give

$$I = \frac{a_0 k_2}{2k_1} + k_2 \sum_n \left[\frac{a_n \cos(n\omega t - \phi_n)}{(k_1^2 + n^2\omega^2)^{1/2}} + \frac{b_n \sin(n\omega t - \phi_n)}{(k_1^2 + n^2\omega^2)^{1/2}}\right] + C\exp(-k_1 t) \qquad \ldots\ldots(4)$$

where the phase angle ϕ_n is given by

$$\tan\phi_n = \frac{n\omega}{k_1} = n\omega\tau \qquad \ldots\ldots(5)$$

which corresponds to the result of Tumerman. The final term is an initial perturbation and becomes negligibly small as t becomes large compared with $1/k_1$, i.e. $tk_1 \gg 1$. Since $1/k_1 = \tau$ is of the order of 10^{-8} sec in the present work this term will very soon vanish. The intensity I of fluorescence thus contains terms corresponding to each term in the expression (3) for the exciting light $J(t)$. The relation between modulation and decay time is most easily seen if we simplify the expression for $J(t)$. If we have a suitable detector we need consider only one frequency component, i.e. for all terms with $n > 1$, $a_n = b_n = 0$, and, by a proper choice of time scale, either a_1 or b_1 can be made zero. We then have

$$J(t) = \tfrac{1}{2}a_0 + b_1 \sin(\omega t) \qquad \ldots\ldots(6)$$

$$I = \frac{k_2 a_0}{2k_1} + \frac{k_2 b_1 \sin(\omega t - \phi)}{(k_1{}^2 + \omega^2)^{1/2}}. \qquad \ldots\ldots(7)$$

The degree of modulation of the exciting light m_e is given by

$$m_e = 2b_1/a_0 \qquad \ldots\ldots(8)$$

and of the fluorescent light by

$$m_f = \frac{2b_1}{a_0}\frac{k_1}{(k_1{}^2 + \omega^2)^{1/2}}. \qquad \ldots\ldots(9)$$

The ratio of these two is

$$M = \frac{m_f}{m_e} = \frac{k_1}{(k_1{}^2 + \omega^2)^{1/2}} \qquad \ldots\ldots(10)$$

or in terms of τ, the decay time

$$\tau = \frac{1}{k_1} = \frac{(1 - M^2)^{1/2}}{\omega M}. \qquad \ldots\ldots(11)$$

Thus if M can be measured, τ may be calculated since ω is known. In practice the amplitudes of the r.f. components of the exciting and fluorescent light are made equal so that M is then just the ratio of the steady components.

§ 4. EXPONENTIAL DECAY OF FLUORESCENCE

Since the present as well as previous methods of measuring decay times depend on the assumption that the decay is exponential, this factor requires investigation. It has been found by Holstein (1947, 1951) that in the case of gases the decay of resonance fluorescence is exponential. This case, however, concerns very narrow emission and absorption bands and a much larger overlap than in organic

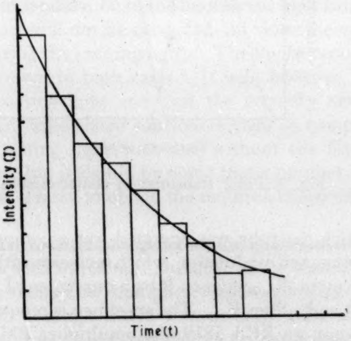

Fig. 1. Calculated decay of fluorescence.

phosphors. As well as affecting the shape of the decay, re-absorption could lead to variations of the decay time over the emission spectrum. The effects in anthracene are shown by the spectra of Fig. 4 which shows how re-absorption reduces the microcrystal spectrum to that for a thick specimen (1 cm thick). The absorption spectrum is obtained from Kortum and Finckh (1942).

The case of anthracene has been investigated by means of a Monte Carlo technique with the result shown in Fig. 1. The histogram shows the calculated decay. The exponential is given by $I=I_0 \exp(-t/\tau)$, with τ as the average of all the lifetimes and I_0 obtained by equating the area under the exponential to that under the histogram. Actual results will not be given here, as the calculation was rather coarse in using only 10 equally probable regions, and it is to be repeated with a larger number of regions. The fit is quite good and justifies the assumption of exponential decay in this case.

§ 5. EXPERIMENTAL

A block diagram of the apparatus is shown in Fig. 2. A crystal controlled power oscillator PO drives an air discharge tube DT to produce the modulated exciting light. The discharge was struck between two pointed electrodes about 1 cm apart by reducing the pressure, after which it was raised to about 5 cm Hg.

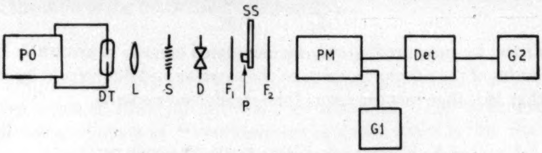

Fig. 2. Block diagram of the apparatus.

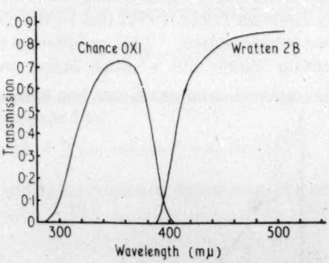

Fig. 3. Filter transmission characteristics.

The pressure at which the tube was operated was a compromise between light output, which decreases, and modulation, which increases with increase of pressure. The light is focused on to the specimen P by a quartz lens L through a shutter S, an iris diaphragm D and a filter F_1. The specimen is mounted on a sliding stage SS so that the detector, an RCA 5819 photomultiplier PM, can view either the exciting or fluorescent light. The filter F_1 (Wood's glass) only transmits light below 4000 Å and the filter F_2 (Wratten 2B) only transmits above 4000 Å so that when the phosphor is being excited only the fluorescent light (above 4000 Å) and no exciting light reaches the multiplier. F_2 is attached to SS and is removed from the light path when the exciting light is being examined. The transmission curves of the two filters, as determined on a Beckman model DU spectrophotometer, are shown in Fig. 3. The Wood's glass was 2 mm thick and the Wratten 2B as normally supplied. In practice a double layer of Wratten 2B was used.

The detector Det was a heterodyne unit consisting of crystal oscillator, harmonic amplifier, mixer, i.f. amplifier and detector. The r.f. signal from the photomultiplier anode was fed directly into the mixer and the rectified output from the detector was measured by galvanometer G2. The d.c. component of the multiplier output was measured by galvanometer G1.

The choice of modulation frequency should be made as far as possible so that $(1-M^2)^{1/2}=M$, as τ will then depend mainly on ω which is accurately known. For the range of τ encountered (3 to 30×10^{-9} sec) this gives a frequency range of 30 to 6·6 Mc/s. In practice the second harmonic component of the light source was used as this effectively eliminated pickup, but in a well-shielded apparatus this should not be necessary. Since the two signals differ in phase and the pickup is of fixed phase, the pickup cannot be simply subtracted and must therefore be reduced to a negligible value. It appeared in practice that the second harmonic was present in the light output from the discharge tube but not in the driving oscillator. A suitable oscilloscope was not available so that a direct investigation could not be made.

The phosphors used were obtained from a number of sources (see Birks and Cameron 1959) and were of the highest purity available. The microcrystalline layers were deposited on glass slips by evaporation from solution and were about 0·1 μ thick. The solvents used were spectroscopically pure (Hopkin and Williams Ltd. and Eastman Kodak Co.). It may be noted that an alternative method with some advantages is described by Northrop and Simpson (1956).

§ 6. CHECK RESULTS AND ACCURACY

It is necessary to test the filters themselves for fluorescence. If F_2 is fluorescent, then the degree of modulation of the fluorescent light from the specimen will be altered. This effect will not be cancelled out since the specimen and F_2 are removed when measuring the exciting light. The fluorescence of F_1 has no direct effect as it will be present in both cases. It will, however, tend to reduce the modulation of the exciting light and thus the accuracy and sensitivity of the apparatus. The filters were tested for fluorescence by comparing the degree of modulation of the exciting light with and without the filter. No significant differences were found, but it should be noted that a number of the filters tested, particularly those heat treated to obtain the required characteristics were strongly fluorescent.

It was also necessary to determine whether the modulation of the light from the discharge tube varied with wavelength, because of the wavelength dependence of specimen absorption, filters and multiplier response. This was done by measuring the modulation through filters transmitting different spectral regions. Some small variations were found, but mainly at long wavelengths whose effects were negligible.

A convenient check on the operation of the apparatus is the measurement of a known decay time. In the past most work has been done on organic dye solutions, and for some of these the decay times appear to be well known. One immediately available in pure form, eosin, was therefore used as the check. The result of this measurement, together with the results of two other investigators are given in Table 2 (Kirchoff 1940, Maercks 1938).

Table 2. Decay Time of Eosin

Phosphor	Decay times (nsec). Present	Kirchoff (1940)	Maercks (1938)
Eosin (10^{-4} g cm^{-3} solution in water)	4·73	4·70	4·70

The linearity of the photomultiplier is the main source of uncertainty in the results. This is a difficult factor to check but they are claimed by the manufacturers to be accurately linear within a specified current range and they were always used well within the range. Frequencies were all crystal controlled and known to within one part in 10^3. The d.c. galvanometer was checked against standard resistors and found to be linear to better than 1%. For materials on which a number of measurements were made the statistical error was found to be about 1%. For the more important materials up to 100 measurements were made on a number of specimens. From these considerations the accuracy of measurement is estimated to be to about 2%.

§ 7. RESULTS

The results obtained have been previously published (Hamilton 1957, Birks and Cameron 1959). There is however a correction to be applied to the microcrystal decay time for anthracene and a number of differences with the results of other workers to be considered. Some results are therefore repeated in Table 1 which also lists the corresponding results of other workers. The two rows for anthracene give the results for pure (upper) and for contaminated specimens (lower), except in the cases marked (g). For these the state of the specimen was unspecified, so that the same value has been entered in both rows. The differences between the present results and those of Birks and Little have already been discussed (Hamilton 1957). The differences were shown to be due to impurities or to probable oxidation of the surface. An instructive experiment showing the oxidation effect is carried out as follows. One face of a long exposed 1 cm cube anthracene crystal was cleaved off. With this new face towards the exciting light the value (c) (Table 1) was obtained. On inverting the crystal, so that an old surface was now towards the exciting light, the value (d) was obtained.

The results of Liebson and Schmillen *et al.* for anthracene appear to lie between the values (c) and (d) and so could be due to an intermediate period of exposure to the atmosphere. The result of Hanle *et al.* (e) is thought to differ from (c) due to a different cause. A reasonable explanation may be based on the fact that their measurements were made by examining the 'reflected' fluorescence from a thick crystal. It is known that the 'reflected' fluorescence spectrum is considerably different from the transmitted spectrum (Birks and Wright 1954), due to decreased self-absorption. This will diminish the effective decay time of the crystal.

Taking rough measurements of the relative areas of the spectra from the above paper, we find the ratio of the reflected to the transmitted to be 0·5. Using the relation (14) (see below) with $\tau_c = 24{\cdot}2$ nsec and $K = 0{\cdot}5$, we find for the 'reflected' decay time the value of 12·1 nsec. Since the spectra are approximate and the exact value will depend on the angle of incidence, this value agrees well enough with (e). The value (f) cannot be considered to be in agreement with (c) since it was also measured by reflection and so underestimated and it is probably influenced by some impurity. Differences for other phosphors are probably due to one or more of the causes discussed for anthracene.

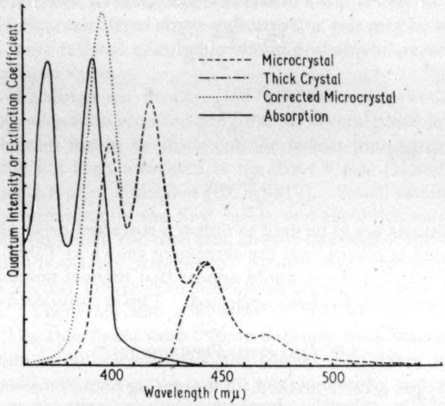

Fig. 4. Absorption and fluorescence spectra for anthracene.

Table 3. Corrections to Anthracene Decay Times

Specimen	K_1	τ_{m1}	K_2	τ_{m2}	K_3	τ_c	τ_{m3}	τ_m
A	0·293	6·55	0·796	5·22	0·234	24·1	5·64	5·43
B	0·340	6·85	0·792	5·42	0·233	22·5	5·25	5·34
C	0·331	6·64	0·755	5·02	0·228	23·9	5·45	5·24
D	0·311	6·58	0·761	5·01	0·236	23·3	5·50	5·26
Means	0·319	6·65	0·776	5·17	0·233	23·5	5·46	5·31

K_1 = ratio of thick to uncorrected micro spectrum.
τ_{m1} = measured micro decay time.
K_2 = ratio of uncorrected to corrected micro spectrum.
$\tau_{m2} = \tau_{m1} \cdot K_2$
K_3 = ratio of thick to corrected micro spectrum.
τ_c = measured thick decay time.
$\tau_{m3} = \tau_c \cdot K_3$.
τ_m = mean of τ_{m2} and τ_{m3}.

Birks and Cameron (1959) have found from spectral measurements that even in the microcrystalline layers used in the present measurements (the specimens were the same ones) there was some residual re-absorption. They have made a correction to the spectrum for this which is shown in Fig. 4. The improved agreement of the K values shown under K_3 (Table 3) compared with the measured values under K_1 adds confirmation to this correction. This re-absorption will also affect the decay time.

The decay time ratio for anthracene $\tau_c/\tau_m = 3{\cdot}8$ is quite close to the ratio of the areas of the spectra after normalization at long wavelengths (Fig. 4: ratio $= 4{\cdot}3$). This approximate agreement is to be expected on Birks' photon cascade theory (Birks 1953) for high quantum efficiency q. If p and k are the radiative and the non-radiative transition probabilities and K the spectral area ratio:

$$K = \frac{\text{area of thick crystal spectrum}}{\text{area of microcrystal spectrum}}$$

Then

$$\frac{\tau_m}{\tau_c} = \frac{pK+k}{p+k} \qquad \ldots\ldots(12)$$

and

$$q = \frac{p}{p+k}. \qquad \ldots\ldots(13)$$

If $q=1$ then $k=0$ and

$$\frac{\tau_m}{\tau_c} = K. \qquad \ldots\ldots(14)$$

If these considerations are to be used to obtain a corrected decay time, a value of $q=1$ has to be used to obtain even the agreement shown in Table 3. Since q is found to be less than 1 (§ 8), it would appear that there is possibly some other process in operation which has been neglected. This is considered in § 8.

§ 8. QUANTUM EFFICIENCIES

Wright (1955) has given a method for measuring photofluorescence quantum efficiencies q from measurements of the decay times and fluorescence spectra of thick and microcrystal specimens. He shows that

$$q = \frac{1 - \tau_m/\tau_c}{1 - (\delta + K - \delta K)} \qquad \ldots\ldots(15)$$

where δ is an escape coefficient. Wright gave a result for anthracene using (15) but he used a value of $\tau_c = 18{\cdot}0$ nsec and $\tau_m = 6{\cdot}7$ nsec and incorrect spectral data. These values were obtained by the method described above but before the effects of oxidation and re-absorption were fully realized. Using the results for the specimens of Table 3 ($\tau_m = 5{\cdot}31$, $\tau_c = 23{\cdot}5$, $K = 0{\cdot}23$) we get $q = 1{\cdot}12$ with $\delta = 0{\cdot}1$ as given by Wright or $q = 1{\cdot}00$ with $\delta = 0$.

If the theory is correct, then these values indicate that there is some error in the measurement or that some other process is operating that has not been taken into account. This is because the efficiency should be somewhat less than 1·0 at room temperature, as it has been found to increase with decrease in temperature (Kucherov and Faidysh 1956). Note that the values given by Kucherov and Faidysh are technical efficiencies Q related to the quantum efficiency q by (Wright 1955):

$$Q = \frac{qK}{1 - q + qK}. \qquad \ldots\ldots(16)$$

At room temperature $Q = 0{\cdot}64$ (Kucherov and Faidysh, Fig. 3, for room temperature) and with $K = 0{\cdot}23$ we obtain $q = 0{\cdot}9$. If τ_m is calculated from (15) with $\delta = 0$ and $q = 0{\cdot}9$, we get $\tau_m = 7{\cdot}5$ nsec.

It has been suggested that the true molecular lifetime of anthracene may be somewhat higher than the value given in Table 1, and that the reason for the lower value actually measured is the approach of the microcrystal size to the mean free path of the excitons in the microcrystal (Kucherov and Faidysh 1956, Simpson 1956). The excitons, representing the excitation energy, move through the crystal until de-excitation occurs. If the mean free path is limited, in this case by the size of the microcrystals, de-excitation occurring at crystal boundaries, then the decay time will be reduced. The thickness of the specimens used in the present measurements ($0{\cdot}1\ \mu$) is approximately equal to the mean free path reported in the above references, so that some decrease in lifetime may be expected. The approximate lifetime calculated above indicates that this may be what is occurring especially as a more realistic calculation would probably increase rather than decrease the calculated value.

The results of Kallman and Brucker (1957) appear to support this idea but there are a number of corrections required and there are several possible sources of error. Firstly, a correction has to be made for the transit-time spread in the photomultiplier which has been measured to be about 6 nsec (Hamilton and Wright 1956) for the same type of multiplier (RCA 5819). Small variations in the times can make large variations in the final result, and since this correction has to be made twice (for equipment rise time also, already included in the values tabulated) there is a possibility of large corrections. Scintillation lifetimes are also generally thought to be slightly longer than photofluorescence lifetimes (see for example Brooks 1956). There are also a number of criticisms of the measurements themselves. The thin flakes were 0·01 to 0·02 mm thick whereas re-absorption is still important in anthracene 0·001 mm thick. The flakes were prepared by heating and sublimation but the vessel was apparently not evacuated. The specimens were therefore probably oxidized. A value of 12·6 nsec has been obtained (Table 1) for a 1 cm crystal which has been long exposed to the atmosphere. This value corresponds very closely to the values given by Kallman and Brucker and adds to the doubt about their values.

The evidence in any case does indicate the possibility of a decrease of lifetime due to the limitation of the exciton mean free path, but further experiments on crystals of various thicknesses will be required to establish this. Measurements on various compounds will also be required, as *p*-terphenyl, which has negligible spectral overlap, does not show a decrease. This may be due to a shorter mean free path for excitons in this material.

ACKNOWLEDGMENTS

Part of this work was done under the direction of Dr. G. T. Wright. I wish to thank Dr. J. B. Birks for discussions, and Dr. A. J. W. Cameron for his close co-operation. I also wish to thank the South African Council for Scientific and Industrial Research for maintenance and research grants.

The Crystalline Field Parameters for Dysprosium Ethyl Sulphate

By M. J. D. Powell† and R. Orbach‡§

† Atomic Energy Research Establishment, Harwell, Didcot, Berks.
‡ Clarendon Laboratory, Oxford

Communicated by B. Bleaney; MS. received 18th May 1961

Abstract. The four crystalline field parameters of the Dy^{3+} ion in the ethyl sulphate, V_2^0, V_4^0, V_6^0 and V_6^6 are fitted at 4·2°K and 58°K to give the known level splittings and g values. It is found that $V_2^0 \sim 125\ \text{cm}^{-1}$, $V_4^0 \sim -26\ \text{cm}^{-1}$, $V_6^0 \sim -31\ \text{cm}^{-1}$, and $V_6^6 \sim 490\ \text{cm}^{-1}$, and there exists a slight variation with temperature between 4°K and 58°K. These values are, however, in serious disagreement with those obtained by the extrapolation procedure of Elliott and Stevens. In particular, V_2^0 is extraordinarily large, in agreement with the previous work of Judd on europium ethyl sulphate. An empirical variation of V_n^m with atomic number is given which is in marked contrast to that predicted by Elliott and Stevens.

§ 1. Introduction

The recent work of Gramberg (1960) has now made it possible to obtain unequivocally the four crystalline field parameters V_2^0, V_4^0, V_6^0, and V_6^6 (Elliott and Stevens 1953 a) for the dysprosium 3+ ion in the ethyl sulphate. Up to now, only a few ions in the first half of the rare earth series have been examined in the ethyl sulphate in great detail. In fact, only for the single salt, europium ethyl sulphate (Judd 1959 a), have there been enough data to fit the crystalline field parameters unambiguously. The investigation of these parameters for the dysprosium 3+ ion is of the utmost significance because of its position well along in the rare earth series, and because it contains an odd number of 4f electrons. The elegant work of Elliott and Stevens (1952, 1953 b) which systematized the crystalline field description of the rare earth trivalent ions assumed that V_n^m varied as $(Z-55)^{-n/4}$, where Z is the atomic number. This followed from the observed empirical variation of the spin–orbit coupling constant (proportional to $\langle r^{-3}\rangle$ where $\langle r\rangle$ is the mean radius of an f electron) with atomic number in the rare earth series, and the added assumption that the 4f wave functions were approximately hydrogenic in nature. No great weight was given to this procedure, but it did serve as a starting point in their analysis. As they had previously fitted the four parameters to the one salt about which there appeared to be sufficient experimental data, cerium ethyl sulphate, they were able to use the extrapolation procedure (1953 b) to approximate the coefficients for the rest of the trivalent rare earth ions in the ethyl sulphate lattice. In general, rather good agreement with the experimental results, as they were then known, was found. Since their work a few other salts have given enough experimental data for better fits to be attempted, specifically the non-Kramers salts (an even number of 4f electrons) praseodymium (Baker and Bleaney 1958) and europium ethyl sulphate (Judd 1959 a). As a result of the fit we shall present for Dy^{3+} ethyl sulphate, and those for Pr^{3+} and Eu^{3+} in the ethyl sulphate, we find it necessary to question some aspects of the Elliott and Stevens extrapolation procedure. We believe the apparent agreement between their extrapolated parameters and the experimental data to be due to comparing rather insensitive quantities. We shall first, however, present our results for dysprosium ethyl sulphate, and then go on to the analysis of the variation of the crystalline field parameters from ion to ion.

§ 2. THE FIT TO DYSPROSIUM ETHYL SULPHATE

The ground multiplet of the dysprosium 3+ ion is a $4f^9$, $^6H_{15/2}$ state. This is split by the ethyl sulphate's crystalline field (having C_{3h} symmetry) into eight levels all doubly degenerate owing to time reversal symmetry. The susceptibility has been measured at helium temperatures (de Haas, van den Handel and Gorter 1933, Cooke *et al.* 1959) and it is found that $g_{\|} = 10{\cdot}8$, $g_{\perp} \sim 0$ which indicates a combination of $J_z = \pm 9/2, \ \mp 3/2, \ \mp 15/2$ levels lowest. Magnetic resonance measurements were performed on the first excited level (Baker and Bleaney 1958) and these together with the temperature independent susceptibility in the perpendicular direction indicate a splitting of 22°K and give $g_{\|} = 5{\cdot}86 \pm 0{\cdot}10$ and $g_{\perp} = 8{\cdot}4 \pm 0{\cdot}5$ in the dilute salt (Dy^{3+} in yttrium ethyl sulphate). This shows the first excited doublet to be a combination of $J_z = \pm 7/2, \ \mp 5/2$ levels ($\equiv \cos\theta|\pm 7/2\rangle - \sin\theta|\mp 5/2\rangle$). Because the $g_{\|}$ and $g_{\perp}$ are related for such a level ($g_{\|} = \frac{4}{3}[7\cos^2\theta - 5\sin^2\theta], g = \frac{4}{3}\sqrt{55}\sin 2\theta$) we cannot fit unambiguously the four crystalline field parameters. Because of Gramberg's (1960) recent optical measurements, however, and his success in identifying three of the eight levels at 4·2°K and five of them at 58°K, we are now assured of enough data with which to fit the crystalline field parameters. His results are listed in Table 1. It is to be noted that the splitting of the second and third levels from the ground doublet, Δ_{12} and Δ_{13} respectively, seems to vary slightly with temperature. This has caused us some trouble in fitting the data and we shall present separate lists of parameters we expect to be appropriate to the liquid helium (~4°K) and the higher (~58°K) temperature regions. In attempting to fit the data in the higher temperature region, we have had no choice but to fit solely to the level splittings given by Gramberg because no *g* values are known for measurements at that

Table 1. The Experimental Results of Gramberg (1960) for Dysprosium Ethyl Sulphate

		4·2°K			58°K
Level	J_z values	Energy splitting Δ_{1i} (cm^{-1})	$g_{\|}$	$g_{\perp}$	Energy splitting Δ_{1i}
I	$\pm 9/2, \ \mp 3/2, \ \mp 15/2$	—	$10{\cdot}76 \pm 0{\cdot}1$	0	
II	$\pm 7/2, \ \mp 5/2$	$16{\cdot}03 \pm 0{\cdot}05$	$5{\cdot}60 \pm 0{\cdot}2$	$7{\cdot}28 \pm 0{\cdot}6$	$16{\cdot}1 \pm 0{\cdot}2$
III	$\pm 11/2, \ \mp 1/2, \ \mp 13/2$	$21{\cdot}20 \pm 0{\cdot}1$	$12{\cdot}50 \pm 0{\cdot}2$	$3{\cdot}90 \pm 0{\cdot}6$	$20{\cdot}4 \pm 0{\cdot}2$
IV	—	—	—	—	$58{\cdot}9 \pm 0{\cdot}2$
V	—	—	—	—	$68{\cdot}1 \pm 0{\cdot}2$

temperature. The fit is thus in reality just a solution of four simultaneous equations in the four parameters. The results are given in Table 2. It is to be noted that the *g* values are not very different from those found at helium temperatures. The very significant point about the fit is the size of V_2^0. Far from lying between about 0 and $-5\ \text{cm}^{-1}$, as would be guessed from the extrapolation scheme of Elliott and Stevens, it is much larger. This would imply, if the extrapolation procedure of Elliott and Stevens were in fact valid, and $V_2^0 \propto (Z-55)^{-1/4}$, a value of 238 cm^{-1} for cerium ethyl sulphate. (They found a value of approximately $-15\ \text{cm}^{-1}$.) This large positive value however hardly seems reasonable at present.

The fitting at 4·2°K is more difficult, strangely enough, because we have seven independent experimental numbers with which to work, five of them relating to *g* values. The trouble lies in the fact that for small changes in the V_n^m the *g* values change very little. Hence, a fit to the *g* values gives an enormous error in the splittings even for a small experimental error in the *g* values. That is, the *g* value error may be small, but the resulting error in the level splittings is not. We thus had to weight the values of Δ_{14} and Δ_{15} to keep them near those found by Gramberg at 58°K, and fit them, together with the $g_\parallel$ values given by Gramberg for the lowest two states and the known splittings Δ_{12} and Δ_{13}. This allows for the slight change of Δ_{14} and Δ_{15} with temperature from 58 to 4·2°K. A computer programme was written for the fitting procedure which calculated the weighted sum of the squares of the differences between the observed and the calculated data. The programme then found the values of the parameters which minimized the weighted sum. The method of finding the minimum is rather more effective than the method of steepest descents and will be described elsewhere (Powell, to be published). The true minimum was assumed to be reached when a change of $\pm 0{\cdot}01\%$ in any one parameter caused the weighted sum to increase. The parameters which gave a good fit to the $g_\parallel$ values of the two lowest levels and to the splittings Δ_{12} and Δ_{13}, and for which the energy splittings Δ_{14} and Δ_{15} differed only slightly from those observed at 58°K, are given in Table 3.

Table 2. The Theoretical Spectrum of Dysprosium Ethyl Sulphate from a Fit to the Crystalline Field Splittings Δ_{12} to Δ_{15} of Gramberg (1960) at 58°K

Level	Wave function	Energy splitting (cm^{-1})	$g_\parallel$	$g_\perp$
I	$0{\cdot}058\vert\pm 15/2\rangle - 0{\cdot}267\vert\pm 3/2\rangle + 0{\cdot}962\vert\pm 9/2\rangle$		10·75	0
II	$-0{\cdot}869\vert\pm 7/2\rangle + 0{\cdot}495\vert\mp 5/2\rangle$	16·10	5·41	8·51
III	$0{\cdot}104\vert\pm 13/2\rangle - 0{\cdot}200\vert\pm 1/2\rangle + 0{\cdot}974\vert\mp 11/2\rangle$	20·40	13·68	1·86
IV	$-0{\cdot}994\vert\pm 15/2\rangle + 0{\cdot}069\vert\pm 3/2\rangle + 0{\cdot}079\vert\mp 9/2\rangle$	58·90	19·72	0
V	$-0{\cdot}983\vert\pm 13/2\rangle + 0{\cdot}129\vert\pm 1/2\rangle + 0{\cdot}131\vert\mp 11/2\rangle$	68·10	16·52	1·64
VI	$0{\cdot}495\vert\pm 7/2\rangle + 0{\cdot}869\vert\mp 5/2\rangle$	148·89	2·75	8·51
VII	$0{\cdot}088\vert\pm 15/2\rangle + 0{\cdot}961\vert\pm 3/2\rangle + 0{\cdot}262\vert\mp 9/2\rangle$	201·76	3·03	0
VIII	$0{\cdot}151\vert\pm 13/2\rangle + 0{\cdot}971\vert\pm 1/2\rangle + 0{\cdot}183\vert\mp 11/2\rangle$	242·18	1·16	10·45

$V_2^0 = 123{\cdot}7\ \text{cm}^{-1}$ $V_4^0 = -26{\cdot}35\ \text{cm}^{-1}$ $V_6^0 = -31{\cdot}02\ \text{cm}^{-1}$ $V_6^6 = 492{\cdot}26\ \text{cm}^{-1}$

There are, however, discrepancies between the results of Table 3 and those of Gramberg in Table 1. The $g_\perp$ values do not seem to be in agreement for levels 2 and 3, and the $g_\parallel$ for level 3 is also in disagreement. A reason for the first two discrepancies may be that Gramberg used fields so large that the Zeeman splitting was no longer linear in the field H, but also contained terms proportional to H^3, and his extrapolation to zero field was in error. Because the perpendicular temperature-independent susceptibility is so high and the levels connected by a perpendicular field so close, it is entirely possible that this may be the case. The reasons for error in the $g_\parallel$ of the third level may also be due to the proximity of the next $J_z = \pm 13/2$, $\pm 1/2$, $\mp 11/2$ level ($\Delta_{15} - \Delta_{13} = 48$ cm^{-1}). We feel that Gramberg must certainly be in error for level 2 because of consistency requirements between $g_\parallel$ and $g_\perp$ which we have previously indicated. Gramberg's results do not fulfil the required relation. Further, the $g_\parallel$ given by Baker and Bleaney (1958) is roughly that of Gramberg, whereas their (consistent) $g_\perp$ is much different. To check our conclusions we have also computed the effects of admixtures from the $J = 13/2$ excited multiplet. In all cases we have found a trivial correction, less than 1%, to the ground multiplet g values.

Table 3. The Theoretical Spectrum of Dysprosium Ethyl Sulphate from a fit to the experimental data (see text) at 4·2°K

Level	Wave function	Energy splitting (cm^{-1})	$g_\parallel$	$g_\perp$
I	$0{\cdot}053\lvert\pm 15/2\rangle - 0{\cdot}261\lvert\pm 3/2\rangle + 0{\cdot}964\lvert\mp 9/2\rangle$	—	10·82	0
II	$-0{\cdot}872\lvert\pm 7/2\rangle + 0{\cdot}489\lvert\mp 5/2\rangle$	16·04	5·50	8·43
III	$0{\cdot}096\lvert\pm 13/2\rangle - 0{\cdot}195\lvert\pm 1/2\rangle + 0{\cdot}976\lvert\mp 11/2\rangle$	21·22	13·76	1·73
IV	$-0{\cdot}995\lvert\pm 15/2\rangle + 0{\cdot}071\lvert\pm 3/2\rangle + 0{\cdot}074\lvert\mp 9/2\rangle$	60·40	19·74	0
V	$-0{\cdot}984\lvert\pm 13/2\rangle + 0{\cdot}129\lvert\pm 1/2\rangle + 0{\cdot}123\lvert\mp 11/2\rangle$	69·59	16·58	1·61
VI	$0{\cdot}489\lvert\pm 7/2\rangle + 0{\cdot}872\lvert\mp 5/2\rangle$	144·80	2·84	8·43
VII	$0{\cdot}088\lvert\pm 15/2\rangle + 0{\cdot}963\lvert\pm 3/2\rangle + 0{\cdot}256\lvert\mp 9/2\rangle$	198·24	3·08	0
VIII	$0{\cdot}150\lvert\pm 13/2\rangle + 0{\cdot}972\lvert\pm 1/2\rangle + 0{\cdot}179\lvert\mp 11/2\rangle$	238·82	1·18	10·46

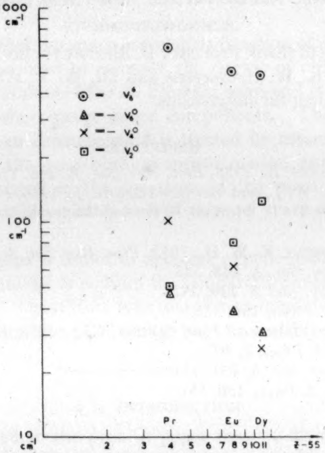
$V_2^0 = 119{\cdot}24$ cm^{-1} $V_4^0 = -26{\cdot}22$ cm^{-1} $V_6^0 = -31{\cdot}24$ cm^{-1} $V_6^6 = 473{\cdot}49$ cm^{-1}

In addition, we have also calculated the temperature-independent susceptibility in both the parallel and perpendicular directions expected in the liquid helium range. We find 0·0181 per mole and 1·104 per mole respectively. The former is in reasonable agreement with the value 0·0152 found by Becquerel *et al.* (1936). The latter agrees well with the value of $1{\cdot}05_6 \pm 0{\cdot}02$ found by Cooke *et al.*

It is interesting to note that V_2^0, V_4^0, V_6^0 and V_6^6 change by only about 4, <1, <1, and 4% respectively between 4·2° and 58°K. This is a weak variation, being practically within the experimental uncertainty.

§ 3. THE EXTRAPOLATION PROCEDURE

We now plot the four crystalline field coefficients for dysprosium, europium, and praseodymium ethyl sulphate against $Z-55$ to determine their functional variation with this quantity. The results are shown in the Figure. The interesting features of this Figure are two-fold. First, if we demand that $V_n^m \propto (Z-55)^p$ then we see that p is roughly independent of m as V_6^0 and V_6^6 appear to have similar slopes. This agrees with Elliott and Stevens (1953*b*). Secondly, $p = +0{\cdot}8$, $-1{\cdot}4$ and $-0{\cdot}33$ for $n = 2$, 4 and 6 whereas Elliott and Stevens have taken $p = -0{\cdot}5$, $-1{\cdot}0$ and $-1{\cdot}5$. Clearly something is wrong. Judd (1959b) has discussed the possibility of screening and has reached the conclusion that such may be quite significant, involving higher configurations of the ionic state. There is as yet, however, no quantitative or even qualitative estimate of this effect. It is intriguing to note that the crystalline field coefficients for these three salts do seem to vary empirically with atomic number in a simple manner (see Figure). For instance, for samarium ethyl sulphate ($4f^5$, $^6H_{5/2}$), we would find $V_2{}^0 \sim 77\ \mathrm{cm}^{-1}$, $V_4{}^0 \sim -48\ \mathrm{cm}^{-1}$, $V_6{}^0 \sim -39\ \mathrm{cm}^{-1}$, $V_6{}^6 \sim 550\ \mathrm{cm}^{-1}$. To first order in perturbation theory this gives $\Delta_{12} \sim 59\ \mathrm{cm}^{-1}$, $\Delta_{13} \sim 65\ \mathrm{cm}^{-1}$ in rough agreement with the values of 53·8 cm⁻¹ and 63·6 cm⁻¹ respectively given by Lämmerman (1958) from optical measurements. These splittings are much better than those found by Elliott and Stevens (1953b) via their extrapolation procedure ($\Delta_{12} \sim 5\ \mathrm{cm}^{-1}$ and $\Delta_{13} \sim 22\ \mathrm{cm}^{-1}$) while they also gave an incorrect ordering for the three levels, viz. I $= |\pm 1/2\rangle$, II $= |\pm 5/2\rangle$, III $= |\pm 3/2\rangle$†.



A log–log plot of the crystalline field parameters, $V_2{}^0$, $V_4{}^0$, $V_6{}^0$ and $V^6{}_6$, for praseodymium, europium and dysprosium ethyl sulphate against $Z-55$, where Z is the atomic number.

Our values for $V_n{}^m$ give, in agreement with the experimental results of Lämmerman (1958), I $= |\pm 1/2\rangle$, II $= |\pm 3/2\rangle$, and III $= |\pm 5/2\rangle$ in the ground ($J = 5/2$) multiplet.

As good as the agreement may seem in this particular case, however, the dangers of extension to other salts are so great in light of past experience as to make us loath to present any general conclusion other than the following. It is clear on the one hand that in complete agreement with what Judd found for europium ethyl sulphate, $V_2{}^0$ is much larger than previously supposed. And, on the other hand, this large value of $V_2{}^0$ does not appear to be a function of whether the ion contains an even or odd number of 4f electrons, in disagreement with his conjecture.

---

† In fairness to Elliott and Stevens these discrepancies may have arisen from their attempt to fit the very peculiar behaviour of the magnetic susceptibility (van den Handel, unpublished). The recent optical measurement of Lämmerman (1958) have solved this dilemma by showing the susceptibility results to be in error.

Thus, the Elliott–Stevens extrapolation formula appears to be in some error for the rare earth salts about which we have sufficient data to fit the crystalline field parameters. In the future, as we obtain more experimental information on the rare earth salts, we may be able to make some sense of their variation with atomic number. In any case, we now see that the hydrogenic approximation may be in very serious error and treatment of the shielding factor seems all-important.

ACKNOWLEDGMENTS

The authors wish to thank Professor B. Bleaney for his interest and encouragement and Professor K. W. H. Stevens and Dr. W. P. Wolf for their reading of the manuscript and helpful suggestions.

Space Correlation and Energy Levels in an Einstein Solid[†]

By T. LUKES

Department of Physics, Northampton College of Advanced Technology, London

Communicated by R. Fürth; *MS. received 27th April* 1961

Abstract. It is shown that the space correlation function of any space-dependent atomic property may be used to estimate the degree of order in a solid. The correlation function is evaluated for an Einstein solid and is shown to have both long-range order and short-range order components. The thermal scattering and band structure of an Einstein solid is treated by means of time-dependent perturbation theory on the loose-binding approximation, and it is shown that the scattering matrix is related to the spectrum of the potential, the short-range and long-range components giving rise to thermal scattering and energy gaps respectively.

The width of the gaps is found to decrease exponentially with temperature; for a one-dimensional model of sodium the temperature coefficient is found to be about 10^{-3} per degree. On a Mott-type one-dimensional model of liquid sodium this implies a 20% contraction of all energy gaps on melting.

§ 1. Introduction

The work reported in the present paper may be divided into two, related, parts. The first of these consists in presenting a method, differing from those hitherto used, for measuring the degree of order in a lattice. The method is applied to the particular case of a lattice subjected to thermal vibration on the Einstein model and has the particular feature that the same function enables the degree of long-range and short-range order to be estimated.

The second part of the paper is a discussion, on the basis of the loose-binding approximation, of the energy levels and scattering in an Einstein solid. The particular feature of the method used is that both the energy levels and thermal scattering emerge from the same treatment, a temperature-dependent energy gap being obtained. The scattering matrix contains expressions which are evaluated in the first part of the paper, and it is found that terms corresponding to the thermal scattering and energy levels can be associated with the degree of short and long range order respectively.

§ 2. Definitions of Statistical Functions

If $y(x)$ is a scalar function in an infinite, one-dimensional space the degree of statistical dependence between the value of y at the points x, $x+\chi$, may be measured by the autocovariance function

$$A(\chi)=\lim_{L\to\infty}\frac{1}{L}\int_{-L/2}^{L/2} y(x)y(x+\chi)\,dx \qquad \ldots\ldots(1)$$

[†] Part (abridged) of the author's thesis for the Ph.D. degree of the University of London (1960). An account of part of this work was presented at the Physical Society's Conference on Electron–Phonon Interaction in Solids, held at Oxford in December, 1959.

where the limit is assumed to exist. In the cases to be considered the function $y(x)$ will be identified with a space-dependent property of the atom (such as the atomic potential) and will be a function of some random parameters (such as the displacement of the atoms from their equilibrium positions). If, in this case, a particular record $y^m(x)$ of the function is obtained, and the corresponding autocovariance $A^m(\chi)$ computed, this will be a function of such random parameters. The value of $A^m(\chi)$ averaged over these parameters will then be denoted by $\langle A^m(\chi)\rangle$. The present discussion will be confined to ergodic, stationary processes and for these the values of $\langle A^m(\chi)\rangle$ and of $A(\chi)$ are, for physical purposes, identical. The correlation function, or normalized autocovariance, is given by

$$\rho(\chi)=\frac{A(\chi)}{A(0)}. \qquad \ldots\ldots(2)$$

The record y^m (x) over a length L may be represented by a Fourier integral

$$y^m(x)=\int_{-L/2}^{L/2} Y(K)e^{2\pi iKx}\,dK. \qquad \ldots\ldots(3)$$

The spectrum $G(K)$ defined by the equation

$$G(K)=\lim_{L\to\infty}\frac{1}{L}\langle|Y^m(K)|^2\rangle \qquad \ldots\ldots(4)$$

is then related to the autocovariance by the Wiener–Khinchine relation

$$A(\chi)=\int_{-\infty}^{\infty} G(K)\cos 2\pi K\chi\,dK. \qquad \ldots\ldots(5)$$

For a three-dimensional solid the following analogous definitions hold:

$$A(\boldsymbol{\rho})=\int_{-\infty}^{\infty} y(\mathbf{r})y(\mathbf{r}+\boldsymbol{\rho})\,d\mathbf{r} \qquad \ldots\ldots(6)$$

$$y^m(\mathbf{r})=\int_{-\infty}^{\infty} Y^m(\mathbf{K})e^{2\pi i\mathbf{K}\cdot\mathbf{r}}\,d\mathbf{K} \qquad \ldots\ldots(7)$$

$$G(\mathbf{K})=\lim_{L^3\to\infty}\frac{1}{L^3}\langle|Y^m(\mathbf{K})|^2\rangle. \qquad \ldots\ldots(8)$$

§ 3. THE CORRELATION FUNCTION AND SPECTRUM OF AN EINSTEIN SOLID

It will be shown in the present section that the space correlation function may be used to estimate the degree of order, on the atomic scale, which exists in an Einstein solid. For this purpose a physical property, such as the atomic potential, is chosen and the corresponding correlation function computed. In general, we denote by $y_0(x)$ a property of the atom which is independent of the interatomic distance. The function $y^m(x)$ defined over a chain of $2N+1$ atoms occupying a length L is then given by

$$y^m(x)=\sum_{r=-N}^{r=N} y(x-rq_0-x_r) \qquad \ldots\ldots(9)$$

where q_0 is the interatomic distance and the x_n are the displacements of the atoms from their equilibrium positions. Taking the Fourier transform of (9), multiplying by the complex conjugate and averaging, we find

$$\langle|Y^m(K)|^2\rangle=|Y_0(K)|^2\left\langle\sum_{r=-N}^{r=N}\sum_{s=-N}^{s=N}\exp\left[2\pi iK\{(r-s)q_0+(x_r-x_s)\}\right]\right\rangle \qquad \ldots\ldots(10)$$

where $Y_0(K)$ is the Fourier transform of $y_0(x)$. For $r=s$ the value of the sum is clearly $2N+1$. On the Einstein model, the x_r are assumed to be independently distributed with a distribution $z(x_r)$. Defining the characteristic function of the distribution by

$$Z(K) = \int_{-\infty}^{\infty} z(x_r) \exp(-2\pi i K x_r)\, dx_r \qquad \ldots\ldots(11)$$

it follows that the characteristic function of the distribution of $x_r - x_s$ is just $|Z(K)|^2$. The spectrum may therefore be written

$$G(K) = \lim_{L\to\infty} |Y_0(K)|^2 \left[2N + 1 + |Z(K)|^2 \sum_{r=-N}^{r=N} \sum_{s=-N}^{s=N} \exp\{2\pi i K(r-s)q_0\} \right].$$

If the term for $n = m$ were included, the double summation would have the value $\sin \pi K(2N+1)q_0/\sin \pi K q_0$. As $N \to \infty$ this function is infinite at the values $K = n/q_0$ and zero at all others; it may therefore be represented as a delta function of strength $(2N+1)/q_0$. Writing L as $2Nq_0$ for large N and taking the limit, one obtains for the spectrum

$$G(K) = \frac{|Y_0(K)|^2}{q_0} \left[1 - |Z(K)|^2 + \frac{|Z(K)|^2}{q_0} \sum_{r=-\infty}^{r=\infty} \delta\left(K - \frac{r}{q_0} \right) \right]. \qquad \ldots\ldots(12)$$

The evaluation of the spectrum for the three-dimensional case offers no new problems, and the expression is given by

$$G(\mathbf{K}) = \frac{|Y_0(\mathbf{K})|^2}{\Omega_0} \left[1 - |Z(\mathbf{K})|^2 + \frac{|Z(\mathbf{K})|^2}{\Omega_0} \sum_{s=-\infty}^{\infty} \delta(\mathbf{K} - \mathbf{R}_s) \right] \qquad \ldots\ldots(13)$$

where Ω_0 is the volume of the unit cell and $\mathbf{R}_s$ is a reciprocal lattice vector.

The correlation function may be evaluated by the use of Eqn (5). For a specific example we consider the one-dimensional case; take $y(x)$ to be the electrical potential, and choose the potential function $y_0(x)$ of a single, isolated atom to be of the Kronig–Penney type, with height h and width s_0. If the atom, of mass M, is represented as a simple harmonic oscillator of frequency ν_E the distribution function $z(x_r)$ is, in the classical limit of continuous levels, Gaussian with variance σ^2 given by

$$\sigma^2 = \frac{kT}{4\pi^2 M \nu_E^2}. \qquad \ldots\ldots(14)$$

The expression for the spectrum then takes the form

$$G(K) = \frac{h^2}{q_0} \frac{\sin^2 \pi K s_0}{\pi^2 K^2} \left[1 - \exp(-4\pi^2 K^2 \sigma^2) + \frac{\exp(-4\pi^2 K^2 \sigma^2)}{q_0} \sum_{r=-\infty}^{r=\infty} \delta\left(K - \frac{r}{q_0} \right) \right]. \qquad \ldots\ldots(15)$$

Substituting into Eqn (5) we obtain the correlation function as $A(\chi)/A(0)$, where

$$\begin{aligned} A(\chi) = \frac{h^2}{q_0} \Bigg[& \frac{2\sigma}{\pi^{1/2}} \exp\left(-\frac{\chi^2}{4\sigma^2} \right) - |\chi| \operatorname{erfc} \frac{|\chi|}{2\sigma} - \frac{\sigma}{\pi^{1/2}} \exp\left(-\frac{(\chi+s_0)^2}{4\sigma^2} \right) \\ & + \frac{|\chi+s_0|}{2} \operatorname{erfc} \frac{|\chi+s_0|}{2\sigma} - \frac{\sigma}{\pi^{1/2}} \exp\left\{ -\frac{(\chi-s_0)^2}{4\sigma^2} \right\} + \frac{|\chi-s_0|}{2} \operatorname{erfc} \frac{|\chi-s_0|}{2\sigma} \Bigg] \\ & + \frac{h^2 s_0^2}{q_0^2} + 2h^2 \sum_{r=1}^{\infty} \exp\left(-\frac{4\pi^2 r^2 \sigma^2}{q_0^2} \right) \sin^2 \frac{\pi r s_0}{q_0} \cos \frac{2\pi r \chi}{q_0}. \qquad \ldots\ldots(16) \end{aligned}$$

$$\begin{aligned} A(0) = \frac{h^2}{q_0} \left[\frac{2\sigma}{\pi^{1/2}} - \frac{2\sigma}{\pi^{1/2}} \exp\left(-\frac{s_0^2}{4\sigma^2} \right) - s_0 \operatorname{erfc}\left(\frac{s_0}{2\sigma} \right) \right] + \frac{h^2 s_0^2}{q_0^2} \\ + 2h^2 \sum_{r=1}^{\infty} \exp\left(-\frac{4\pi^2 r^2 \sigma^2}{q_0^2} \right) \sin^2 \frac{\pi s_0 r}{q_0}. \qquad \ldots\ldots(17) \end{aligned}$$

It is seen that the correlation function consists of essentially two terms whose relative magnitude is determined by the variance σ^2. The first has appreciable magnitude for an interval χ of the order of the interatomic distance; the second is a periodic function. These may be interpreted as reflecting, respectively, the degree of short-range and long-range order in the system. In the limit of vanishing thermal fluctuations only the periodic component remains, while in the limit $\sigma \gg q_0$—hardly realizable in a solid—the periodic component vanishes and the correlation function and spectrum have the same shape as for a single, isolated atom. The result obtained in this limit is the same as if the distribution of the atoms on the line was of the Poisson type (Carson 1931, Lukes 1961 **a**).

§ 4. Thermal Scattering and Energy Levels in an Einstein Solid

The effect of thermal vibration on the band structure of semiconductors has been discussed by Fan (1951) using second-order stationary perturbation theory; applying his theory to the case of germanium and silicon, he obtains an energy gap which decreases linearly with temperature, a result which is in good agreement with experiment. A treatment of the energy levels in a short-range order system, corresponding to a one-dimensional model of a liquid, again using second-order stationary perturbation theory, has, since the completion of the present work, been published (Sah and Eisenschitz 1960). For the case of periodic lattices, the results of the loose-binding approach are well known (Sommerfeld and Bethe 1934); for the one-dimensional case, this leads to energy gaps of magnitude $2|V_r|$ situated about values of electron wave number given by $k = \pm \pi r_s/q_0$, where V_r is the rth Fourier coefficient of the potential.

In the present method, the interaction of electrons with the atoms of an Einstein solid is investigated, using time-dependent perturbation theory. As the unperturbed wave functions are taken to be those of free electrons this amounts to using the first Born approximation. The object is to obtain a unified approach from which both the thermal scattering and the energy levels can be derived and, in particular, to see the effect of thermal vibration on the band structure.

We consider, as in the previous section, atoms along a line of length L, vibrating about equilibrium positions on the Einstein model, and take as the unperturbed wave functions

$$\psi(k) = L^{-1/2} e^{ikx}. \qquad \ldots\ldots (18)$$

Treating k as a continuous variable the expression for the probability of a transition per unit time dp/dt from state k to state k' is given by (Landau and Lifshitz 1959)

$$\frac{dp}{dt} = \frac{2\pi}{\hbar} D(E) |V^m_{kk'}|^2 \delta(E_k - E_{k'}) \qquad \ldots\ldots (19)$$

where $V^m_{kk'}$ is the matrix element for a particular 'frozen in' sequence of atomic positions, given by

$$V^m_{kk'}(k-k') = L^{-1} \int_{-L/2}^{L/2} \exp(ikx) v^m(x) \exp(-ik'x)\, dx \qquad \ldots\ldots (20)$$

and $D(E)$ is the density of states; $v^m(x)$ is the potential field for this particular sequence. The average probability of scattering is given by averaging $|V^m_{kk'}|^2$ over all atomic positions. Taking for the density of states the free electron value, the average probability of scattering takes the form

$$\left\langle \frac{dp}{dt} \right\rangle = \frac{4\pi^2}{h^2} \left(\frac{m}{2E} \right)^{1/2} \lim_{L\to\infty} \langle |V^m(k-k')|^2 \rangle \delta(E_k - E_{k'}) \quad \ldots\ldots (21)$$

where

$$V^m(k-k')=LV^m_{kk'}(k-k').$$

The term $\lim_{L\to\infty}\langle|V^m(k-k')|^2\rangle$ which occurs in Eqn (21) is simply the spectrum of the potential, expressed as a function of $(k-k')/2\pi$, and may therefore be obtained from Eqn (12). In this way one obtains after some calculation

$$\left\langle\frac{dp}{dt}\right\rangle=\frac{4\pi^2}{h^2}\left(\frac{m}{2E}\right)^{1/2}\frac{|V_0(k-k')|^2}{q_0}\left[1-\exp\{-\sigma^2(k-k')^2\}\right.$$
$$\left.+\exp\{-\sigma^2(k-k')^2\}\sum_{r=-\infty}^{\infty}\delta\left(\frac{k-k'}{2\pi}-\frac{r}{q_0}\right)\right]\delta(E_k-E_{k'}).\quad\ldots\ldots(22)$$

The contributions of the terms in square brackets must be separately considered. The term $1-\exp\{-\sigma^2(k-k')^2\}$ (where, in the one-dimensional case, $k=-k'$) can clearly be associated with thermal scattering in the lattice; if the exponential is expanded to first order in σ^2, this is exactly equivalent to the usual procedure of calculating the effect of thermal scattering by expanding the potential in a Taylor series, since

$$\left\langle\left|\int_{-\infty}^{\infty}\exp(ikx)\frac{d}{dx}v_0(x)\exp(-ik'x)\,dx\right|^2\right\rangle=(k-k')^2|V_0(k-k')|^2.\quad\ldots\ldots(23)$$

Our expression for scattering is, however, also valid for large displacements and for $\sigma k\gg 1$ the expression coincides with that which would be obtained if the atoms were arranged completely at random; since for the case of an alkali metal (to which one would expect a loose-binding approximation most nearly to apply) the Fermi level is given by $k=\pi/2q_0$ this is a case hardly realizable in a solid.

Considering the contribution of the terms in the sum in (22), the conditions specified by the two delta functions can be simultaneously satisfied only if

$$k=-k'=\frac{\pi r}{q_0}.\quad\ldots\ldots(24)$$

Thus the effect of the summation term in (22) is to ensure certain reflection for values of k given by (24), and the procedure of representing the unperturbed wave function by the incident wave breaks down. Instead, we assume as a first approximation that transitions only occur between the two degenerate states and therefore represent the wave function by a superposition of the incident and reflected waves,

$$\psi(x)=L^{-1/2}\{c_1\exp(ikx)+c_2\exp(-ikx)\}.\quad\ldots\ldots(25)$$

Solving for the energy in the usual way by equating the determinant of the coefficients to zero we obtain for the change of energy produced by the perturbation

$$\Delta E_r=V_0(0)\pm\left|V_0\left(\frac{2\pi r}{q_0}\right)\right|\exp\left(-\frac{2\pi^2r^2\sigma^2}{q_0^2}\right).\quad\ldots\ldots(26)$$

It follows that there is an energy gap of magnitude $E_g(r)$ where

$$E_g(r)=2\left|V_0\left(\frac{2\pi r}{q_0}\right)\right|\exp\left(-\frac{2\pi^2r^2\sigma^2}{q_0^2}\right).\quad\ldots\ldots(27)$$

Comparison of the result with the usual treatment for a periodic lattice shows that the energy gaps differ by a factor of $\exp(-2\pi^2r^2\sigma^2/q_0^2)$; the effect of taking thermal vibrations into account is therefore seen to be an energy gap which decreases in width exponentially with temperature.

Comparison of the results with those of § 3, shows that the terms in the scattering matrix which give rise to thermal scattering and energy gaps are precisely those which, in the expression for the spectrum of the potential, Eqn (12), are associated respectively with short- and long-range order.

The expression for the probability of scattering in three dimensions shows no new features and follows from Eqn (13). Assuming the solid to be isotropic, we obtain

$$\left\langle \frac{dp}{dt} \right\rangle = \frac{4\pi^2}{\hbar^2}\left(\frac{m}{2E}\right)^{1/2} |V_0(\mathbf{k}-\mathbf{k}')|^2 \Big[1-\exp\left(-|\mathbf{k}-\mathbf{k}'|^2\sigma^2\right) + \frac{1}{\Omega_0}\exp\left(-|\mathbf{k}-\mathbf{k}'|^2\sigma^2\right) \sum_s \delta\left(\frac{\mathbf{k}-\mathbf{k}'}{2\pi}-\mathbf{R}_s\right)\Big]. \qquad \ldots\ldots(28)$$

The summation term of Eqn (28) shows that the approximation breaks down at values of k given by

$$\mathbf{k}-\mathbf{k}' = 2\pi\mathbf{R}_s. \qquad \ldots\ldots(29)$$

Following the same procedure as before we see that the results for the periodic lattice may be taken over if the term $|V_0(2\pi\mathbf{R}_s)|$ which occurs in the periodic lattice expression is replaced by $|V_0(2\pi R_s)|\exp(-2\pi^2|R_s{}^2|\sigma^2)$.

As regards the thermal scattering term, if the probability of scattering per unit time is denoted by $P(k, k')$ is it well known that, for a spherically symmetrical potential, this is a function of the scattering angle θ only. Subject to certain simplifying assumptions (Mott and Jones 1958) the probability of scattering may be related to the relaxation time τ by the equation

$$\frac{1}{\tau} = \int (1-\cos\theta)\, P(\theta)\, dS \qquad \ldots\ldots(30)$$

where the integral is taken over the Fermi surface of which dS is an element. The relaxation time τ is in turn related to the conductivity σ by the equation

$$\sigma = \frac{ne^2\tau}{m}. \qquad \ldots\ldots(31)$$

Eqns (30) and (31) assume the validity of the Boltzmann equation in deriving the electrical conductivity; it appears, however, that, at least at high temperatures, more modern approaches yield the same result (Lukes 1961 b).

From Eqns (28) and (30) the relaxation time is given by

$$\frac{1}{\tau} = \frac{16\pi^2 m^2 k_{\mathrm{F}}}{h^3\Omega_0}\int_0^{\pi} |V_0(\theta)|^2 \left[1-\exp\left(-4k_{\mathrm{F}}{}^2\sin^2\frac{\theta}{2}\,\sigma^2\right)\right] \sin^3 \tfrac{1}{2}\theta\cos\theta\, d\theta. \qquad \ldots\ldots(32)$$

§ 5. Discussion of Results

The results of the last section predict a decrease of energy gap with temperature as a result of thermal vibration. We estimate the magnitude of this change for the one-dimensional case, taking the case of sodium as an example, since it is to this metal that the free electron approximation is known most nearly to apply. In order to calculate the value of σ^2 we take the Debye temperature as an approximation to the Einstein temperature; however, some doubt appears to exist as to the correct value for this in the case of sodium (Blackman 1961, Bradshaw and Pearson 1956). Taking $\theta_{\mathrm{D}} = 150°\mathrm{K}$ as a reasonable value the quantity $2\pi^2 r^2\sigma^2/q_0{}^2$ turns out to be about 1×10^{-3} per degree for the first energy gap. For small temperatures, using Eqn (27) we may therefore write for the first gap

$$E_{\mathrm{g}}(T) = E_{\mathrm{g}}(0)[1-aT]$$

where a is of the order of 10^{-3} per degree; inspection of Eqn (28) shows that this order of magnitude is not altered in three dimensions.

The method presented here has not been applied to a short-range order system, such as a liquid, since it is believed that (as in the case of the Einstein solid) the first Born approximation is not valid near the band edges. An equivalent conclusion appears to have been reached by Sah and Eisenschitz (1960). Since, for a short-range system, the reflected electrons are spread over a much wider range of k values some modification of the present method would be required. An approximate approach to liquids is, however, provided by Mott's theory of the electrical properties of liquid metals (Mott 1934).

On this theory—originally applied to the resistivity of liquid metals—a liquid metal near the melting point is treated as an Einstein solid with an Einstein temperature lower than that of the solid; the Einstein temperature of the liquid is obtained from that of the solid on the assumption that no change of structural entropy takes place on melting. Taking θ_E for the solid sodium as 150°K its value for the liquid is about 113°K. For the one-dimensional model, melting then results in a contraction of all energy gaps by about 20%.

ACKNOWLEDGMENTS

I wish to thank Dr. R. Fürth, of Birkbeck College, for his interest and encouragement during the course of this work. I am indebted to Dr. N. Cusack, of Birkbeck College, for a number of discussions on liquid metals.

The Stopping Power for Alpha Particles of Ethyl Alcohol and Carbon Tetrachloride in the Liquid and Vapour States

BY R. B. J. PALMER

Department of Medical Physics, Royal Free Hospital School of Medicine,
8 Hunter Street, London, W.C.1

MS. received 1st *May* 1961

Abstract. Range–energy relations for 8·78 MeV alpha particles in ethyl alcohol and carbon tetrachloride in the liquid and vapour states have been determined experimentally using nuclear emulsion and scintillation counting techniques. The range in liquid alcohol was found to be greater than the value previously published. The stopping power for both liquids was found to be different from that of the corresponding vapour, and it is suggested that polarization of the absorbing medium is mainly responsible.

§ 1. INTRODUCTION

RANGE–ENERGY relations for alpha particles in liquid water and water vapour have previously been determined experimentally (Palmer and Simons 1959). The range values obtained for alpha particles of various energies in liquid water were higher than earlier published values (de Carvalho and Yagoda 1952, Aniansson 1955). The differential stopping power of liquid water relative to air was also found to be lower than the values published (Appleyard 1951, McInally 1956) and lower than the differential stopping power of water vapour, particularly at low energies. It was suggested that this might be due to a low energy ' density effect ', and it seemed desirable to obtain range–energy relations in other materials in the liquid and vapour phases for comparison. For this purpose ethyl alcohol and carbon tetrachloride were selected.

§ 2. EXPERIMENTAL METHODS

Each range–energy relation involved two different types of experiment: a measurement of the total range of 8·78 MeV alpha particles from ThC in the medium concerned and a measurement of residual particle energy after a series of known path lengths in the medium had been traversed.

For range–energy determinations in the vapour phase the apparatus previously described for measurements with air was used (Palmer and Simons 1959). In this apparatus 8·78 MeV alpha particles traversed a fixed path length in vapour at known pressures and were recorded in nuclear emulsions. Vapour at the required pressure was introduced into the apparatus by including in it a known volume of liquid inside a sealed capsule which could be punctured after the apparatus had been evacuated. Measurements were made at twenty-two different pressures for both alcohol and carbon tetrachloride vapours. The mean residual track length corresponding to each vapour pressure was calculated from at least 80 track lengths. The graphs of residual track length against vapour pressure are shown in Fig. 1.

For the determination of the total alpha particle range in vapour the photographic emulsion was replaced by a silver-activated zinc sulphide screen and photomultiplier, and the change in counting rate was observed as the pressure of the vapour in the apparatus was reduced. Assuming the Bragg–Kleeman rule to hold for vapours within the limits of pressures used in these experiments, the alpha particle range in vapour could be deduced at any required pressure within these limits. Great care was taken to ensure that the alcohol used was dry, and for this reason experiments were carried out using three different drying agents in the vapour chamber: 'Hi-drite', freshly heated calcium oxide and silica gel. Fourteen 'stopping pressure' values obtained using the first two drying agents were all within ± 1·2% of their mean value. The values obtained using silica gel as drying agent were all between 1·2% and 2·0% higher than this mean, and since this could have been due to the presence of traces of water vapour these results were rejected. Seven separate determinations of the 'stopping pressure' were made for carbon tetrachloride vapour. The values were all within ± 0·7% of their mean value. Increased amplification of the pulses from the photomultiplier had no significant effect on the 'stopping pressure' value obtained, so it was assumed that the alpha particles were being detected by the scintillator when at the extreme end of their range. Typical graphs of counting rate against pressure are shown in Fig. 2.

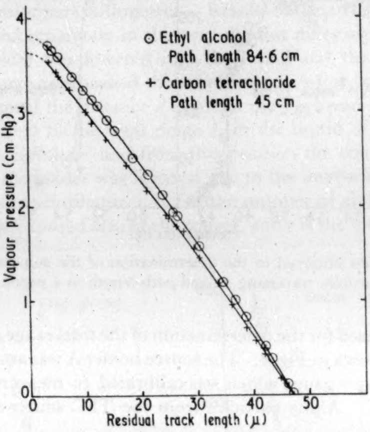

Fig. 1. Relation between vapour pressure throughout an absorbing path of fixed length and residual alpha particle track length in emulsion

The relations between alpha particle residual energy and the corresponding path length traversed in liquid ethyl alcohol and carbon tetrachloride were determined by a nuclear emulsion technique previously described for liquid water (Palmer and Simons 1959). They were compiled from approximately 260 track measurements in each of five plates for liquid alcohol and from similar measurements in seven plates for carbon tetrachloride. Results are shown in Fig. 3.

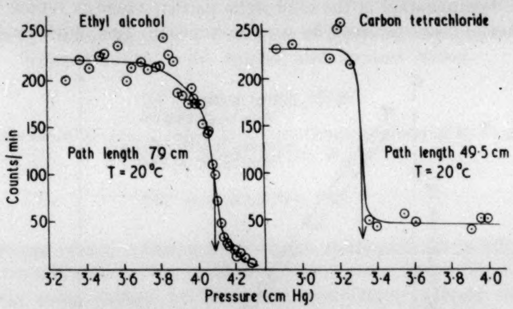

Fig. 2. Typical graphs obtained in the determination of the stopping pressure for alpha particles traversing a fixed path length in a vapour.

The apparatus used for the determination of the total range of alpha particles in the liquid state is shown in Fig. 4. The source holder A was attached to the spindle of a micrometer screw gauge which was calibrated to measure movements with an accuracy to 0·2 μ. Alpha particles from the ThC source at B passed through

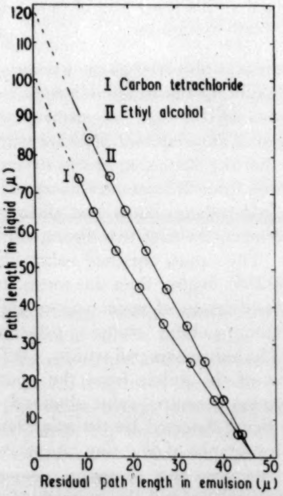

Fig. 3. The relation between the path length traversed by alpha particles in liquid ethyl alcohol and carbon tetrachloride and the residual path length in C2 emulsion.

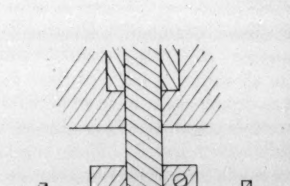

Fig. 4. Apparatus for measuring the range of alpha particles in liquids.

1·4 mm of air and through the Formvar film C into the liquid and were detected by the scintillator at D. The scintillator was a 'Perspex' disk surfaced with small crystals of silver-activated zinc sulphide. The crystals were inset in the Perspex by compressing them between the Perspex and a piece of flat glass at about 120°C. By this means a scintillator was obtained which was flat within $\pm 1\,\mu$ over an area of several square millimetres. Results obtained using several different scintillators prepared separately in this way did not differ significantly.

The source holder was lowered into the liquid and the counting rate was observed as the source approached the scintillator. A low background counting rate was observed until the distance d between the Formvar–liquid interface and the detector was equal to the total range L in the liquid of the alpha particles emerging from the Formvar, and from this position the counting rate began to increase as the source holder was lowered due to the increasing number of alpha particles reaching the scintillator. If I is the number of alpha particles emitted per second from the exposed area of the source, and r is the total distance between the source and detector it can be shown that the alpha particle counting rate is $I(L-d)/2r$ for values of $L-d$ which are small compared with L. The counting rate was found to vary with the thickness of the liquid layer d as shown in Fig. 5, the non-linear part of the graph being caused by straggling. The straight line part of the graph was extrapolated to the level of the background counting rate and the value of d at the point of intersection was taken as the mean range of alpha particles in the liquid. A correction was made for absorption in the air and the Formvar film. The measurements were carried out at three different pulse amplifications and there was found to be no significant difference in the range values obtained. Mean values taken from eleven measurements with ethyl alcohol and ten measurements with carbon tetrachloride gave range values of $119 \pm 2\,\mu$ and $100 \pm 1\,\mu$ respectively for the two liquids. A mean of nine separate measurements carried out with water as the absorbing medium gave

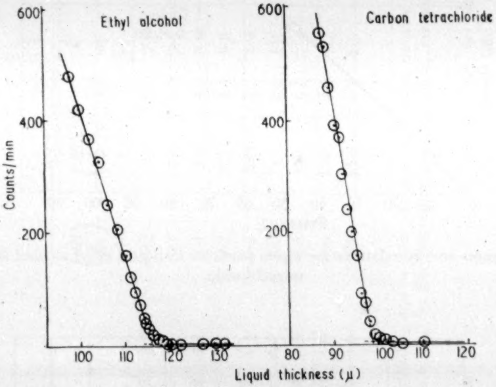

Fig. 5. Typical graphs obtained in the determination of the total range of alpha particles in liquids.

a range of $101 \pm 2\mu$ which is higher than the value of $96{\cdot}_6 \pm 1{\cdot}_7\mu$ obtained in previous experiments using a nuclear emulsion technique (Palmer and Simons 1959).

§ 3. RESULTS

The range–energy relations for alpha particles in ethyl alcohol and carbon tetrachloride in the liquid and vapour states are shown in Figs 6 and 7. The range indicated for alpha particles of 5·3 MeV energy in liquid alcohol is seen to be very much higher than the value of 46·5 μ obtained by Aniansson (1955).

The specific energy loss in liquids $(dE/dx)_L$ and in their vapours at the same density $(dE/dx)_V$ are given in MEV cm^{-1}. The differential stopping powers in liquids s_L and in the corresponding vapours s_V are calculated per molecule relative to one ' atom ' of air.

The specific energy losses at various alpha particle energies in ethyl alcohol and carbon tetrachloride in the liquid and vapour phases have been determined from the range–energy relations and are shown in the Table. Values for water previously determined (Palmer and Simons 1959) are given for comparison. In each case the experimental value for the specific energy loss in the vapour phase has been multiplied by the ratio of the molecular densities in the liquid and vapour phases under experimental conditions, so that the value given for the vapour is 'corrected' to the same density as the liquid. The differential stopping powers relative to air, s_L and s_V have been derived from these values of $(dE/dx)_L$ and $(dE/dx)_V$ and from the range–energy relation for air previously published (Palmer and Simons 1959). The main source of error in the values of specific energy loss arise in constructing the line through the experimental points. This may give rise to errors of $\pm 2\%$ in the specific energy loss at medium and high energies. At low energies the errors may be greater than this as they will be augmented by errors in the total range determination.

It can be seen that the stopping powers of all three liquids relative to air decrease with decreasing energy. The stopping powers of the vapours vary to a much smaller extent with energy and in differing ways. At high energies there is no significant difference in the stopping power of liquid alcohol and alcohol vapour. The stopping power of carbon tetrachloride vapour appears to be significantly lower than that of the liquid at 7 MeV and above. At energies below 5 MeV the stopping power of the vapour is significantly higher than that of the liquid for all three compounds, and the ratio s_V/s_L increases with decreasing alpha particle energy.

§ 4. CONCLUSIONS

It would appear from these results that several factors may be responsible for the different absorbing properties of liquids and vapours. At high energies the stopping power of carbon tetrachloride is less in the vapour than in the liquid phase, and this may be due to differences in the electronic binding energies in the two phases. At low energies a shielding effect due to polarization of the medium by the alpha particles could account for the lower values of the stopping power in the liquid phase. This effect has been discussed by Palmer and Simons (1959) with particular reference to the difference in the molecular stopping power of water and water vapour. At very low energies the rate of energy loss may be further complicated by the capture of electrons by the alpha particles. Neufeld (1954) considers this problem with particular reference to condensed media, and concludes that the mean alpha particle charge will be greater in a condensed medium than in the corresponding vapour. If this is so, the increased probability of electron loss in a condensed medium should tend to counteract the effect of polarization of the medium and to decrease the ratio s_V/s_L at very low energies. The relative importance of these two effects will depend on the liquids concerned, but at alpha particle energies above 2 MeV the polarization effect would seem to be the overriding factor.

ACKNOWLEDGMENTS

The author would like to thank Dr. H. A. B. Simons for helpful discussion concerning this work and Mr. F. R. Dennis for constructing most of the apparatus required.

Antiferromagnetic Resonance in the Extreme Infra-red

The magnetic ions in a simple antiferromagnetic crystal like MnF_2 are aligned by exchange interactions so that they form two interpenetrant and equivalent sub-lattices which are spontaneously magnetized in opposite directions. There is a preferred crystallographic axis to which the sub-lattice magnetizations are bound by anisotropic forces arising from dipole–dipole interactions and from crystal field effects. If an alternating magnetic field is applied perpendicularly to the preferred axis the sub-lattice magnetizations will undergo precessional motion which, at 0°K, should be resonant at the frequency below, as deduced by Kittel (1951) and by Nagamiya (1951).

$$\nu = \frac{\gamma}{2\pi}\{[2H_A(H_E + H_A)]^{1/2} \pm H\}.$$

H_A and H_E are *effective* fields representing the forces constraining the sub-lattice magnetizations to the preferred axis. H_A measures the anisotropy force and H_E the exchange force which is exerted on each ion by the ions forming the other sub-lattice. γ is $ge/2mc$, where g is the g-factor of the ions and will be close to the spin-only value, 2. H is a static externally applied field in the preferred direction whose application leads to two resonant conditions rather than one.

Keffer (1952) has derived theoretical values for H_A and H_E for manganous fluoride. He finds $8{\cdot}8 \times 10^3$ oersteds for H_A and $5{\cdot}4 \times 10^5$ oersteds for H_E. In zero applied field resonance is therefore predicted at 273 Gc/s, or $9{\cdot}10\,\text{cm}^{-1}$, which corresponds to a wavelength of 1·1 mm. There are two ways in which the resonance frequency can be reduced below this value so that resonance can be observed by microwave methods, which normally do not extend to frequencies as high as 273 Gc/s. The first is to raise the temperature, when both H_A and H_E fall towards zero at the Néel point. The second is to apply a sufficiently large magnetic field for the branch of lower frequency in the equation above to become accessible to measurement. Both methods have been used by Johnson and Nethercot (1959) to study the resonances of manganous fluoride. In this note we report the use of special *infra-red* techniques to observe zero-field low temperature resonances in MnF_2. The measured resonance frequencies are in good agreement with the theoretical values and with the values obtained by the extrapolation of Johnson and Nethercot's values to zero field and zero temperature.

A grating monochromator was used, with a mercury discharge lamp as source and with a superconducting bolometer as detector, permitting measurements to be made to wavelengths exceeding 1·4 mm (Bloor, Dean, Jones, Martin, Mawer and Perry 1961). The fractional transmission through a crystal of MnF_2 is shown in Fig. 1 as a function of wavelength and for three temperatures. The depth of the absorption lines is about 15% and the two sets of points for 16°K were obtained using different bolometers. The frequencies at which the minima in transmission occurred are as follows:

$8{\cdot}77 \pm 0{\cdot}16\,\text{cm}^{-1}$ at $5{\cdot}5 \pm 0{\cdot}3$°K
$8{\cdot}55 \pm 0{\cdot}16\,\text{cm}^{-1}$ at $16{\cdot}0 \pm 1{\cdot}0$°K
$7{\cdot}20 \pm 0{\cdot}25\,\text{cm}^{-1}$ at $42{\cdot}5 \pm 1{\cdot}0$°K.

The last of these temperatures overlaps the lowest temperature at which Johnson and Nethercot detected zero-field resonance. We have plotted their data together with ours in Fig. 2. The curve drawn in the figure is the modified Brillouin curve which should fit the experimental points if the sub-lattice spontaneous magnetization M_s varies with temperature in the manner suggested by the simple molecular field model of Néel (1936) and of Van Vleck (1941), and if both H_A and H_E are proportional to M_s. Johnson and Nethercot extrapolated their zero-field frequencies to zero temperature and their low temperature frequencies to zero

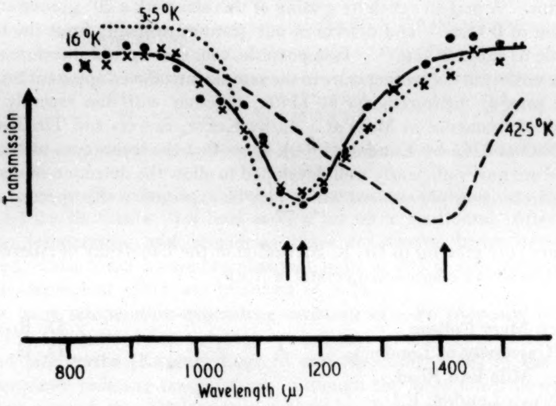

Fig. 1. The relative transmission of MnF_2 as a function of wavelength and temperature.

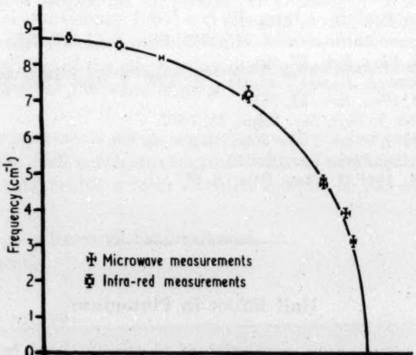

Fig. 2. The temperature dependence of resonance frequency as determined by microwave methods (Johnson and Nethercot) and the infra-red methods.

field, and obtained the value 8·73 cm^{-1} for the zero-field resonance frequency at 0°K. Our most probable value for 0°K is between $\frac{1}{2}$% and 1% higher than this, but this difference is within the estimated uncertainty of our determinations. The arrows in Fig. 1 indicate the points at which Johnson and Nethercot's extrapolation procedure would suggest the transmission minima should appear. The results are clearly in good agreement with Keffer's calculations.

The curves of Fig. 1 are unlikely to provide a true measure of the line-breadths. The superconducting bolometers are sufficiently sensitive for the resolution to be limited, not by the available energy, but by the 6 in. × 6 in. grating in the monochromator. A perfect echelette grating of this size with a 20° groove angle has a resolution of 0·1 cm^{-1}, and defects in our gratings probably limit the resolution attainable to about 0·3 cm^{-1}. It is possible, too, that optical interference effects and non-uniformity of temperature in the sample introduced apparent broadening.

The present measurements at 1140μ, together with the recently reported detection of resonance in MnO at 364μ by Keffer, Sievers and Tinkham (1961) and in NiO at 274μ by Kondoh (1960), show that the techniques of the extreme infra-red are now sufficiently well developed to allow the detection of many of the magnetic resonance phenomena which may be expected in this spectral region.

We are very grateful to Dr. R. Stevenson of the University of Aberdeen, who provided us with a magnificent crystal of MnF$_2$.

Hall Effect in Plutonium

Many low temperature properties of plutonium have been interpreted in terms of electronic structural changes at temperatures below 150°K. To explore this possibility further, the Hall effect has been measured in specimens of α-plutonium (maximum impurities 1000 parts per million) and δ-plutonium (stabilized at room temperature by the addition of 3·4 at.% Al) at 77°K and 293°K.

Conventional d.c. equipment was used incorporating a permanent magnet of 4·4 kOe field strength. Preliminary measurements on samples of silver, uranium and thorium gave results in good agreement with published data, and additionally a value for thorium at 77°K of $-9{\cdot}8 \pm 0{\cdot}6 \times 10^{-11}$ m^3 c^{-1} was obtained. The results for plutonium are shown in the following table; in each case the value given is the mean of 15–20 observations on each of three samples. The errors quoted arise principally from uncertainty in the specimen thickness.

Temperature (°K)	R_H (m^3 c^{-1}) × 10^{11}	
	δ-Pu	α-Pu
293	$+11{\cdot}1 \pm 1{\cdot}0$	$+6{\cdot}9 \pm 0{\cdot}5$
77	$+16{\cdot}2 \pm 1{\cdot}5$	$-9{\cdot}5 \pm 0{\cdot}6$

All three α-Pu samples showed a continuous increase in R_H (up to $-18{\cdot}0 \pm 1{\cdot}2 \times 10^{-11}$ m^3 c^{-1}) if held at 77°K for up to six hours. After warming to room temperature and remaining there for twelve hours or more, the tabulated values were invariably obtained both at 293°K and initially at 77°K. No time-dependent effect was observed in δ-Pu.

The large temperature-dependent variation in α-Pu (opposite in direction to that for δ-Pu), involving a change in sign, may be analogous to the behaviour of some rare earths (Kevane, Legvold and Spedding 1953) in the region of their magnetic ordering temperatures, although the large effect in dysprosium occurring around the Néel temperature (Liu, Behrendt, Legvold and Good 1959) is in the opposite direction to that in α-Pu.

The observed time dependence in α-Pu may be related to the detailed thermal cycling reported by Sandenaw and co-workers in specific heat measurements (Sandenaw, Olsen and Gibney 1961) and effects of a similar kind are also shown in some rare earths (McHargue and Yakel 1960). However, we would not exclude the possibility of the effect being due, in this case, to strains remaining in the α samples from the various mechanical and thermal processes of their history.

Projected measurements of the temperature dependence and possible field dependence of the Hall coefficient together with an extension to liquid helium temperatures should enable a more detailed analysis of the effect to be made.

CORRIGENDUM

Explanation of Some 'Forbidden' Transitions in Paramagnetic Resonance, by B. Bleaney and R. S. Rubins (*Proc. Phys. Soc.*, 1961, **77**, 103).

We are indebted to Mr. F. I. B. Williams of the Clarendon Laboratory for drawing our attention to some third-order terms omitted from Eqn (7) of this paper. The last term of this equation includes only the contributions arising from terms off-diagonal in the nuclear magnetic quantum number; the omitted terms are diagonal in this quantum number, and arise from the modification of the value of $\langle S_z \rangle$ through admixtures to the state $|M\rangle$ by the crystal field operator. The last term in Eqn (7) should be replaced by

$$\left\{\frac{D\sin 2\theta}{4g\beta H}\right\}^2 \left\{\frac{2Am}{M}\right\}\{[M^2-S(S+1)]^2-M^2\}$$

$$+\left\{\frac{D\sin^2\theta}{4g\beta H}\right\}^2 2AmM\{2M^2+1-2S(S+1)\}.$$

This change does not affect Eqn (8), but Eqn (9) etc. should read

$$\Delta H = x(y\cos^2\theta - z\sin^2\theta)\sin^2\theta \qquad \ldots\ldots(9)$$

where $\delta = (Am/4g\beta H)\ \{4S(S+1)+1\}$ and $z = 1 + (Am/g\beta H) = 1 + \epsilon$. Eqn (10) becomes

$$\delta H = x\left\{z + \frac{y^2}{4(y+z)}\right\} \qquad \ldots\ldots(10)$$

which, for small values of $(Am/g\beta H)$, reduces to

$$\delta H = \left(\frac{25x}{9}\right)\left\{1 - \frac{32\delta - 13\epsilon}{45}\right\}.$$

REVIEWS OF BOOKS

Electronic Processes in Solids, by P. R. AIGRAIN, R. J. COELHO and G. ASCARELLI. Pp. x+67. (London: John Wiley, 1961.) 32*s*.

In 1957, Professor Aigrain was Visiting Professor at the Massachusetts Institute of Technology and gave a course of lectures in which he examined the foundations of the currently accepted methods of treating transport processes in solids. Starting from the complete crystal Hamiltonian, the various stages leading to transport theory, such as the Born–Oppenheimer approximation, and the solutions of the resulting nuclear and electronic equations were developed. Scattering theory and various scattering mechanisms were considered and led to a discussion of transport theory.

This book was prepared by the authors from notes taken at these lectures, and acording to the preface they have extended some of the topics and have presented others in a slightly different way. Their declared object in doing so was to reach a wider audience possessing a " fair background in calculus and in elementary wave mechanics ".

It must be admitted that the question of what is a fair background is one of the most difficult ones to answer before writing a book on any advanced topic and the answer tends to vary greatly from one individual to another. Making due allowance for this, however, I still think that the authors have tried to squeeze too much into a book of only sixty-two pages (small ones at that). A comparatively small increase in length, used to include arguments by which one equation is derived from another and to provide general continuity, would have been very well worth while. It would have given the reader a much easier task in attempting to follow the mathematical arguments. As things stand, I very much doubt whether this can be done with the present book unless the reader already knows a good deal about the subject and is thoroughly familiar with quantum mechanics. Even in this case, the attempt is likely to be confused by the absence of an adequate explanation of symbols and by the presence of numerous misprints in the book.

To quote a few examples, in the first equation on page 2, the summation sign appears in both primed and unprimed form with no explanation of the distinction between the two. On page 3, the first equation contains a very confusing misprint (H_r instead of H). A few lines further along a symbol V_a is introduced without any explanation of its significance. On page 6, ω_k should appear as ω_k^2 on the left-hand side of Eqn (3.4). An integral sign is missing in Eqn (6.3). The lack of continuity between sections 6 and 7 is particularly bad. In the former the electronic wave equation is formulated and in the latter the solution is given, but it is practically impossible to see that the same equation is being dealt with in both cases.

These are the sort of things which occur in all lecture notes. It is well known that such notes are usually unintelligible to anyone except the person who has taken them. This book suffers from this fault. A little more care in editing and a little more explanation would have done much more justice to the subject and to Professor Aigrain's treatment of it. J. R. DRABBLE.

Röntgenstrahl-Interferenzen, by MAX VON LAUE. Pp. x + 476. (Frankfurt: Akademische Verlagsgesellschaft, 1960.)

The character of this third edition is essentially the same as that of its predecessors. The original aim of Professor von Laue's book was to form a bridge between crystallography and wave mechanics, and in this it succeeds admirably. This is not a book on methods of structure analysis; it deals with the basic physical and optical principles of X-ray diffraction. The most detailed part of the book concerns the treatment of the dynamical theory of X-ray diffraction from crystals. This section has been brought up to date by a thorough discussion of the anomalous absorption effect, and of the path of the X-rays in the crystal. There is no doubt that Professor von Laue's treatment of all aspects of dynamical theory remains the most comprehensive and authoritative work on this subject.

In preparing this third edition Professor von Laue was conscious of the considerable progress made in our knowledge and understanding of crystal defects. He therefore included a discussion of ' paracrystals ', a selection which was no doubt influenced by the fact that this particular topic was developed in his institute.

Although this book also contains the basic principles of structure analysis, calculations of atomic scattering factors, an account of temperature diffuse scattering and of several other topics, to the reviewer this work stands out as the classical exposition of dynamical theory by the father of X-ray diffraction.

P. B. HIRSCH.

An Introduction to Celestial Mechanics, by T. E. STERNE. Pp. xi + 206. (New York, London: Interscience, 1960.) 34*s*.

Celestial mechanics has not been promoted as vigorously during the last few decades as it was last century. Thus we find students are somewhat unprepared for the exacting demands of the new space science which presents a wide range of celestial mechanical problems requiring quick and accurate answers. The basic methamatics is known but not very readily available to those with limited background knowledge and limited time to press further. The interscience tract under review should go far to help this situation.

Any author attempting to deal with the dynamical problems of the space age has to consider whether his approach will be through classical methods or whether suitable progress can be made without them. The present work does take the classical line. It is intended for students at about young graduate level and with a physics or engineering background. The non-astronomer may acquire his basic information on orbital problems from the first three chapters. The serious dynamics begins in chapter 4 where the author takes one quickly, although systematically, through Lagrange's equation, the Hamiltonian form, contact-transformations, the Hamilton–Jacobi equation. All of these steps lead up to the solution of perturbed systems and thus to the orbital variations of space science. There are two treatments of the problem of satellite revolution around a non-spherical planet, one of which might be considered standard, and the other a new treatment with certain advantages in application. The atmospheric density in relation to resistance to the motion and the life of a satellite is also treated fully. Finally, there is a useful chapter on numerical methods of integrating differential equations.

This introduction could be used as a textbook or for ancillary training. It is also useful as a reference source of formulation in dynamics. It should be available in all libraries dealing with mechanics and many private copies will be sought. C. W. ALLEN.

Plasma Physics and the Problem of Controlled Thermonuclear Reactions, Vol. II, edited by M. A. LEONTOVICH. Pp. vi+457. (London, New York, Paris, Los Angeles: Pergamon Press, 1960.) £8.

As mentioned in the review of Vol. III (*Proc. Phys. Soc.*, 1960, **76,** 591), the four volumes contain translations of Russian reports dealing with work on controlled thermonuclear fusion from 1951 to 1958. The general comments in the previous review are relevant; for example, the reports are written for the specialist, cover a wide range of topics, and include both theoretical and experimental work.

There are twelve purely theoretical papers in the present volume, of which eight deal with cylindrical plasma columns with steady and time-varying internal and external magnetic fields, axial currents, etc. These include two on the conditions for hydromagnetic stability. Of the four other theoretical papers, one is on nuclear reaction rates, one on bremsstrahlung, and two on relativistic plasmas with sections on relativistic beams.

The experimental papers include three dealing with neutron and X-ray production in cylindrical deuterium discharges, one on current and electric field distributions within the discharge as obtained by using magnetic probes, and one on electrical conductivity in a low frequency (270 c/s) high current linear discharge.

The remaining three papers are concerned with a particular plasma experiment, in which a ring current is induced in a low pressure gas in an apparatus rather similar to a betatron. The ring is then collapsed to form a ball of plasma. This is discussed experimentally in detail following a brief theoretical account.

The volume will repay careful study by all those engaged on research into the properties of plasmas. R. LATHAM.

Electromagnetic Structure of Nucleons, by S. D. DRELL and F. ZACHARIASEN. Pp. 111. (London: Oxford University Press, 1961.) 12*s.* 6*d.*

This little book arrived for review at about the same time as I had undertaken to give a lecture on electromagnetic nucleon structure; it was therefore subjected to rather more than the first quick reading that many books must get from their reviewers. I found it immensely informative and helpful at just the level I required, and surprisingly self-contained. The first chapter defines with great clarity what is meant by the form factors. The second chapter sets about the analysis of experiments from which form factors may be obtained. The third chapter deals with the calculation of form factors by means, in the main, of dispersion theory which it starts off by explaining without being at all frightening. The fourth and final chapter briefly considers the validity of quantum electrodynamics. The book is an excellent addition to a series which is already commanding great respect. Although the subject of the book is expanding fast, so that in detail it may quickly be out of date, there is sufficient in it of substance that it is likely to remain useful for a good many years.

B. H. FLOWERS.

Kinematics of Nuclear Reactions, by A. M. Baldin, V. I. Gol'danskii and I. L. Rozenthal. Pp. xiii + 303. (London, New York, Paris, Los Angeles: Pergamon Press, 1960.) 42*s*.

An adequate and lucid translation of a book originally published in Russian and dealing with a very useful subject from a practical point of view is always welcome. One has to spend so much time calculating tricky kinematical factors that to find almost every conceivable one written down, together with many useful diagrams and tables, is a great relief, particularly to the more indolent theoretician. It is therefore even more to be deplored that the translation was obviously not checked before publication by a competent physicist who could easily have put right so much of the translator's phraseology. Although such defects do not always obscure the meaning completely, they certainly do not help the reader. One example should suffice, dealing with three-body reactions which are considered as the limits of two-body ones: " These limiting cases are, in point of fact, different variants of the substitution of a one-act formation of many particles by several acts, in each one of which up to two particles is formed."

B. H. FLOWERS.

The Theory of Transition-metal Ions, by J. S. Griffith. Pp. x + 455. (London: Cambridge University Press, 1961.) 95*s*.

This book is concerned with the theory of metal ions having a partly filled d-shell, and particularly with the theoretical properties of these ions in solids when they are under the influence of a crystalline or ligand field. This subject is of considerable current interest having been much investigated during the past few years, especially in the areas of paramagnetic resonance and optical absorption in paramagnetic crystals.

Chapters 1 to 6 deal with mathematical techniques and include a detailed chapter on the structure of free atoms and ions, and also a chapter on groups and their matrix representation. Chapters 7 to 9 then give the theoretical methods used for calculating the properties of complex ions in solids, the cases of weak and strong ligand fields each being dealt with very thoroughly. The last three chapters, 10 to 12, apply the theory to the behaviour of paramagnetic substances and include discussions of susceptibility, optical absorption spectra and paramagnetic resonance. There are a number of appendices which include many useful tables of theoretical and experimental data. All of the above refers to transition group ions with partly filled 3d, 4d or 5d shells—those with partly filled 4f or 5f shells are not treated.

The book will be very valuable to theoretical workers in the field, particularly for the treatment of calculations of energy levels of complex ions. These are necessary, for example, for understanding optical absorption spectra. It is also a useful reference book with many energy level diagrams and tables of theoretical and experimental parameters as well as original references. The treatment throughout tends to be rather formal and mathematical, and the book might have reached a wider audience had there been, in places, a little more simple physical discussion and explanation. Also, some topics are, surprisingly, omitted. For example, in the long chapter (58 pages) on paramagnetic resonance there is barely a mention of hyperfine structure from ligand nuclei, yet one would have thought that this was one of the most direct applications of this technique to the study of the structure of complex ions. However, these are small criticisms of a good book which gives what is probably the best formal introduction to ligand field theory at present available. J. OWEN.

The Hall Effect and Related Phenomena, by E. H. PUTLEY. Pp. viii + 263. (London: Butterworths, 1960.) 50*s*.

I have heard it said that Dr. Putley has measured more Hall voltages than any other scientist. Whether or not this is true, he is well qualified to write this book.

The subject of the book is transport phenomena in semiconductors and it is written from the experimentalists' viewpoint. Methods of measurements are described and various transport equations are derived which in some other publications are only quoted. This makes the book particularly useful for the final year undergraduate who is interested in semiconductors, and for anyone who is beginning research in this field.

The first chapter of 21 pages on 'Conduction processes in semiconductors' provides the standard introductory discussion. There follows 40 pages in which the various thermo-galvanomagnetic effects are defined and the methods of measurement described. Amongst other things, this is a good place for looking up the signs, a feature which will be welcomed by many readers other than those already referred to. Either the right hand or the left hand can be used for turning the pages !

Chapter 3 is called 'Conduction in an isotropic solid'. Here the equations for the various transport effects are derived. Chapter 4 is the best chapter in the book, containing a detailed discussion of the transport properties of, primarily, germanium and silicon. There are some traps for students though. For instance, after a paragraph on carrier scattering by the acoustic modes of atomic vibrations the author writes: "In addition to the longitudinal vibrations of the lattice, transverse modes are possible . . . These are the optical modes . . ." The author gives the impression that the two types of atomic vibrations are: acoustical (longitudinal) and optical (transverse). One would not have expected this from the Royal Radar Establishment where one would have thought that T.A. and L.O. were, so to say, everyday words.

In the final chapter the work on other semiconductors is summarized. This is of necessity brief and is the chapter which suffers most from the continued rapid development of the subject. A major criticism here is that references are not given for the values quoted in the comprehensive Table 5.2 and it is frequently not possible to decide, with the aid of the text, whose value is being quoted. It is also misleading to speak of 'the hexagonal' form of silicon carbide when many hexagonal varieties exist, each a particular stacking fault in the zinc blende structure. Perhaps the data about the 0·25 ev difference in the band gaps of two of the hexagonal modifications were not available at the time of writing, nevertheless it was a gross simplification to write of 'the hexagonal' form.

These are points indicating a certain untidiness of detail. The book as a whole can be recommended to final year undergraduates and to anyone starting research on these topics.

At £2 10*s*. it seems to me expensive and I should have thought that, in view of the potential undergraduate and research student market, a paper backed edition at half the price would be welcome. E. W. J. MITCHELL.

Modern Aspects of the Vitreous State, Vol. 1, edited by J. D. MACKENZIE. Pp. viii + 226. (London: Butterworths, 1960.) 50*s*.

The subjects dealt with in this edited symposium on the properties of glass include discussions of the results of x-ray diffraction, nuclear magnetic resonance, infra-red and high-temperature studies of the vitreous state, and fundamental discussions of crystallization kinetics and the formation of glasses and of the 'glass transition'. There is also a chapter on the constitution of phosphate glasses. Although the book is labelled Volume One, there is no indication as to what future volumes will contain, so that it is difficult to comment on the scope of the present volume.

It is true, as the editor states in his introductory remarks, that "the structure of glassy materials has long been a topic of much controversy" and that "... comparatively little scientific progress was made in the last three decades". Unfortunately, the contents of this symposium, which sets out to survey the modern aspects of the vitreous state, are extremely variable both in quality and outlook. There are three excellent chapters: by D. Turnbull and M. H. Cohen, P. J. Bray and A. H. Silver, and I. Simon; four chapters which, though worthy, are not at all modern in outlook, and one which is simply eccentric. If the editor has attempted to co-ordinate or reconcile the contributions, he has not succeeded. In the present dearth of literature on glass this volume would be a useful source book of references for the active worker in the field, but of little use to the beginner, or the outsider. G. O. JONES.

CORRIGENDUM

Selected Scientific Papers, by B. VAN DER POL, edited by H. BREMMER and C. J. BOUWKAMP (*Proc. Phys. Soc.*, 1961, **78**, 636).

The price is £6 13*s*. for both volumes together, and not £6 13*s*. per volume as stated.

An Investigation into the Mechanism of Self-quenching Geiger–Müller Counters containing Argon with Small Quantities of Xenon, Oxygen and Nitrogen

By A. J. L. COLLINSON, I. C. DEMETSOPOULLOS AND J. M. ZARZYCKI

Borough Polytechnic, London, S.E.1

MS. received 14th April 1961, in revised form 8th June 1961

Abstract. The time distribution of spurious pulses in counters with treated and untreated cathodes was studied by pulse interval analysis, and plateau characteristics, charge per pulse and Geiger threshold potential are plotted as functions of the xenon concentration. In all the counters investigated, the presence of a minimum threshold indicates an optimum xenon concentration of 3·5%. Measurements of the corona threshold with argon and argon–xenon filling mixtures show a pressure dependent increase in gas multiplication with addition of xenon. This increase in ionization is tentatively explained by the hypothesis of two-body collisions between xenon atoms and argon excited molecules leading to the formation of the molecular ion AXe^+. Mobilities obtained from transit time measurements identify the ions involved as A_2^+ (1·82 cm sec^{-1} (v cm^{-1})$^{-1}$), possibly NO^+ (2·45 cm sec^{-1} (v cm^{-1})$^{-1}$) this ion appearing after the counters have been in continuous discharge, and an ion of mobility 1·64 cm sec^{-1} (v cm^{-1})$^{-1}$, which is not inconsistent with the postulated AXe^+ molecular ion.

§ 1. INTRODUCTION

GEIGER–MÜLLER counters containing simple gases (e.g. argon, oxygen, hydrogen, air, etc.), generally designated as 'slow', have been little used for many years. With these fillings the discharge produced by an ionizing event has a strong probability of producing a further discharge which has to be suppressed by inserting a very high value resistor (~ 10^9 ohms) in the anode or by the use of an external quenching circuit, otherwise the counter runs virtually into continuous discharge. Consequently such counters have been largely superseded in favour of those containing polyatomic vapour or halogen which do not require external quenching.

The basic mechanism of Geiger counter action, namely the quenching of the discharge by the slow moving positive ion sheath formed close to the anode, was first explained by Montgomery and Montgomery (1940) who attributed the train of secondary discharges after each discharge in a slow counter to positive ions releasing electrons on arrival at the cathode. This explanation seems to have had fairly general acceptance (Korff 1958), although the work of Ramsey (1951) on argon–oxygen counters indicated that some secondary discharges arose before the positive ion sheath reached the cathode.

The counters which are the subject of the present investigation containing xenon (~ 3·5%), oxygen (~ 0·3%), nitrogen (~ 1%) with argon to a total pressure of about 700 mm Hg were discovered by Shore (1949) and are remarkable in that while the filling gases are those normally associated with slow counters, the characteristics are typical of organically quenched counters. That is, they have flat plateaux obtainable with only a small anode series resistor. The present authors have mainly confirmed Shore's findings and this work has already been briefly reported (Collinson, Demetsopoullos, Dennis and Zarzycki 1960). The object of the present work was to investigate the performance of the counters in more detail, particularly as to the part played by the xenon. The present investigation does not cover the role of the nitrogen which is subsidiary (Collinson *et al.* 1960).

§ 2. APPARATUS AND EXPERIMENTAL PROCEDURE

2.1. *Counters and Filling Procedure*

The counters mainly used in this investigation were of the 'gamma' type, glass bodies with cylindrical cathodes 2 cm diameter and tungsten anodes 0·127 mm or in some cases 0·075 mm diameter. The active length of the counters was 20 cm. Cathode materials of copper, nickel, stainless steel, chrome iron, lead and silver have been used.

A conventional, all-glass vacuum system was used including a glass mercury vapour diffusion pump and every precaution was taken to exclude mercury from the system by the use of appropriate cold traps. The argon used was of 99·95% commercial grade but no attempt was made to remove the main impurities, oxygen (0·0005%) and nitrogen (0·05%), as these were normally present in much larger quantities in the filling mixtures. Water vapour and other condensible impurities were removed by passing the argon slowly through a liquid oxygen trap. The other gases used were of 'spectrally pure' quality, the xenon containing not more than 0·5% krypton as an impurity.

The counters were normally baked at 350 °c before filling which was not carried out unless the pressure in the system had previously held to less than 1×10^{-4} mm Hg overnight with pumps shut off.

2.2 *Measurements of Plateau Characteristics and Charge per Pulse*

When measuring plateau characteristics the anode e.h.t. was fed via a 4·7 megohm resistor and a linear feedback amplifier of gain variable from 25 to 400 was used, the higher gain being sometimes necessary to ensure that all pulses were counted, particularly with counters having poor plateaux, when a large number of small, possibly spurious pulses occurred.

Two methods were employed for measurement of the charge per pulse of the counters. In the first, a standard capacitor was connected between the counter cathode and earth, the potential difference across the capacitor resulting from a known number of counts being determined by an electrometer valve circuit. Provided the count rate was low enough for the chance of a discharge taking place with the positive ion sheath (or part of it) from the previous discharge still in the counter to be small, and that the number of spurious pulses was small, this method was quite satisfactory. However, spurious discharges, if present, gave rise to a smaller charge and the method described above yielded values lower than those represented by a normal discharge. A second method was therefore employed which consisted in measuring the height of the voltage pulse at the anode of the tube by an oscilloscope, the arrangement being calibrated by injecting a known charge from a pulse generator via a small capacitor. Graphs of charge per pulse against voltage obtained from both methods coincided at low overvoltages, the latter being defined as the excess of the operating voltage over the threshold voltage, but diverged at the end of the plateau, as would be expected. In practice both methods were used, the capacitor method yielding more accurate results at or near the counter threshold.

2.3 *Time Distribution of Spurious Pulses*

Spurious pulses occurring in the various gas mixtures were investigated by the method of pulse interval analysis originally used by Putman (1948) and also by Beretta and Rostagni (1949), for argon–alcohol Geiger counters.

A modified version of the circuit due to Putman (1948) was used to measure I, the rate of arrival of pulse intervals between t and $t+\delta t$. The spurious pulse distribution was determined by comparing the measured interval distribution with that expected from a truly random distribution where the number of intervals recorded in unit time is $n^2 \exp(-nt)\delta t$, by the Poisson law, n being the mean count rate.

The transit time of the positive ion sheath across the counter was measured for the various mixtures at different overvoltages by observation of the current pulse due to the discharge. The latter was viewed by connecting an oscilloscope to the cathode of the counter, a resistor R_K being connected from cathode to earth. The pulse (see figure 1) rises to a maximum value in a few microseconds after the initiation of the discharge and then falls away more slowly, a discontinuity where the current starts to fall more rapidly being present at a few hundred microseconds. The positive ion sheath as it moves across the counter distends under the action of its own field. The observed discontinuity corresponds to the time t_F when the front of the sheath reaches the cathode, and the time t_R, the recovery time when all ions are cleared from the counter, is given by the time at which the pulse returns to zero.

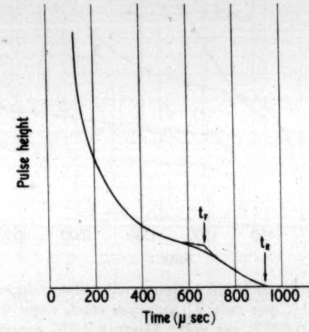

Figure 1. Typical cathode pulse shape.

§ 3. EXPERIMENTAL RESULTS

3.1. *Preliminary Experiments*

Observations were made using counter fillings of argon alone and then argon and xenon (3·54%) the total pressure in each case being 700 mm Hg. With both these fillings no Geiger region was observed, the discharge passing abruptly from the proportional to the corona region. In neither case were any pulses recorded when a quenching probe was used. Using a ^{137}Cs source the proportional pulses were observed with an amplifier of a maximum gain of 10^6 and an oscilloscope. With both fillings it was clear that the onset of the corona region was due to photon–cathode action similar to the observations of Colli and Facchini (1952) with pure argon. In neither case were the familiar pulses, typical of build-up along the anode with positive ion space charge quenching, observed. The chief difference between the two fillings was that the corona threshold was reduced by 500–600 volts by the presence of the xenon.

Although no accurate measurements were made of the gas multiplication, it was clear it increased more rapidly with the argon–xenon mixture than with the argon alone. Just before the respective corona thresholds, the pulse heights in the case of the argon–xenon mixture were about ten times those from the argon alone.

The addition of small quantities of oxygen to either argon or argon–nitrogen mixtures altered the character of the discharge entirely, Geiger pulses typical of discharge build-up along the anode with positive ion space charge quenching being seen on the oscilloscope with many spurious pulses. Mixtures containing 0·3% and 3% of oxygen respectively with total pressures of 700 mm Hg were investigated, plateaux being non-existent. Good plateaux were, however, obtained with both these mixtures using a quenching probe, plateau slopes and lengths being somewhat better with the lower oxygen concentration.

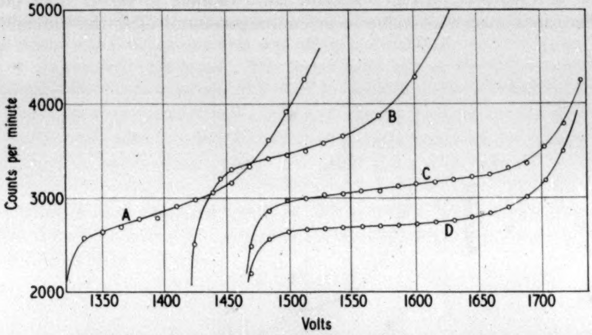

Figure 2. Plateau curves for different cathodes: A, silver, slope 0·17% per volt; B, chrome iron, slope 0·11% per volt; C, stainless steel, slope 0·053% per volt; D, oxidized copper, slope 0·025% per volt. Mixture 2·2% xenon, 0·35% oxygen, 1·1% nitrogen; total pressure, 706 mm Hg.

The counters were next filled with several mixture compositions, fairly close to the optimum amounts recommended by Shore, behaving as self-quenching counters and having plateaux varying in length between 60 and 180 volts and in slope between 0·03% and 0·15% per volt, for the various mixtures and cathodes used; silver was an exception in that the plateau slopes could be as high as 1·2% per volt. It was found that not only the type but also the state of the cathodes affected the performance. This was particularly so with copper cathode counters which after being filled, used and refilled several times gave an improved and consistent performance. This was attributed to a slow oxidation and conditioning of the cathode surface. A number of typical plateaux are shown in figure 2. It was also established during these experiments that for a stable cathode the plateau slope increased with the oxygen concentration, the optimum value of the latter being about 0·3%.

From the pulse interval analysis curves obtained with the different counters and mixtures it was clear that the spurious pulses fell into two categories as far as time incidence was concerned. If the voltage was set so that the counter was working on the plateau then a small number of spurious pulses were detected and these were fairly uniformly spread between the dead time and the recovery time. With the counter voltage set beyond the end of the plateau, the incidence of the spurious pulses was a maximum at the end of the dead time and fell away towards the recovery time. Typical curves illustrating these effects are shown in figure 3 (curves A and B) for a stainless steel counter. From the many curves obtained, it was concluded that with these mixtures and cathodes spurious pulses due to ion–cathode effect were not present in any significant quantity otherwise a peak at the positive ion transit time would have been observed.

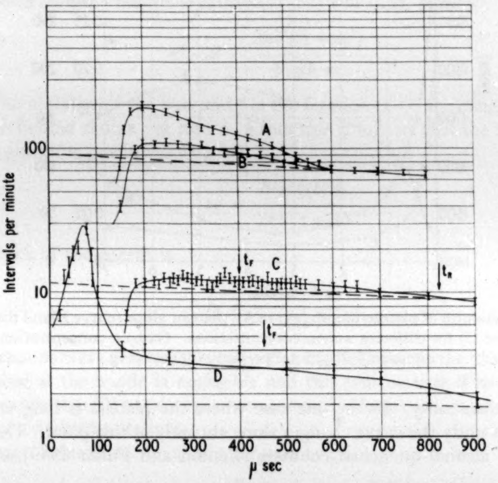

Figure 3. Pulse interval analysis curves for oxidized cathodes: A and B, stainless steel cathodes, overvoltages 175 and 100 volts, xenon concentration 2·23%; C, copper cathode, overvoltage 120 volts, xenon concentration 3·5%; D, copper cathode, overvoltage 6 volts, xenon concentration 0·10%. Dotted lines here and in figure 7 refer to the theoretical Poisson distribution, $I = n^2 \exp(-nt)\delta t$.

3.2. *Variation of Xenon Concentration*

Using two counters with copper cathodes of identical construction the counter characteristics were studied as the xenon concentration was varied from zero to 7%, the other constituents being maintained constant, oxygen at 0·3% and nitrogen at 1·1% with argon to a total pressure of 700 mm Hg. The variation of starting voltage, plateau slope and length are shown in figure 4, the optimum value of xenon concentration being obviously about 3·5%. Curves of *m* against overvoltage for the different mixtures are shown in figure 5, where *m* is the ratio of the charge per pulse to the static charge on the wire, and $m = 2Q\log(b/a)V$, V being the anode potential, b and a the cathode and anode diameters respectively, and Q the charge in the ion sheath per unit length of the wire. Plotted in this form the curves are almost straight lines where m is less than unity. In the one case where the plateau is long enough for m to be greater than unity the curve changes slope abruptly at this point. This behaviour is also typical of alcohol-quenched counters (Fenton and Fuller 1949) and has been explained by Wilkinson (1948). It will be observed that the slopes of the charge per pulse–overvoltage curves increase rapidly with admission of xenon varying from 0·24 per 100 volts to 0·66 per 100 volts.

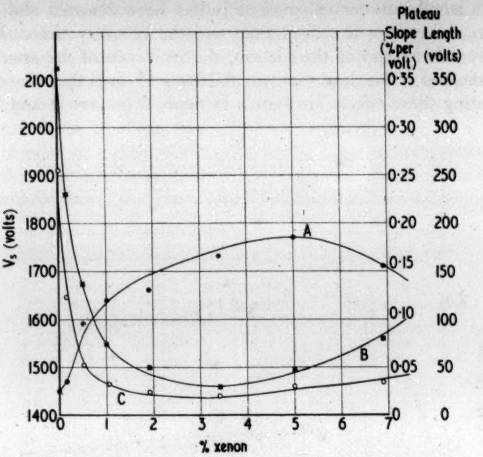

Figure 4. Variation of plateau length (curve A), plateau slope (curve B)and threshold voltage (curve C) for different xenon concentrations. Oxygen concentration 0·3%, nitrogen 1·2%, total pressure 700 mm Hg.

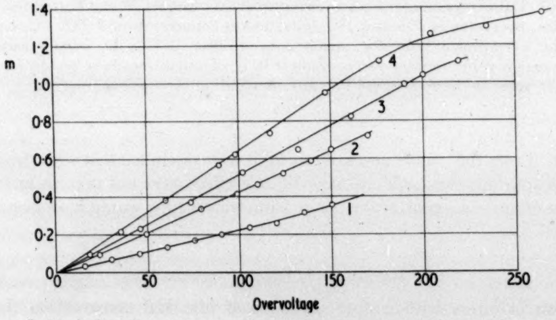

Figure 5. Variation of *m* with overvoltage for xenon concentrations 0·5% (curve 1), 1·07% (curve 2), 1·91% (curve 3), 3·44% (curve 4).

Pulse interval analysis curves obtained with these mixtures showed similar characteristics to those obtained in the preliminary experiments. However, at xenon concentrations less than 1% the dead times were much shorter as spurious pulses from curves taken just at the end of the very short plateau had a maximum incidence at 30 to 50 μsec, whereas with the larger concentrations dead-times were of the order of 150 to 200 μsec. Two typical curves are shown in figure 3, curves C and D, one for the mixture with 0·16% xenon and the other with 3·5% xenon.

From the measured values of the transit times of the front of the ion sheath, the mobility of the fastest ions could be calculated and hence, it was hoped, the ions identified. For this a formula due to Wilkinson (1952) was used, namely

$$r^2-a^2 = \frac{2kVt(1+mf)}{\log(b/a)} \tag{1}$$

where k is the mobility of the ions and f is the fraction of Q, the charge per unit length in the sheath behind radius r at time t. From this it follows that the transit time of the front of the sheath is, assuming $b^2 \gg a^2$,

$$t_{\mathrm{F}} = \frac{b^2\log(b/a)}{2kV(1+m)} \tag{2}$$

and of the back of the sheath is

$$t_{\mathrm{R}} = \frac{b^2\log(b/a)}{2kV}. \tag{3}$$

These expressions were derived assuming that the field due to the charge $-Q_{\mathrm{a}}$ per unit length induced at the anode is negligible and this will be true if $m \ll 1$. In order to correct the expression (2) to take this into account for larger values of m, an approximate correction was derived as follows.

The charge induced on the anode per unit length

$$-Q_{\mathrm{a}} = \int_{R'}^{R} \frac{\log b-\log r}{\log(b/a)}\frac{d(fQ)}{dr}\,dr \tag{4}$$

where R is the radius of the front of the sheath and R' that of the back and from (1), $R' = R/(1+m)^{1/2}$. To evaluate (4) substitute df/dr obtained from (1) and integrate giving

$$-Q_{\mathrm{a}} = \frac{QR^2}{4ktV(1+m)}\log\left\{\left(\frac{b}{R}\right)^2\frac{\mathrm{e}}{(1+m)^{1/m}}\right\}. \tag{5}$$

From (1) putting $r^2-a^2 = R^2$ and $f = 1$ and substituting in (5) we find

$$-Q_{\mathrm{a}} = \frac{Q}{2\log(b/a)}\log\left\{\left(\frac{b}{R}\right)^2\frac{\mathrm{e}}{(1+m)^{1/m}}\right\}, \tag{6}$$

e being the base of the Napierian logarithms.

The velocity of the front of the ion sheath is given by

$$\frac{dR}{dt} = \frac{2k}{R}\left\{Q_0+Q-\frac{Q}{2\log(b/a)}\log\left[\left(\frac{b}{R}\right)^2\frac{\mathrm{e}}{(1+m)^{1/m}}\right]\right\} \tag{7}$$

where Q_0 is the static charge on the anode per unit length and equal to $V/2\log(b/a)$.

Integrating (7) gives the transit time of the front of the ion sheath to radius R

$$t(R) = \frac{1}{X}\frac{[\log(b/a)]^2}{kVm}\{\overline{\mathrm{Ei}}(\log R^2X) - \overline{\mathrm{Ei}}(\log a^2X)\} \tag{8}$$

where

$$X = \frac{(1+m)^{1/m}}{b^2\mathrm{e}}\left(\frac{b}{a}\right)^{2+2/m}.$$

Substituting $R = b$ in (8), expanding the exponential functions and neglecting small terms gives

$$t_{\mathrm{F}} = \frac{b^2\log(b/a)C}{2kV(1+m)} \tag{9}$$

where

$$C = \frac{1+[m^{-1}\log(1+m)+[2(1+m)m^{-1}]\log(b/a)-1]^{-1}}{1-[m-\log(1+m)]/2(1+m)\log b/a}.$$

Thus the expression (2) requires correction by the factor C above. In practice this correction increases with m and was about 7% at $m = 1$. Plotting $1/t_{\mathrm{F}}$ against $V(1+m)/C$ gave, except in the case for the mixture with zero xenon concentration, a straight line passing through the origin from which the mobility was calculated. However, the accuracy could not be expected to be better than ±5% owing to the error in measurement of t_{F}. A typical graph (xenon concentration 1·07%) is shown in figure 6.

During the transit time measurements, a curious effect was observed in that after the counter voltage had been increased beyond the end of the plateau all the transit

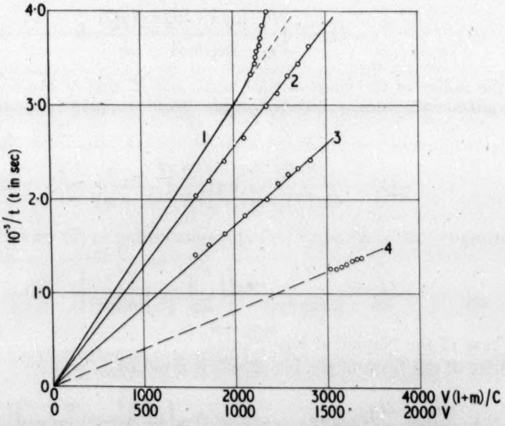

Figure 6. Plot of $1/t_{\mathrm{F}}$ against $V(1+m)/C$ for xenon concentrations, zero (curve 1), 1·07%, mixture in state B (curve 2), 1·07%, mixture in state A (curve 3). Plot of $1/t_{\mathrm{R}}$ against V, xenon concentration 3·44% (curve 4).

times were significantly reduced and a new set of values was obtained. Furthermore, the transit times were found to be similarly changed in the other counters on the manifold. Hence it was clear that a change had occurred in the mixture, although there appeared to be no significant change in the plateau or charge per pulse characteristics. Also, the change in the mixture appeared to be permanent. For purposes of discussion the first phase of the mixture will be referred to as state A and the second as state B. The effect was found to take place in nearly all the mixtures investigated and generally the change was quite sudden having taken place as a result of a sharp corona discharge at high overvoltage, this being observed on the oscilloscope as a burst of multiple pulses followed by a temporary blacking out of the trace. In practice, it was found difficult to avoid the mixture changing to state B but in the case of three of the mixtures a complete set of transit time measurements was made for state A. In a few cases, the mixture was found to be in state B when the transit times were first measured, the changeover presumably having taken place during other measurements.

The values of the mobilities for state B, excluding the mixture with zero xenon concentration, were found to be constant within ±5%, after reduction to 760 mm Hg pressure at 0 °c, and to zero xenon concentration using the expression for mobility in mixtures (Blanc 1908). No correction was made for the presence of the nitrogen and oxygen as the concentrations were small. The mean value obtained was 2·46 cm sec^{-1} $(\text{v cm}^{-1})^{-1}$. The set of transit time measurements obtained for three of the mixtures in state A (xenon concentrations 1·07%, 0·498% and 3·44%) yielded straight lines through the origin, the mobilities corrected as above having a mean of 1·82 cm $\text{sec}^{-1}(\text{v cm}^{-1})^{-1}$.

The transit time measurements for the mixture containing zero concentration of xenon did not yield a straight line through the origin (see figure 6), t_F decreasing more rapidly than expected from the change in charge per pulse. The inference from this was that, although a plateau was obtained, the discharge did not, even at the highest overvoltage where a measurement was made, spread completely along the anode wire, so that the effective m was higher than that measured. The value of the mobility of the ion could only be obtained in this case by extrapolation of the transit time to zero charge per pulse whence substitution in (2) gave the mobility as 3·0 cm sec^{-1} $(\text{v cm}^{-1})^{-1}$.

Although measurements of t_R could not be made with the same accuracy as t_F, there was evidence from such measurements of the existence of a slower ion. It was found that measurements of t_R were more accurate when the counters were in state A as the point at which the cathode pulse returned to zero was better defined. A plot of $1/t_R$ against V is shown for one of the mixtures in state A in figure 6, which, using expression (3), gives a value of the mobility, after correction, of 1·64 cm sec^{-1} $(\text{v cm}^{-1})^{-1}$.

As the ions spend most of the time in the low field towards the cathode, the values of mobility will correspond to those at low X/p. If argon ions are present in the space charge, they will, at these pressures, most certainly be molecular ions A_2^+. The mobility of such ions at low X/p has been measured by Lauer (1952), Schütt (1955) and Maushart (1958) whose values, reduced to 0 °c, are 1·81, 1·81 and 1·84 cm sec^{-1} $(\text{v cm}^{-1})^{-1}$ respectively. The ion detected in state A is thus most likely to be A_2^+.

The faster ion detected in state B has the same mobility as the oxygen ion O_2^+ which has been measured by Maushart (1958) who gives the value as 2·46 cm sec^{-1} $(\text{v cm}^{-1})^{-1}$. However, it seems unlikely to be O_2^+ since, if it were, there is no valid reason why it should not appear from the first. The most likely possibility seems to be that the ion is NO^+ which, as its mass is only slightly less than that of the oxygen molecular ion, would have a mobility only slightly greater, and certainly the difference would not be resolved by these measurements. A small quantity of nitric oxide is likely to be formed, possibly fairly slowly during the normal operation of the counters but rapidly when the counter suffers a sharp discharge as described above. In order that the NO^+ ion should appear, charge transfer should take place between this ion and the argon molecular ion, a necessary condition being that the ionization potential of the nitric oxide should be less than that of the argon molecule by, at least, the latter's dissociation energy. The last two values are not known but the appearance potential of the argon molecular ion has been determined from its formation from argon excited states (Hornbeck and Molnar 1951) as between 14·3 and 15·22 volts. The ionization potential of the nitric oxide is lower than that of oxygen (O_2^+), the values being 9·25 and 12·2 volts respectively so that if the argon (A_2^+) ionization potential is about 14 volts and its energy of dissociation about 2 volts, then this would explain the formation of the NO^+ ion.

3.3 *Cathode–Ion Effects*

The entire absence of any effect attributable to release of electrons by positive ions at the cathode was somewhat surprising, so an attempt was made to produce such effects by suitable conditioning of the cathodes. Four new counters were used for this, of identical construction, two with nickel and two with copper cathodes. On filling with the mixture corresponding to the optimum of figure 4 (concentration of xenon 3·5%), plateaux of length of about 120 volts were obtained. The cathodes in this case had been exposed to air and were likely to be slightly oxidized, the cathode–ion effect being absent. The system was now evacuated and the cathodes heated to red heat for some minutes by induction heating. The counters were then refilled when it was found that the plateau had almost disappeared being 8 volts in length for the nickel cathodes and 15 volts for the copper cathodes. Threshold voltages were almost the same for the two types of cathode but lower by a few volts than the previous filling. Pulse interval analysis curves showed that nearly all the spurious pulses occurred after the transit time t_F. In this case measurement of transit time showed that the mixture was in state B and the pulse interval analysis curves showed a small peak just after t_F followed by a larger peak. Presumably, the small peak is due to the NO^+ ions and the larger due to the A_2^+ ions. Two such curves for overvoltages of 4 volts and 20 volts are shown in figure 7. As there is only a suggestion of a peak corresponding to the faster ion for the lower overvoltage it is possible that the mixture had not changed to state B when these measurements were taken. The counters were evacuated and refilled with the same mixture and pulse interval analysis curves obtained at low counting rates in order to avoid, if possible, transition to state B. The curve so obtained is shown at C in figure 7; the transit time t_F measured from the cathode pulse corresponded to the A_2^+ ion and also to the beginning of the single peak.

The interval analysis also afforded a confirmation of the existence of a slower ion mentioned in § 3.2. The width of the peaks was greater than would be expected if a single ion were present. Taking the back edge of the peak as corresponding to the transit time of the slower ion and substituting in equation (3) gave a mean value, from a number of determinations, of the mobility as $1{\cdot}64\ \mathrm{cm\ sec^{-1}\ (v\ cm^{-1})^{-1}}$, in agreement with that obtained previously. The cathodes were reoxidized by induction heating in oxygen, at a pressure of a few mm Hg, and the counters were evacuated and refilled with the same mixture proportions. It was found that the counter characteristics improved steadily with operation, the plateau length in a typical case increasing from 9 to 180 volts after operating the counter at a high count rate for several days, the threshold rising by 12 volts.

During this series of experiments the threshold voltages were remarkably constant and changed little with the state or material of the cathode.

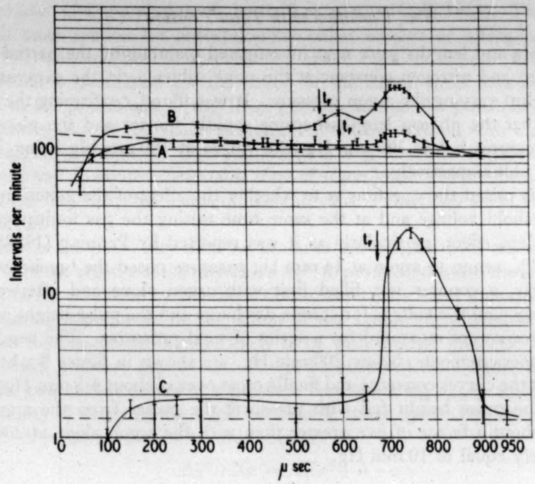

Figure 7. Pulse interval analysis curves after cleaning of cathodes by induction heating in vacuo. A and B, copper cathode, mixture in state B, overvoltages 2 v and 17 v. C, copper cathode, mixture in state A, overvoltage 22 v.

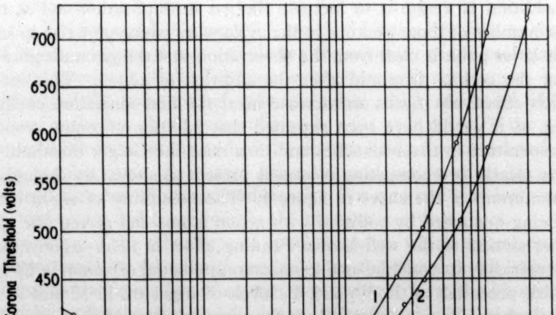

Figure 8. Corona threshold votages plotted against pressure for argon (curve 1) and argon + 2% xenon (curve 2).

3.4. *Variation with Total Pressure*

Plateau slopes and lengths were next investigated maintaining the partial pressures of xenon, oxygen and nitrogen constant at the same values as in the experiments described in § 3.3, but varying the argon pressure. It was found, confirming the results of Shore (1949), that the plateau lengths became rapidly shorter and the plateau slopes increased at pressures below 300 mm Hg, the values at 100 mm Hg being 27·5 volts and 0·56% per volt respectively.

These results raised the question as to whether the effect of the xenon in lowering the corona threshold voltage and at the same time raising the gas multiplication is a pressure-dependent effect, particularly as it was reported by Penning (1928) that the addition of 0·03% xenon to argon at 14 mm Hg pressure raised the breakdown potential. Accordingly, a counter was filled first with argon alone and afterwards with argon + 2% xenon, and the voltage for corona discharge and the pulse height just before the onset of corona were measured for a series of total pressures. The results of the corona voltage measurements, below 200 mm Hg, are shown in figure 8 where it will be observed that the curves converge and finally cross over at about 4·5 mm Hg pressure. The ratios of the pulse height fell with pressure, the pulses from the argon–xenon mixture being about a factor of five greater than with the argon alone at 200 mm Hg but approximately equal to 10 mm Hg.

§ 4. DISCUSSION OF RESULTS

4.1. *Effect of Xenon*

It is apparent from the experiment on the argon–xenon mixture that one of the effects of the addition of xenon is to increase the gas multiplication and at the same time reduce the number of those photons in the avalanches which give rise to secondary electrons. This latter point is clear from the observation that the gas multiplication was much higher at the corona threshold after the addition of xenon. This increase in ionization, which effectively means an increase in α, the first ionization coefficient, is most surprising, as it would have been expected that addition of xenon would lower the electron temperature in the avalanches and thus raise the Geiger threshold voltage. In fact there are clearly two competing processes present as shown by the existence of the threshold minimum of the curve in figure 4. The possibility of argon metastable excited atoms being quenched by collision with xenon atoms and giving rise to ionization in a manner similar to the well-known Penning effect in neon–argon mixtures is ruled out as energetically impossible, as the ionization potential of xenon is 12·127 volts and the metastable potentials of the $^3P_2$ and $^3P_0$ levels of argon are 11·53 and 11·72 volts respectively. It is therefore necessary to look for some other mechanism which would give rise to ionization. It has been shown (Colli and Facchini 1952) for pure argon that, at these pressures, the photons which give rise to photoelectrons at the cathode are mainly those which arise from the decay of the excited molecule A_2^* rather than by resonance photons. Higher excited states above the metastable and resonance levels only rarely decay directly to the ground state but usually through some intermediate state by the emission of photons of about 4 ev. The decay of the metastable excited states of argon take place through either two or three body collisions (Phelps and Molnar 1953), the decay probability being given by $Ap+Bp^2$ where $A = 40\ \text{sec}^{-1}\ \text{mm}^{-1}$ and $B = 9\ \text{sec}^{-1}\ \text{mm}^{-2}$. The second process is predominant at the pressures used in this investigation and leads to the formation of the A_2^* excited molecules which have a decay time of 3·4 μsec giving a photon of about 10 ev energy (Colli 1954). This photon has a very small cross section for absorption by either oxygen or nitrogen (Weissler and Po Lee 1952) and will not be absorbed by either argon or xenon. Consequently any process which is postulated for the action of the xenon must account for the large reduction in the production of the 10 ev photons so that the possibility that the additional ionization due to the xenon is brought about by collision with the higher excited states of argon is unlikely. One possibility is a three-body collision involving two xenon atoms and an excited metastable state of argon leading to the formation of a xenon molecular ion Xe_2^+ but this seems unlikely in view of the fairly small xenon concentrations involved.

This leaves the possibility that the xenon atoms interact with the argon metastable states, or with the argon excited molecules A_2^*, to produce ions and the only way in which this could occur would be by the formation of an argon–xenon molecular ion. In view of the pressure dependence of the action of the xenon, mentioned in § 3.4, it would appear that the interaction is more likely to be with the A_2^* molecule as the formation of this is itself pressure dependent. It will be observed from figure 8 that the cross-over of the two curves occurs at a pressure corresponding to $Ap \simeq Bp^2$, that is when the probability of decay of the argon metastable states by the two alternative processes are equal. A possible reaction would therefore be

$$A_2^* + Xe = AXe^+ + A + e^-.$$

This suggestion is put forward very tentatively in view of the strong theoretical objections to the existence of such an ion. Bearing in mind the unreliability of identifying ions from their mobilities, nevertheless the existence of the slow ion of mobility 1·64 cm sec^{-1} (v cm^{-1})$^{-1}$ is not inconsistent with this hypothesis. Assuming that the mobility varies as $(1+M_{\text{atom}}/M_{\text{ion}})^{1/2}$ in accordance with the Langevin expression, this gives, based on the value of 1·84 for the A_2^+ ion, a figure of 1·66 for the AXe^+ ion, 1·715 for the Xe^+ ion and 1·62 cm sec^{-1} (v cm^{-1})$^{-1}$ for the Xe_2^+ ion, so that the observed ion could be any of these three, considering the accuracy of the measurements and the not too close agreement of the Langevin expression with experiment.

Consider now the two types of spurious pulses which are found with the counters with oxidized cathodes. Both types obviously arise as a result of the photon–cathode effect, those which occur at the end of the plateau being due to delayed photons which increase in number with the charge per pulse and whose effect becomes significant when the dead-time has shortened sufficiently. For zero and very low xenon concentrations the dead-times and consequently the plateaux are very short.

The incidence of the other type of spurious pulses which appear on the plateaux is clearly proportional to the charge per pulse as the plateaux are straight. They are probably due to the formation of oxygen negative ions from the photoelectrons arising during and immediately after the discharge. The fact that the plateau slopes increase with oxygen concentration and that the spurious pulses appear more or less uniformly spread between dead-time and recovery time support this view. Also, the addition of xenon reduces the plateau slope because of its effect in quenching the excited argon molecules which would otherwise decay to emit the 10 ev photons producing the photoelectrons.

If N_0 is the number of metastable argon atoms produced during the discharge and N the number at any subsequent time t, the decay can be expressed by

$$N = N_0 \exp(-\beta t)$$

where $\beta = Ap + Bp^2$, assuming that the probability of decay through collision with nitrogen or oxygen molecules is small. For the pressure used in these experiments, the value of Ap is $2{\cdot}52\times10^{3}$ sec^{-1} and Bp^2 is $4{\cdot}77\times10^{6}$ sec^{-1}, so the predominant mode of decay of the metastable states of the argon atoms is to produce the metastable molecules. If N' is the number of such molecules in the discharge at time t, then

$$\frac{dN'}{dt} = Bp^2N_0\exp(-\beta t)-N'\left(\frac{1}{\tau_{\mathrm{m}}}+cx\right) \tag{10}$$

where τ_{m} is the mean lifetime of the metastable molecules, equal to $3{\cdot}4$ μsec and cx is the probability of destruction by collision with xenon atoms for a xenon concentration x.

Integration of (10) gives

$$N' = \frac{Bp^2N_0}{\beta-(1/\tau_{\mathrm{m}}+cx)}\left\{\exp\left[-t\left(\frac{1}{\tau_{\mathrm{m}}}+cx\right)\right]-\exp(-\beta t)\right\}. \tag{11}$$

The number of photoelectrons released per discharge is

$$\gamma_{\mathrm{p}}\int\frac{N'}{\tau_{\mathrm{m}}}\,dt = \frac{\gamma_{\mathrm{p}}Bp^2N_0}{(1+\tau_{\mathrm{m}}cx)\beta} \tag{12}$$

by integration after substitution from (11); γ_{p} is the probability that a photon will release a photoelectron at the cathode. If it is assumed that the number of metastable states N_0 is approximately equal to the number of ions produced then $N_0 = Q/e_0$ where Q is the charge per pulse and equal to kV_0, k being a constant for a particular mixture, V_0 the overvoltage, and e_0 the electronic charge.

The number of spurious pulses per discharge can be written from (12) as

$$N_{\mathrm{sp}} = \frac{\gamma_{\mathrm{n}}\gamma_{\mathrm{p}}Bp^2kV_0}{(1+\tau_{\mathrm{m}}cx)\beta e_0} \tag{13}$$

where γ_{n} is the probability that a photoelectron will produce a spurious pulse after capture to form an oxygen negative ion. The plateau slope S is given by N_{sp}/V_0 so substituting in (13) gives

$$\frac{1}{c\tau_{\mathrm{m}}}+x = \frac{\gamma_{\mathrm{n}}\gamma_{\mathrm{p}}Bp^2}{\beta c\tau_{\mathrm{m}}}\,\frac{k}{Se_0}.$$

A plot of k/Se_0 against x is shown in figure 9 using the values of k, S and x, obtained from the experiments described in § 3.2, yielding a fairly reasonable straight line. This gives support to the assumption of a two-body interaction leading to the AXe$^+$ molecular ion rather than the three-body interaction leading to the Xe$_2$$^+$ ion as the latter case would yield a straight line only when k/Se_0 is plotted against x^2. The intercept on the x axis is $1/c\tau_{\mathrm{m}}$ giving an approximate value of $c = 2{\cdot}4\times10^{8}$ sec^{-1}. This means that at a xenon concentration of 2% the number of photoelectrons produced is reduced by a factor of about 20 as is clear from equation (12). The value of c above yields a cross section for destruction of the excited states of the argon molecules as approximately $1{\cdot}9\times10^{-16}$ cm^2. Also from the slope of the graph a value of $\gamma_{\mathrm{n}}\gamma_{\mathrm{p}} = 5\times10^{-11}$ is obtained. It was reported by Colli and Facchini (1954) that the value of γ_{p} for the 10 ev argon photons for nickel and brass cathodes is of the order of 10^{-3} and was not strongly dependent upon the condition of the cathode surface. Assuming similar values for the copper cathodes used in these experiments, this means that γ_{n} is of the order of 10^{-8}.

It should be pointed out however that the evidence in favour of the two-body as against the three-body interaction is not necessarily conclusive because it has been assumed above that the small concentrations of xenon do not affect the value of γ_n. It is not clear to what extent the presence of xenon will affect the electron temperature and therefore the probability of photoelectron attachment to form O_2^- ions.

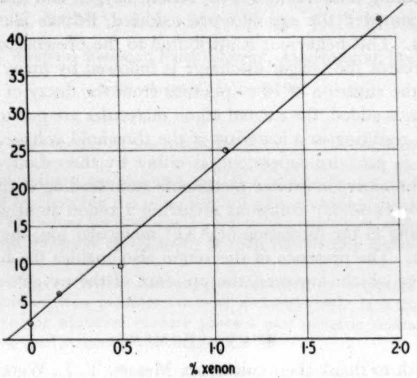

Figure 9. Variation of k/Se_0 with xenon concentration.

4.2. *Spread of the Geiger Discharge*

It is clear that the presence of oxygen is a necessary condition for the spread of the Geiger discharge along the anode wire. The propagation of this type of discharge is generally attributed to secondary electron production in the quenching gas by photoionization from the high energy photons of the main gas. Huber (1955) has shown that this mechanism explains the formation of the Geiger discharge when a small quantity (~ 1%) of oxygen is added to nitrogen. However, some difficulties arise if this mechanism alone is postulated to explain the action of the oxygen in the counters described in this paper, because the argon resonance photons have insufficient energy to cause photoionization in the oxygen. The comparatively few photons of higher energy (~ 14 ev) arising from the decay of the upper excited levels of argon will have mean free paths for photoionization of about 1·5 cm in the oxygen at the partial pressures (3·5 mm Hg) employed in these counters (Wainfan, Walker and Weissler 1955). This possibly explains the results obtained with mixtures of zero and low xenon concentrations. The discharge would probably be propagated in rather large steps and not fully developed, resulting in incomplete quenching and very short dead times (figure 3, curve D). The addition of larger amounts of xenon (concentrations greater than 0·5%) assists in the propagation of the discharge inasmuch as the latter now becomes a true Geiger discharge similar to that observed in organically quenched counters. The argon metastable states have mean lifetimes of $1/Bp^2$ (~ 0·2 μsec) against the formation of metastable excited molecules, and these in turn have lifetimes against formation of ions by collision with xenon atoms of $1/cx$, the total time being about 0·3 μsec. It is therefore suggested that further avalanches are formed in a small zone surrounding the wire by the diffusion of the excited atoms and molecules. The part played by photon action at the cathode in the spreading of the discharge is only subsidiary because the threshold voltage appears to be little affected by the type or condition of the cathode as shown in § 3.3.

§ 5. CONCLUSION

Counters containing mixtures of argon, xenon, oxygen and nitrogen in appropriate proportions will, provided the cathodes are oxidized, behave similarly to organically quenched counters. This behaviour is attributed to the presence of the xenon. When the latter is not present the Geiger discharge is followed by many spurious discharges caused mainly by the emission of 10 ev photons from the decay of excited argon molecules. When xenon is added, the excited argon molecules are quenched to produce ions instead of photons resulting in a lowering of the threshold voltage. The nature of the interaction, which is pressure-dependent, is either by three-body collisions involving two xenon atoms and an argon excited metastable atom leading to the formation of Xe_2^+ molecular ion, or by two-body collisions involving a xenon atom and an argon excited molecule, and leading to the formation of AXe^+ molecular ion, the evidence appearing to favour the latter. The presence of the xenon also enables the full realization of the Geiger discharge for which, however, the presence of the oxygen as a vehicular gas is necessary.

ACKNOWLEDGMENTS

The authors wish to thank their colleagues Messrs. T. L. Watkins, B. R. Hookway and A. K. M. Haque for their generous assistance; Mr. E. R. Kerkin for valuable work in construction of apparatus and Mr. R. K. Munn for help in preparation of the diagrams; also Dr. J. E. Garside, Principal of the Borough Polytechnic and Mr. V. Pereira-Mendoza, in whose department the work was carried out, for their encouragement and interest.

The Radiative Capture Cross Section of ^{236}U for Neutrons in the Energy Range 0·3 to 4·0 MeV

By J. F. BARRY, J. L. BUNCE and J. L. PERKIN

Atomic Weapons Research Establishment, Aldermaston, Berkshire

MS. received 1st *June* 1961

Abstract. The cross section of the reaction ^{236}U(n, γ) ^{237}U has been measured for neutrons in the energy range 0·3 to 4·0 MeV using an activation method. Fission products in the irradiated samples were removed chemically and the ^{237}U produced was determined by counting the γ-ray activity with a sodium iodide scintillation spectrometer. The cross section was found to increase from about 300 mbn at 0·3 MeV to about 400 mbn at 1·1 MeV. It then fell sharply to some 30 mbn at 4 MeV.

The shape of the excitation function for this reaction is typical of that found for other heavy even–even nuclides far from a closed shell. It is due to the competition between the radiative capture process and inelastic scattering from the similar collective level structures of these nuclides.

§ 1. INTRODUCTION

THE MEASURED radiative capture cross sections of heavy even–even nuclides far from a closed shell do not fall with increasing neutron energy according to the orthodox statistical theory. Lane and Lynn (1957) have explained this behaviour in terms of the competition between the radiative capture process and the inelastic scattering of neutrons from the rotational energy level structure of these nuclides.

Two such nuclides have been examined in detail to date, namely ^{232}Th and ^{238}U (Barry, O'Connor and Perkin 1959, Hughes and Schwartz 1958). In these experiments the radiative capture cross section of another heavy even–even nuclide ^{236}U has been measured over the energy range 0·3 to 4·0 MeV. An activation method was used involving the measurement of the ^{237}U (6·75 d) activity produced.

§ 2. NEUTRON IRRADIATIONS

The ^{236}U samples irradiated consisted of some 60 mg of ^{236}U dissolved in 0·2 M HNO_3. The isotopic composition (atomic %) of this uranium was as follows: ^{236}U (98·46%) ^{235}U (1·1%) ^{238}U (0·42%) and ^{234}U (0·02%). Thin-walled Perspex cells with flat cylindrical cavities (1·74 cm × 0·076 cm) were used to contain the samples during the neutron irradiations and the ^{237}U determinations described later.

Neutrons for these irradiations were obtained from the p–T reaction. A tritium gas target was contained in a cylinder 2·5 cm long and was bombarded with protons from the Atomic Weapons Research Establishment 6 MeV Van de Graaff accelerator. In order to obtain the high neutron output required the technique described by Nobles (1957) was used to obtain proton beam currents of up to 10 μA into the gas target. In this technique the beam enters the gas target through two thin nickel foils which are cooled by helium gas pumped through the space between them.

The ^{236}U samples were irradiated in the forward direction at a distance of 1·4 cm from the end of the gas target. The neutron flux through the samples was measured with a ^{235}U fission counter which was placed at the back of the Perspex cell. Only the thickness of the walls of the cell and counter separated the ^{236}U sample from the ^{235}U deposit in the counter. The circular areas of the ^{235}U foil and the uranium solution subtended the same angle at the neutron source and they were positioned with their centres on the line of the proton beam.

The fission counter contained about 1·5 mg of ^{235}U and was calibrated by irradiation in a known flux of 14·1 Mev neutrons from the d–T reaction. This calibration was carried out by placing the counter at a distance of 20 cm from a thick zirconium tritide target and at an angle of 90° to a deuteron beam of 300 kev. The associated α-particles from the reaction were counted in a known geometry at an angle of 135°. The neutron and α-particle yields with respect to the angle of emission and the incident deuteron energy for thick tritium targets of the type used were evaluated. With this information the neutron flux at the counter position was calculated and the fission counting rate per incident neutron $\text{sec}^{-1}\,\text{cm}^{-2}$ was found. Experiments with and without cadmium shielding around the counter showed that any errors due to a thermal neutron background were smaller than those due to the fission counting rate statistics.

The efficiency of the counter was calculated at other neutron energies by using the known variation of the ^{235}U fission cross section with energy (R. L. Henkel 1961, private communication, Adams, Batchelor and Green 1961, A. Moat 1961, private communication).

The difference between the mean neutron flux through the uranium samples and that through the uranium foil of the fission counter due to the variation of neutron flux with distance from the source and the scattering and absorption by the sample and holder, was measured experimentally. From the variation of flux with distance, the flux through a sample was found to be between 22 and 11% greater than that measured by the fission counter over the neutron energy range 0·3–4·0 Mev. The effect of scattering and absorption was found by measuring the change in neutron flux through the counter when a sample and holder were removed. This change varied from -6% to $+5\%$ according to the neutron energy over the range 0·3–0·4 Mev.

During the irradiations the neutron flux through the samples was about $2\times10^{7}\,\text{cm}^{-2}\,\text{sec}^{-1}$ and the length of the irradiations was about 10 hours.

§ 3. CHEMICAL PURIFICATION

3.1. *Procedure*

In order to resolve the ^{237}U activity produced it was necessary to remove fission products from the irradiated ^{236}U samples. These fission products originated mainly from ^{236}U when the irradiation was made at neutron energies above the fission threshold for this isotope ($\sim$0·6 Mev). Also present were fission products from the small amounts of the other uranium isotopes in the samples (see § 2) at neutron energies above their respective fission thresholds.

The ^{236}U solution was first evaporated to dryness in a platinum crucible and the residue was redissolved in a solution containing 3 ml of saturated ammonium nitrate and 0·3 ml of 6 M nitric acid. Uranium was then extracted with ether for a period of 30 minutes in an apparatus in which the ether was bubbled through the uranium solution and recirculated by means of a reflux condenser (Wayman and Wright 1945). The ethereal solution was evaporated to dryness and a few drops of $HClO_4$ were added. The solution was then heated strongly to remove any ruthenium fission products present as these are particularly difficult to remove by any other method.

After dissolving in 2 ml of 6 M HCl the uranium was absorbed on a column of an anion exchange resin and washed with 10 ml of 4 M HCl to remove most of the residual fission products. Uranium was then eluted from the column with 15 ml of 0·5 M HCl. After removal of the hydrochloric acid by evaporation the uranium was redissolved in nitric acid, transferred to a weighed platinum crucible, evaporated to dryness and converted to U_3O_8 in order to determine the chemical yield of the purification procedure.

As the value of this uranium sample was considerable, care was required to minimize losses. The use of platinum and polythene to reduce adsorption, the repeated use of the same apparatus for all the separations performed and the preservation of all the residues enabled a chemical yield of approximately 95% to be achieved for each individual separation.

3.2. *Efficiency for removing Fission Products*

It was essential that any fission product activity remaining after the purification process should be negligible compared with the lowest ^{237}U activity observed. The greatest number of fissions produced in a sample in these experiments amounted to about 2×10^8. This occurred in the irradiations with 4 MEV neutrons where the ^{236}U fission cross section is 0·95 bn and the capture cross section is low. To determine the efficiency of the chemical separations for removing fission products, a subsidiary experiment was performed with a uranium sample containing fission products from about 10^{10} fissions but with practically no ^{237}U present.

The fission products were obtained by irradiating a small (0·5 mg) sample of enriched (99·9%) ^{235}U in a reactor (HERALD A.W.R.E.). The low percentage of ^{238}U in the sample minimized the production of ^{237}U from the ^{238}U (n, 2n) ^{237}U reaction with fast neutrons in the reactor. Natural uranium was added to the sample after irradiation to make the total weight the same as that of the ^{236}U samples.

The purified sample when counted (see § 4) had an initial activity which was less than the ^{237}U activity of the ^{236}U sample irradiated with 4 MEV neutrons even though the original fission product activity present was fifty times greater. It is clear that even if all the residual activity in the subsidiary experiment is due to fission products the amount to be expected in the purified ^{236}U samples is negligible compared with the ^{237}U activity found.

§ 4. DETERMINATION OF THE ^{237}U ACTIVITY

Uranium 237 decays by a complex and low energy β-particle emission. (Rasmussen, Canavan and Hollander 1957). The weight of the ^{236}U samples in these experiments was too large to enable precise measurements to be made of the ^{237}U β-particle activity produced. Consequently the method employed was to measure the γ-ray emission using a cylindrical (5·7 cm diam. × 5·7 cm) sodium iodide scintillation spectrometer.

The γ-ray spectrum observed from an unirradiated sample of ^{236}U is similar to that shown in figure 1(*b*). This is a complex spectrum due to the presence of ^{234}U, ^{235}U and ^{238}U and their daughters (see § 2). Above 60 kev the spectrum is due to ^{235}U and its daughter ^{231}Th (25·64 h) and ^{238}U and its daughters ^{234}Th (24·1 d) ^{234}Pa (6·66 h) and ^{234m}Pa (1·17 min). Using the calculated conversion coefficients of Rose (1958) it can be shown that the peak at about 50 kev is mainly due to the 50 kev ^{232}Th

γ-ray from the decay of ^{236}U although the other nuclides present must also contribute to it. The main features of the spectrum from a ^{237}U source are the ^{237}Np γ-ray peaks at 59 and 203 kev and the 100 kev x-ray peak from the internal conversion of the 203 kev γ-ray. A convenient measure of the ^{237}U activity throughout these experiments was the integrated spectrum between 40 and 250 kev. The stability of this energy 'gate' and the overall efficiency of the spectrometer was periodically checked with standard γ-ray sources in conjunction with a 100 channel pulse height analyser.

Each irradiated and purified ^{236}U sample was redissolved in 0·2 M HNO_3 and returned to a Perspex cell. Sufficient extra ^{236}U to make good any losses in the chemical separations was added to ensure that the γ-ray absorption and scattering properties of the sample were the same as any other. The cell was then clamped in a rigid holder about one millimeter from the flat face of the sodium iodide spectrometer and was counted at different times over a period of three weeks to follow the decay of the ^{237}U.

The absolute efficiency of the counter for ^{237}U activity was found by counting cells containing weighed amounts from a stock solution of ^{237}U prepared by the α-particle decay of ^{241}Pu. This solution was standardized by counting weighed amounts in a 4π proportional counter. In order to simulate the γ-ray self absorption of the ^{236}U samples the same weight of natural uranium was added to the cells used for calibration. The counting rates from these cells were corrected for the activity of the natural uranium.

§ 5. RESULTS

The γ-ray spectrum from an irradiated sample of ^{236}U is shown in figure 1. That part which has decayed after two weeks has the same characteristic spectrum as that from the decay of ^{237}U.

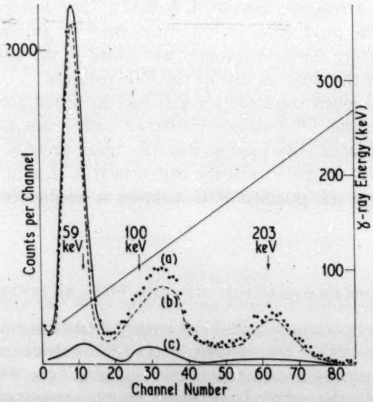

Figure 1. The γ-ray spectrum from a sample of ^{236}U measured (*a*) 2 days and (*b*) 13 days, after irradiation with 464 kev neutrons. Curve (*c*) was obtained by subtracting (*b*) from (*a*).

In order to determine the relatively small amount of ^{237}U activity present the gross γ-ray activity between 40 and 250 kev was plotted (figure 2, curve A) as a function of $\exp(-0{\cdot}693t/T)$, where t is the time elapsed since the end of the irradiation and T is

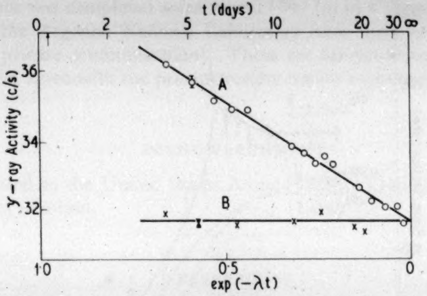

Figure 2. Decay of the γ-ray activity in the energy range 40 to 250 kev from a sample of ^{236}U after irradiation with 560 kev neutrons (curve A). Curve B was obtained with a similar unirradiated sample after chemical purification. The arrow indicates the time at which the chemical separations were performed.

the half-life of ^{237}U (6·75 d). The slope of the resultant straight line gives directly the ^{237}U activity present at the end of the irradiation.

Activity measurements made within about three days after the chemical separations were performed lie a little below a line through the later points, due to the fact that the ^{235}U present did not have sufficient time to re-establish an equilibrium amount of its daughter ^{231}Th. The re-establishment of the daughters of ^{238}U is a much slower process. Measurements made with a chemically purified but unirradiated ^{236}U sample (figure 2, curve B) show however, that this process was not detectable in these experiments and can cause no significant error in the method described for estimating the ^{237}U activity.

The Radiative Capture Cross Section of ^{236}U

E_n (Mev)	0·360	0·464	0·560	0·655	0·705	0·850	0·943
ΔE_n (Mev)	0·070	0·070	0·070	0·070	0·070	0·070	0·075
σ (mbn)	311	308	403	271	301	297	351
Error (mbn)	26	30	32	25	34	29	41
E_n (Mev)	1·063	1·220	1·310	1·585	2·020	2·790	3·970
ΔE_n (Mev)	0·075	0·075	0·080	0·085	0·100	0·120	0·150
σ (mbn)	350	536	196	147	88	68	28
Error (mbn)	43	68	47	30	10	10	10

The calculated values of the (n, γ) cross sections are given in the table and figure 3. Errors quoted for the cross section include counting statistics as well as estimates of errors in the calibration of the counting arrangement, the fission counting rate, fission counter calibration, knowledge of the fission cross section excitation function for ^{235}U, and deduction of the mean neutron flux through the sample from the measured flux at the fission counter. The calculated shape of the energy spectrum for neutrons through the samples varies considerably with the mean neutron energy of the irradiation due to the variation in the energy loss of the proton beam in the target and in the angular distribution of neutrons from the p–T reaction. The energy limits quoted include more than 90% of the neutrons.

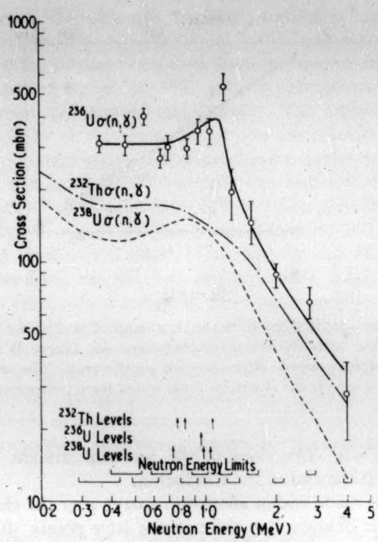

Figure 3. The radiative capture cross section of ^{236}U. The radiative capture cross sections of ^{232}Th and ^{238}U (obtained by drawing smooth curves through the published data) are shown for comparison.

Also shown in figure 3 are the radiative capture cross sections for ^{232}Th and ^{238}U (Barry, O'Connor and Perkin 1959, Hughes and Schwartz 1958). There is an obvious similarity between the shapes of the three excitation functions shown. As seen in the Introduction these shapes are dependent on the level structure of the nucleus concerned.

The positions of the levels found in these nuclei above about 400 kev (Cranberg and Levin 1958, Batchelor and Towle 1959, Durham, Rester and Class 1960, McGowan and Stelson 1960) are shown in the figure. Levels based on the ground state rotational band in this region (Stephens, Diamond and Perlman 1959) have been omitted because of their high spins which make them relatively difficult to excite by inelastic neutron scattering. The fall in the ^{236}U excitation function at about 1 Mev suggests that a group of levels exists in this nucleus similar to that observed in ^{232}Th and ^{238}U.

It can be seen that the absolute value of the cross section for ^{236}U is about double that for ^{238}U and ^{232}Th. The capture cross section in this energy region is proportional to $(\Gamma_\gamma \times \Gamma_n)/(D \times \Gamma)$ in the usual notation (e.g. Kinsey 1957). The ratio Γ_n/Γ is about the same for the three neighbouring nuclei under consideration. Using the method described by Lane and Lynn (1957) the value of Γ_γ/D for a particular neutron energy (400 kev) was calculated for each nucleus. The main factor in these calculations was the dependence of the level spacing D on the neutron binding energy [^{238}U (4·87 kev) ^{232}Th (5·16 Mev) ^{236}U (5·45 Mev)]. The values found for Γ_γ/D for the nuclei in this order were in the ratio of approximately 1 : 1·5 : 3. At 400 kev the corresponding ratio of the observed cross sections is 1 : 1·4 : 2·6 which is in quite good agreement with the theoretical estimate.

Since this work was completed some recent ^{236}U (n, γ) ^{237}U cross section measurements made at the Argonne National Laboratory have been brought to our notice (Stupegia 1961, private communication). These are for neutrons in the energy range 0·3 to 1·5 MEV and agree with the present results within experimental error.

ACKNOWLEDGMENT

We are indebted to the United States Atomic Energy Commission for the loan of the ^{236}U enriched uranium.

A Note on the Carr–Purcell Method of Measuring Nuclear Magnetic Resonance Relaxation Times

BY H. PURSEY

Basic Physics Division, National Physical Laboratory, Teddington, Middlesex

MS. received 12*th July* 1961

Abstract. In measuring T_2 by the Carr–Purcell method the number of 180° pulses which can be used in a given sequence is limited by the accumulation of errors in pulse length, which causes a progressive departure of the freely precessing magnetic moments from the equatorial plane. Several methods have been devised to overcome this limitation, but in all cases it is assumed that phase coherence exists between the precessing nuclei and the pulsing radio-frequency field. Under such conditions the errors will accumulate linearly in the orthodox Carr–Purcell experiment, but in fact the order of stability implied in the assumption is unlikely to exist unless special care is taken to obtain it. It has been found experimentally, however, that good Carr–Purcell trains can be obtained in an incoherent system and in the present paper the reasons for this are analysed. It is shown that in such a system the errors add as if they were coplanar vectors of random direction, so that the statistical r.m.s. value of the error after n pulses is proportional to $\sqrt{n}$. Hence, one would expect to obtain a satisfactory train with up to 10^4 pulses, and it is shown that this is in agreement with observations.

THE 'SPIN-ECHO' method of measuring transverse nuclear magnetic relaxation times was first described by Hahn (1950). In a subsequent paper H. T. Carr and E. M. Purcell (1954) showed that the influence of molecular diffusion on the results obtained by Hahn's method could be virtually eliminated by using a modified technique which is now generally known as the 'Carr–Purcell method'. It consists in applying a 90°radio-frequency pulse to the sample at $t = 0$, followed by a train of 180° pulses at $t = \tau, 3\tau, 5\tau$, etc., 2τ being short compared with the diffusion time constant of the sample. 'Spin-echoes' are produced at $t = 2\tau, 4\tau, 6\tau$, etc. and the envelope of the echo maxima gives the T_2 decay curve of the material under tests.

For samples with short diffusion and long relaxation times it may be necessary to use a large number of 180° pulses to obtain an adequate decay curve, and the problem then arises as to how small errors in the length of the 180° pulses will accumulate. If we assume the magnetic dipoles are always rotated about the same axis relative to the total nuclear magnetic field component in the xy plane (treating z as the axis along the direction of the static field H_0), then errors must accumulate linearly, severely limiting the number of pulses which could be used in any particular train.

Methods of overcoming this limitation have been suggested by Meiboom and Gill (1958), who show that by shifting the phase of the initial (90°) pulse by 90° relative to the succeeding (180°) pulses the errors due to adjacent pulses can be made to cancel, while Shev and Norberg (1960) have shown that a similar improvement can be obtained by applying a linear sweep to the steady field along Oz.

In supposing that each 180° pulse induces rotation of the nuclear magnets about the same axis in the rotating coordinate system it is implied that, for the duration of each pulse train, phase coherence is preserved between the nuclei precessing in H_0 and the radio-frequency pulses themselves. This implies very high stability (of the order of parts in 10^8) of H_0 relative to the radio-frequency oscillator from which the pulses are derived. In a system where no special care is taken to stabilize H_0 relative to the radio frequency, it is meaningless to talk of rotation about a particular axis in the rotating co-ordinate system, and each 180° pulse will induce rotation about an axis in the xy plane whose direction is independent of any previous rotations which have occurred.

Observations on such a system show that surprisingly good Carr–Purcell trains can be obtained, using several thousand pulses in each train, without taking any special trouble to ensure that the 180° pulses are of the correct length, and it is the purpose of this paper to show that this is in fact predicted by an analysis based on the Bloch equations.

Now if the pulses are derived from an oscillator whose angular frequency is ω, and if H_0 and H_1 are the respective amplitudes of the static z component and the rotating xy plane component of the magnetic field, we have (neglecting relaxation effects)

$$\dot{M}_x' = (\omega_0-\omega)M_y' \tag{1}$$

$$\dot{M}_y' = \mu M_z+(\omega-\omega_0)M_x' \tag{2}$$

$$\dot{M}_z = -\mu M_y' \tag{3}$$

where M_x', M_y' and M_z are the components of nuclear magnetization in a coordinate system rotating about the z axis with angular velocity ω, $\omega_0 = \gamma H_0$, $\mu = \gamma H_1$ and γ is the nuclear gyromagnetic ratio.

From (1), (2) and (3) we derive

$$\ddot{M}_y' = -\{\mu^2+(\omega_0-\omega)^2\}M_y'. \tag{4}$$

Let us assume for simplicity that $\omega = \omega_0$. Then

$$\ddot{M}_y' = -\mu^2 M_y' \tag{5}$$

whence

$$M_y' = A\sin(\mu t+\phi) \tag{6}$$

and from (3) and (6)

$$M_z = A\cos(\mu t+\phi). \tag{7}$$

Let M be the total nuclear magnetic moment, and let the components of magnetic moment at the start of the nth pulse be P_n in the xy plane and Q_n along Oz.

Then at $t = 0$ we have

$$\begin{aligned} M_x' &= P_n\cos\psi_n \\ M_y' &= P_n\sin\psi_n = A\sin\phi \\ M_z &= Q_n = A\cos\phi \end{aligned}$$

where ψ_n is the azimuthal angle of M. Let us now apply a pulse such that $\mu t = \pi+\delta$, where δ represents a small error in pulse length.

Then at the end of the pulse we have

$$\begin{aligned} M_x' &= P_n\cos\psi_n \\ M_y' &= A\sin(\pi+\phi+\delta) = -P_n\sin\psi_n\cos\delta-Q_n\sin\delta \\ Q_{n+1} = M_z' &= A\cos(\pi+\phi+\delta) = P_n\sin\psi_n\sin\delta-Q_n\cos\delta. \end{aligned}$$

Thus

$$Q_{n+1} = -Q_n\cos\delta+(\sin\psi_n\sin\delta)\sqrt{(M^2-Q_n^2)}.$$

So long as Q_n is small compared with M we have

$$Q_{n+1} \simeq -Q_n \cos\delta + M \sin\psi_n \sin\delta$$

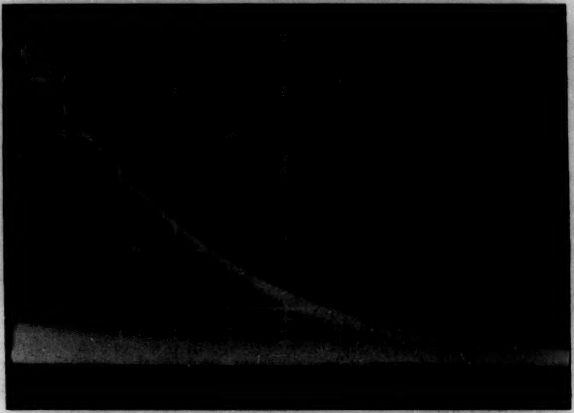
and hence

$$Q_n = (-1)^n Q_0 \cos^n\delta + M \sin\delta \sum_{r=1}^{n} \sin\psi_{n-r} \cos^{r-1}\delta.$$

If we assume the ψ_{n-r} are a random set then each term of the above summation has a variance of $\frac{1}{2}(\cos\delta)^{2r-2}$, so that the variance of Q_n is

$$\tfrac{1}{2}M^2 \sin^2\delta \sum_{r=1}^{n} (\cos\delta)^{2r-2}.$$

Furthermore, if $\delta \ll 1$ and $n \ll 1/\delta^2$ then the variance of Q_n is approximately $(n/2)M^2\sin^2\delta$, so that the r.m.s. value of M_z after n pulses is $(n/2)^{1/2}M \sin\delta$.



This analysis shows that the induction signal will fall off as the square root of n, instead of directly with n as would be the case if phase coherence were preserved. Since the pulse length can be set with an accuracy to about 1% we should expect to obtain satisfactory Carr–Purcell trains containing up to about 10^4 pulses, and this in fact proves to be the case. The figure shows a typical decay curve. The sample is water at room temperature containing a small amount of paramagnetic impurity, so that its transverse relaxation time is about 3·5 sec. The sweep speed is 1 cm sec^{-1}, and the pulse recurrence rate is 1 kc/s, so that the total sweep contains just 10^4 pulses.

In conclusion, it is perhaps worth pointing out that if the magnet instability is increased beyond a certain point a further deterioration of the Carr–Purcell train takes place. This is due to the fact that a phase change will now occur during the time of application of a radio-frequency pulse, so that the resultant nuclear magnetic vectors will no longer be coplanar, but will form a complex figure of eight pattern, as described by Hahn (1950). Thus the condition under which maximum echo amplitude is obtained, with all the magnetic vectors collinear, will never be completely recovered and it will not be possible to obtain a satisfactory Carr–Purcell train.

Zero-field Paramagnetic Resonance of Fe^{3+} in Methylamine Alum

BY G. S. BOGLE AND H. F. SYMMONS
Division of Physics, National Standards Laboratory, Commonwealth
Scientific and Industrial Research Organization, Sydney

MS. received 3rd July 1961

Abstract. The splitting of the ground level of Fe^{3+} in $(CH_3NH_3)Al(SO_4)_2 . 12H_2O$ in the absence of a magnetic field has been measured directly. At 90 °K the separation of the $S_z = \pm 3/2$ states from the $\pm 1/2$ is equivalent to 12 227 ± 5 Mc/s, and that of the $\pm 5/2$ from the $\pm 3/2$ to 22 043 ± 10 Mc/s. The deduced values of the coefficients in the usual spin-Hamiltonian for the ferric alums are $D = +0{\cdot}1893 \pm 0{\cdot}0002$ and $a - F = +0{\cdot}0171 \pm 0{\cdot}0001$ cm^{-1}, and it is probable that $a \simeq +0{\cdot}013$, $F \simeq -0{\cdot}004$ cm^{-1}. The material is promising for a zero-field maser, with predicted amplifying and pumping frequencies of 12 290 ± 15 and 34 460 ± 45 Mc/s respectively at liquid-helium temperatures.

§ 1. INTRODUCTION

WE HAVE RECENTLY discussed the need for direct measurements of paramagnetic energy level splittings at zero magnetic field, and have described equipment for the range 8 to 18 Gc/s (Bogle *et al.*, 1961). We have now extended our equipment to cover the additional range of 18 to 26 Gc/s (K-band) and this has enabled us to determine the energy level scheme of Fe^{3+} in methylamine alum $(CH_3NH_3)Al(SO_4)_2 . 12H_2O$, at 90·2 °K.

§ 2. THE PARAMAGNETISM OF THE FERRIC ALUMS

The paramagnetic resonance of several ferric alums has been studied by Bleaney and Trenam (1954), who have given a full discussion of the crystal structure and the appropriate symmetry of the spin-Hamiltonian. The unit cell of the alums is cubic and contains four Fe^{3+} ions. Each of these is surrounded by six water molecules forming an octahedron. If the octahedron were regular and if the more distant environment were neglected the crystalline electric potential would have the form

$$V = C(\xi^4+\eta^4+\zeta^4-\tfrac{3}{5}r^4)$$

where ξ, η and ζ are Cartesian coordinates referred to the cubic axes of the octahedron with origin at its centre. With this simplified potential the spin-Hamiltonian would have the form

$$\tfrac{1}{6}a[S_\xi^4+S_\eta^4+S_\zeta^4-\tfrac{1}{5}S(S+1)(3S^2+3S-1)]$$

where S_ξ is the ξ-component of the spin operator, and so on, and a is a constant. The levels in zero-field for Fe^{3+}, which has $S = 5/2$, would be a doublet and a quadruplet separated by $3a$.

In the alums, however, the actual electric field consists of the cubic field together with one of axial symmetry, the axis lying in a [111] direction of the octahedron, or, equivalently, a [111] direction (body diagonal) of the unit cell. Each of the four body diagonals is such an axis for one of the four Fe^{3+} sites per unit cell. Calling this axis the z-axis, the additional terms which must be added to the spin-Hamiltonian are

$$D[S_z^2-\tfrac{1}{3}S(S+1)]+\tfrac{1}{180}F[35S_z^4-30S(S+1)S_z^2+25S_z^2-6S(S+1)+3S^2(S+1)^2]$$

these forms having been chosen so that they transform under rotation like spherical harmonics (Bleaney and Stevens 1953). The complete spin-Hamiltonian in zero field is

$$\mathscr{H} = D(S_z^2-\tfrac{35}{12})+\tfrac{1}{6}a(S_\xi^4+S_\eta^4+S_\zeta^4-\tfrac{707}{16})+\tfrac{7}{36}F(S_z^4-\tfrac{95}{14}S_z^2+\tfrac{81}{16}) \qquad (1)$$

where for simplicity we have substituted the numerical value of S.

Bleaney and Trenam have made a complete analysis of the spectrum of Fe^{3+} in rubidium sulphate alum and potassium selenate alum, and Meijer has done the same for ammonium sulphate alum. The results are collected on p. 342 of the review article by Bowers and Owen (1955), and it may be seen that, though D varies from 22 to 160×10^{-4} cm^{-1} for the three materials and is temperature-dependent, $|a|$ varies only from 127 to 134×10^{-4} cm^{-1} for the three and is temperature-independent. The term F is much smaller, only of the order of 1×10^{-4} cm^{-1}. This behaviour is consistent with the expectation that the cubic component of the crystalline potential, which determines $|a|$, is mainly due to the octahedron of water molecules which surround the Fe^{3+} ion and so is relatively insensitive to changes of constituents outside the octahedron. The results show, too, that the value of D is much more sensitive to such changes.

In the case of methylamine alum, which Bleaney and Trenam also investigated, using the classical paramagnetic resonance technique of fixed frequency and adjustable magnetic fields, the spectrum at 90 °K consisted of a very large number of lines. Because the analysis would have been difficult, recourse was had to a process which, in spirit, was a zero-field measurement. The positions of the three lowest-field lines were measured at a series of frequencies in the then available range between 9·0 and 9·9 Gc/s, and the zero-field frequency of each line was found by extrapolation. This process yielded three frequencies, 11·70, 11·76 and 11·88 Gc/s, and in view of the errors (± 300 Mc/s), Bleaney and Trenam concluded that there was probably a single absorption line at 11 800 ± 300 Mc/s. Similar measurements at K-band indicated the existence of another absorption line at 22 200 ± 300 Mc/s.

In order to fit these results to the spin-Hamiltonian it is necessary to calculate the energy eigenvalues of (1). Before giving the accurate solutions it will be helpful to examine what the states and energies would be if the Hamiltonian were simply $D(S_z^2-35/12)$. It may be seen by inspection that the eigenstates would be simply the eigenstates $|M\rangle$ of S_z and that the eigenvalues would be $D(M^2-35/12)$. The disposition of energy levels for positive D would be as in figure 1(a). Bleaney and Trenam identified the 22 Gc/s absorption with the 5/2, 3/2 transition and the 12 Gc/s with the 3/2, 1/2; this is the most natural identification since it describes methylamine alum as differing from the other alums almost entirely in regard to D, which we know to be structure sensitive, and only slightly in regard to $a-F$ (see below), which we know to be insensitive.

To refine the analysis we now need a more accurate solution of the eigenvalue equation from (1). Bleaney and Trenam (1954) have given the exact solutions; but when a is small compared with D, as here, the following forms for the differences between the energies (W) are useful:

$$W_{5/2}-W_{3/2} = h\nu(\tfrac{5}{2},\tfrac{3}{2}) = 4D-\tfrac{4}{3}(a-F)+\frac{20a^2}{3(18D+a-F)}+\mathrm{O}\left(\frac{a^4}{D^3}\right)$$

$$W_{3/2}-W_{1/2} = h\nu(\tfrac{3}{2},\tfrac{1}{2}) = 2D+\tfrac{5}{3}(a-F)+\frac{20a^2}{3(18D+a-F)}+\mathrm{O}\left(\frac{a^4}{D^3}\right). \tag{2}$$

Making the simplifying assumption that F was negligible, Bleaney and Trenam calculated the following values of spin-Hamiltonian coefficients at 90 °K (in units of $10^{-4}\ \mathrm{cm}^{-1}$):

$$D = (-)1880 \pm 140; \qquad a = (-)100 \pm 40.$$

The signs are not determined by this type of measurement, but only the relative signs

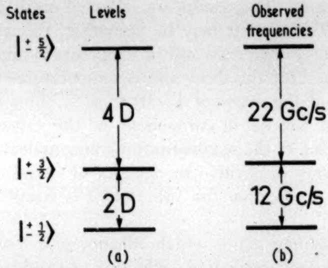

Figure 1. (*a*) Disposition of the energy levels of Fe^{3+} in methylamine alum with simplified Hamiltonian. (*b*) Identification of the observed frequencies.

of D and $a-F$ (or D and a if F is negligible). The above signs were inferred on the supposition that a was negative, as it appeared to be in potassium rubidium alum.

One question was not answered conclusively by the above measurements: is there more than one set of splittings for the Fe^{3+} ion? In the alums at room temperature the four Fe^{3+} sites differ only in the directions of their z axes and so should have identical splittings in zero magnetic field. In the 'classical' paramagnetic resonance experiment, i.e. one using a fixed frequency and adjustable magnetic field, a single alum crystal should in general give four distinct spectra because of the different z directions, each spectrum consisting of five strong lines giving a total of twenty. Bleaney and Trenam observed over sixty lines, which seemed too many to be accounted for by the above model even allowing for semi-forbidden lines, and suggested that there might be a change of crystal structure in methylamine alum producing either more than four z directions or more than one set of zero-field levels, or both.

The time is now ripe for a re-appraisal of Fe^{3+} in methylamine alum because of the following subsequent developments:

(i) Cooke, Meyer and Wolf (1956) have measured the Schottky specific heat anomaly of ferric methylamine alum and found good agreement with that calculated for levels separated by 12 and 22 Gc/s, provided that the arrangement is as in figure 1. This shows that D and $a-F$ are positive, contrary to the earlier assignment. It also shows that, if a multiplicity of level schemes does exist, these schemes do not differ markedly from each other.

(ii) Geschwind (1959) has repeated the experiment on Fe^{3+} in rubidium alum under more favourable conditions than in the earlier work and has found a to be positive. Hence we consider it highly likely that a is positive in all the ferric alums, contrary to the earlier view.

(iii) The new technique of zero-field spectrometry is capable of resolving the question whether or not there are several distinct sets of level arrangements. It can also yield more accurate values of the absorption frequencies, which are important for zero-field maser design as well as for a precise evaluation of D and $a-F$.

We have, therefore, re-measured the zero-field absorption frequencies of Fe^{3+} in methylamine alum; the results are reported below.

§ 3. EXPERIMENTAL METHOD

The only experimental techniques not already described by Bogle *et al.* (1961) are the use of a motor-driven 2K33 klystron to scan the spectrum near 22 000 Mc/s and the provision of frequency-marking pips while scanning (cf. figure 2).

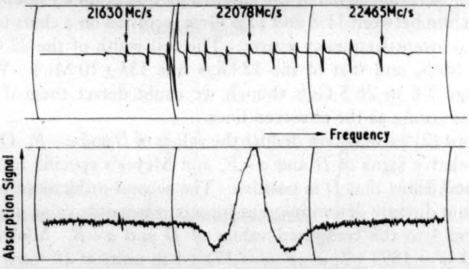

Figure 2. Chart recording of the 22 Gc/s absorption signal of Fe^{3+} in methylamine alum at 80·8 °K. The frequency markers are about 80 Mc/s apart. (The resonance frequency has to be corrected for misalignment of the recorder pens.)

The pips are produced in the following way: part of the microwave power is coupled out of the main waveguide run and led to the entrance iris of a transmission cavity resonator which we call an 'echo tunnel'. This consists of a 150 cm length of standard K-band waveguide short-circuited at each end. Small irises in the short-circuiting diaphragms allow coupling to the external circuitry. When the frequency is such that the echo tunnel length is equal to an integral number of half wavelengths-in-the-guide the tunnel resonates and transmits some power which is detected by a crystal rectifier. The loaded Q is several thousand, and over K-band the interval between resonances varies from 60 to 85 Mc/s.

In principle the echo tunnel resonances could be recorded by using d.c. methods; but for higher sensitivity we use a radio-frequency modulation method. The klystron is frequency-modulated at about 500 kc/s, and hence when the microwave frequency is near an echo tunnel resonance the transmitted microwave power is amplitude-modulated at 500 kc/s. The use of a phase-sensitive detector gives the pip shape shown in figure 2. This method allows the amplification to be done in the 500 kc/s region where crystal detector noise is much lower than at low frequencies.

The echo tunnel resonant frequencies are calibrated in a separate experiment, and are reproducible from day to day to within 1 Mc/s. However, the wavemeter used is not calibrated to better than ± 5 Mc/s. A shorter echo tunnel is simultaneously used to produce more widely spaced pips which aid identification; one such is present on the chart in figure 2. The temperature of the long-echo tunnel is monitored by a mercury-in-glass thermometer strapped to the waveguide.

§ 4. RESULTS

We have used a polycrystalline sample of aluminium methylamine alum

$$(CH_3NH_3)Al(SO_4)_2 \,.\, 12H_2O$$

containing nominally one per cent of the corresponding ferric compound.

At 90·2 °K, the same temperature as used by Bleaney and Trenam, we find a line at $22\,043 \pm 10$ Mc/s (shown in figure 2) and another at $12\,227 \pm 5$ Mc/s. In figure 3 we show (*a*) the absorption signal of the latter as plotted point by point using a klystron, and (*b*) the spectrum between 11·8 and 17·5 Gc/s recorded on a chart using a backward-wave oscillator as swept-frequency source. The full width of the 22 Gc/s line at half-height is 75 ± 5 Mc/s, and that of the 12 Gc/s line 135 ± 10 Mc/s. We find no other lines in the range 7·8 to 26·5 Gc/s though we could detect them if they were more than one-tenth as strong as the observed lines.

Using equations (2) we may now deduce the values of D and $a-F$. Our measurements determine the relative signs of D and $a-F$, and Meyer's specific heat measurements, already mentioned, show that D is positive. The second-order term in (2) depends on a^2 which we do not directly determine; but for any reasonable value of a this contributes only $-0{\cdot}0001$ cm^{-1} to the computed values of D and $a-F$. Allowing this amount, the values are $D = +1893 \pm 2$; $a-F = +171 \pm 1$ in units of 10^{-4} cm^{-1}.

The values of $|a|$ for the three other alums so far studied (Bowers and Owen, 1955, p. 342) are 127, 128 and 134 in the same units, and, as already discussed, the sign is probably positive for all three. Hence we offer, as the best guess for methylamine alum, $a = 130$; $F = -40$ in units of 10^{-4} cm^{-1}. The other alums have $|F|$ about twenty times smaller, but they also have $|D|$ ranging from ten to one hundred times smaller. A definitive theory of the dependence of D and F on the axial crystalline field has not, as far as we know, been worked out; but it does seem reasonable that the stronger axial field in methylamine alum, which makes $|D|$ larger than in the other alums, should have a similar effect on $|F|$.

For zero-field maser design it is desirable to know the frequencies at liquid helium temperatures. We have measured the frequency of the 22 Gc/s line at 81 °K; it is $22\,069 \pm 10$ Mc/s. The uncertainty in the change of frequency between 90·2° and 80·8 °K is not as great as may appear at first sight because the absolute error of the wavemeter is not involved. Thus we give the change of frequency as 26 ± 5 Mc/s. The variation of frequency near absolute zero is probably of the form $\nu(T) = \nu_0 + \alpha T^2$, since all temperature coefficients are zero at zero temperature according to the third law of thermodynamics, and we shall make the possibly bold assumption that this form holds even as far as $T = 90$ °K. If so, $d\nu/dT \equiv 2\alpha T \simeq -(26 \pm 5)/10$ Mc/s per degree at 85 °K. This determines α, and the frequency at 4 °K is predicted to be 123 ± 20 Mc/s higher than at 90 °K: that is, 22 170 ± 30 Mc/s.† The temperature dependence of the frequencies is mainly a reflection of that of D, so the other frequency at 12 Gc/s, which involves $2D$ instead of $4D$, should increase by half of 123, i.e. 60 ± 10, becoming 12 290 ± 15 Mc/s at liquid helium temperatures. It is interesting to notice that Cooke, Meyer and Wolf (1956) obtained good agreement between the theoretical and measured specific heats of pure ferric methylamine alum on the assumption that the above frequencies were 21 900 and 12 000 Mc/s This indicates that there is little change of frequency on dilution with the aluminium salt, confirming Bleaney and Trenam's observations at 90 °K.

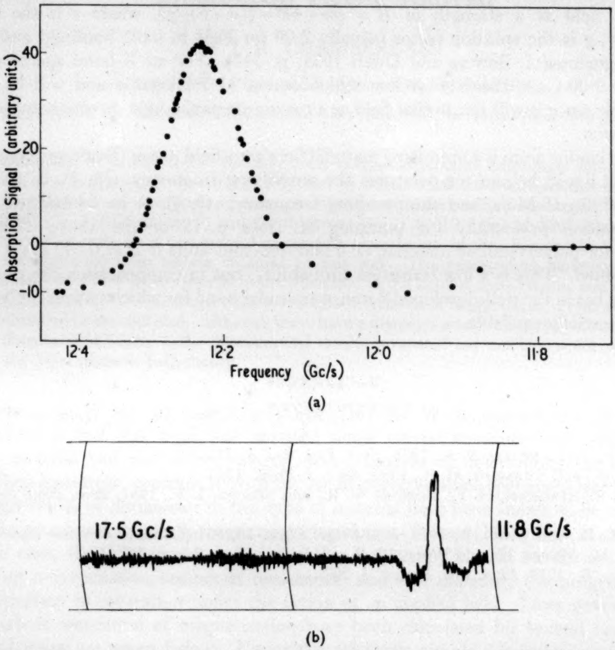

Figure 3. (*a*) The 12·2 Gc/s absorption signal of Fe^{3+} in methylamine alum at 90·2 °K (modulation 80 gauss). (*b*) The absorption spectrum between 11·8 and 17·5 Gc/s.

§ 5. CONCLUSIONS

There is only one type of zero-field energy level scheme for Fe^{3+} in methylamine alum at 90 °K. The multiplicity of lines observed for single crystals of the alum in the earlier experiments of the classical paramagnetic resonance type (fixed frequency, adjustable field) must therefore be due either to the existence of more than the expected four z directions or else to the presence of unexpectedly strong 'forbidden' lines. Now that the spin-Hamiltonian coefficients have been established by zero-field resonance it will be easier to discover the number of distinct z directions by repeating the classical experiment, for we may predict that the highest line will occur for the z direction of magnetic field at a strength of $B = [h\nu+4D-\frac{4}{3}(a-F)]/g\beta$, where ν is the (fixed) frequency, g is the splitting factor (usually 2·00 for Fe^{3+} in ionic bonding) and β the Bohr magneton (cf. Bowers and Owen 1955, p. 341). For an X-band spectrometer, with $\nu = 9{\cdot}00$ Gc/s, the highest line will occur at 11·1 kilogauss and will be easily identifiable since it will rise to that field as a maximum as the field direction approaches a z direction.

---

† *Note added in proof.* The measured frequencies at 4°K are 22 080 ± 5 and 12 230 ± 5 Mc/s.

Methylamine alum is a promising material for a zero-field maser (Bogle and Symmons 1959). At liquid helium temperatures the amplifying frequency, $\nu(\frac{3}{2}, \frac{1}{2})$, is predicted to be 12 290 ± 15 Mc/s, and the pumping frequency, $\nu(\frac{5}{2}, \frac{1}{2})$, to be 34 460 ± 45 Mc/s. The transition probability for pumping is, from p. 15 of the above reference, $10a^2/9D^2$ for polycrystalline material, or 0·006 free-spin units if $a = 0{\cdot}013\ \text{cm}^{-1}$ as we have assumed. This is a low transition probability, but in compensation the pumping frequency lies in the well-developed 8 mm-wave radar band for which powerful klystrons are commercially available.

Magnetocrystalline Anisotropy and Coercivity in a 'Square-loop' Ferrite Material

By J. R. CHAMBERLAIN

Department of Physics, The University, Sheffield 10†

Communicated by W. Sucksmith; MS. received 11th May 1961, in revised form 18th July 1961

Abstract. It is shown that the first order magnetocrystalline anisotropy constant K_1 of a 'square-loop' ferrite material can be determined from measurements of the approach to saturation of magnetization in a polycrystalline specimen. The energy ($\gamma = 0{\cdot}20$ erg cm^{-2}) and the thickness ($\delta \sim 1{\cdot}6 \times 10^{-5}$ cm) of 180° domain boundary walls in a commercial manganese magnesium ferrite, Ferroxcube D.1, are estimated from results obtained in this way. The temperature variation of coercivity in the same material is also discussed in the light of these results, and it is found that the Goodenough theory of domain creation is inapplicable. Pores were observed in the material. Although these have a diameter greater than the estimated domain wall width δ, the experimental results presented are not consistent with the Néel disperse field theory.

§ 1. INTRODUCTION

At the time that this work was initiated single crystal specimens of 'square-loop' ferrite material had not been prepared, and a method of determining the magnetocrystalline anisotropy constant K with the aid of polycrystalline specimens was required.

High values of remanence in this type of material have been shown to be associated with the occurrence of small or zero magnetostriction (Baltzer (1955) Wijn *et al.* (1954)). In this case, the dominant magnetocrystalline anisotropy should be the only agency directing magnetization vectors at remanence, and also impeding the progress of the magnetization to saturation under the action of an applied field. Laws governing the approach to saturation of magnetization have been calculated for several cases. The relevant cases are given below. Under the relatively simple conditions prevailing in the type of material under consideration, it appeared that the use of such laws should give an easy means of determining the required magnetocrystalline anisotropy.

This communication describes experiments in which the approach to saturation of magnetization in a commercial manganese–magnesium ferrite (Ferroxcube D.1) has been measured at different temperatures. From the results of these experiments values of K have been calculated. These values have then been used to estimate the energy and thickness of domain boundary walls and in a discussion of coercivity in the material.

§ 2. MAGNETOCRYSTALLINE ANISOTROPY

2.1. *Theory*

For the case of a strain-free material with [111]-type easy directions Gans (1932) has given the following law of approach to saturation:

$$I = I_s\left(1 - 0{\cdot}07619\left(\frac{K^2}{I_s^2}\right)\frac{1}{H^2} - 0{\cdot}02362\left(\frac{K^3}{I_s^3}\right)\frac{1}{H^3}\ldots\right) \tag{1}$$

---

† Now at the National Research Council, Ottawa, Ontario, Canada.

in which I is the magnetization per unit volume of a polycrystalline specimen in a field strength H, I_s is the saturation magnetization and K the first order magnetocrystalline anisotropy constant. The law is valid in relatively high fields and has been tested by Czerlinski (1932) and Polley (1939). An equation calculated on a similar basis for materials with [100]-type easy directions has also been found valid.

If interaction between crystallites is apparent in a given material then equation (1) gives an underestimate of K. This problem has been considered by Holstein and Primakoff (1941) and Néel (1948), who agree that for the case $H \ll 4\pi I_s$, the underestimate in K is $\sqrt{2}$.

For the case of a strained material with negative magnetostriction, Becker and Polley (1940) have calculated

$$I = I_s - \frac{3}{5}\frac{\lambda^2 \sigma_i^2}{I_s H^2}. \tag{2}$$

In this equation, λ is the (isotropic) magnetostriction constant of the material and σ_i the internal stress. This was found valid in strained nickel.

2.2. *Experimental*

Preliminary measurements showed that in field strengths of 50–180 Oe, at room temperature, the magnetization in a specimen of Ferroxcube D.1 was 0·9 to 0·96 I_s. In this region, equations of the type discussed above should be applicable, so that a relatively simple ballistic galvanometer method was used.

The specimen was a toroid with mean diameter 1·1 cm. This was wound first with a secondary coil, and the primary coil was wound over that. In this way the area turns in the secondary coil could be estimated more accurately. Some heating of the specimen was observed when larger currents were passed through the primary. This was checked by attaching a thermocouple to the specimen and readings were taken only when the specimen was initially at the temperature of the particular bath in which it was immersed.

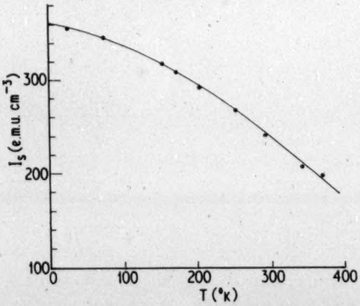

Figure 1. The temperature dependence of the saturation magnetization in Ferroxcube D.1.

The procedure adopted was to observe the deflection of a galvanometer connected across the secondary coil when the current in the primary was reversed. When larger currents were employed, the change in magnetization from the remanent state, on the application of a given field, was determined.

The saturation magnetization of the material was determined as a function of temperature with the aid of a Sucksmith ring-balance. This involved the measurement of the magnetization (per gramme) of an ellipsoidal specimen at a given temperature as a function of applied field, in field strengths up to 12 kOe. After taking account of the demagnetizing factor of the specimen, the magnetization was extrapolated to zero field strength to give σ_0, the saturation magnetization per gramme. The density of the material was determined by a water displacement method and the volume saturation magnetization determined using this. The saturation magnetization is plotted as a function of temperature in figure 1, and the tabulated results are as follows:

T °K	26	79	153	171	203	250	293	345	373
I_s e.m.u. cm^{-3}	355	345	317	308	292	265	240	208	196

2.3. *Results*

The experimental results (at room temperature) were compared with equation (1) in the form

$$(I_s - I)H^3 = \Delta IH^3 = \alpha H + \beta \tag{3}$$

where $\alpha = 0{\cdot}07619(K^2/I_s)$, $\beta = 0{\cdot}02362(K^3/I_s^2)$. The parameter ΔIH^3 was plotted against H. The straight line given in figure 2 was obtained. The intercept gives a negative value of β which in turn depends upon K^3. This means that K is in fact negative, and the easy directions of magnetization in the material are [111]-type directions, as was assumed. From the gradient and intercept of the line in figure 2 the respective values $K = 3{\cdot}56 \times 10^4$ and $3{\cdot}62 \times 10^4$ erg cm^{-3} were calculated. These appeared consistent enough to justify extending the experiments to other temperatures. This was done by immersing the specimen in baths of (*a*) liquid nitrogen (79 °K), (*b*) crushed solid carbon dioxide in methylated spirits (200 °K), (*c*) boiling water (373 °K). The approach to saturation was measured at each of these temperatures and the results

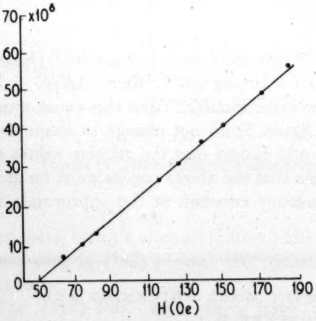

Figure 2. Approach to saturation at room temperature plotted in the form of equation (3).

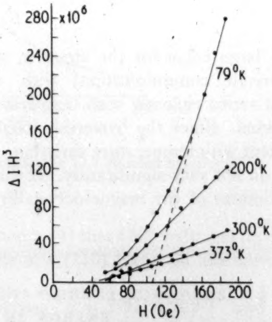

Figure 3. Complete set of results of approach to saturation plotted in the form of equation (3).

plotted in the form of equation (3). A complete set of results is given in figure 3 and the values of K calculated from these are tabulated below. (These have been corrected for the effect of interaction between grains.)

T (°K)	79	200	296	373
$K_1 \times 10^4$ (ergs cm^{-3})(α)	17·3	8·5	5·03	3·88
$K_1 \times 10^4$ (ergs cm^{-3})(β)	17·5	8·4	5·1	3·96

2.4. *Discussion of Results*

The consistency of these results gives confidence in the method. The values of K given above can be compared with a value $K = 3 \times 10^4$ erg cm^{-3} obtained by Standley and Peters (1957) by resonance experiments on a manganese–magnesium ferrite.

It is possible to indicate the effects of stress on the above results with the aid of equations (1) and (2). In the presence of both stress and magnetocrystalline anisotropies the value of K_1 determined above is related to the real value K by

$$K_1^2 = K^2 - \frac{3\lambda^2\sigma_1^2}{5 \times 0{\cdot}07619}.$$

Hence for $\lambda\sigma_1 \ll K$ and $K_1 \sim K$,

$$\frac{\Delta K}{K_1} \simeq \frac{4\lambda^2\sigma_1^2}{K_1^3}.$$

Using a large value for the stress $\sigma_1 = 3 \times 10^9$ dyn cm^{-2} and $\lambda \simeq 2 \times 10^{-7}$ (Knowles 1959, private communication) with $K_1 = 3{\cdot}6 \times 10^4$ erg cm^{-3}, then $\Delta K/K \sim 10^{-8}$. Unless λ varies violently with temperature, the error incurred from this cause must be infinitesimal. Since the hysteresis loops (see figure 5) do not change in shape to any great extent with temperature variation, one would expect that the relative values of K and $\lambda\sigma_1$ do not vary significantly. It thus seems that the above results must be at least good estimates of the magnetocrystalline anisotropy constant at the appropriate temperatures.

§ 3. EXCHANGE ENERGY AND DOMAIN WALL THICKNESS AND ENERGY IN FERROXCUBE D.1

The results of the saturation magnetization in Ferroxcube D.1 given in figure 1 were fitted to the Bloch equation (Bloch 1930)

$$I_s = I_0(1 - CT^{3/2}) \tag{4}$$

in which I_s is the saturation magnetization in a ferromagnetic material at temperature T, and I_0 the saturation magnetization at the absolute zero. From Herring and Kittel (1951) it can be inferred that the exchange constant A is related to the constant C in equation (5) by

$$A = \left(\frac{I_0}{2\mu_B}\right)^{1/3}\left(\frac{k}{13{\cdot}3C^{2/3}}\right) \tag{5}$$

where μ_B is the Bohr magneton and k Boltzmann's constant.

Figure 4 shows a plot of I_s against $T^{3/2}$, from which the values $I_0 = 362$ e.m.u. cm^{-3} and $C = 6{\cdot}79 \times 10^{-5}$ c.g.s. units were obtained. Using these values and $\mu_B = 9{\cdot}21 \times 10^{-21}$ erg Oe^{-1}, $k = 1{\cdot}38 \times 10^{-16}$ erg deg^{-1} in equation (5),

$$A = 2{\cdot}02 \times 10^{-7} \text{ erg cm}^{-1}.$$

This can be compared with values:

(i) for iron (Kittel and Galt 1956)	$A = 2 \times 10^{-6}$ erg cm^{-1}
(ii) for magnetite (Galt 1954)	$A = 1{\cdot}24 \times 10^{-6}$ erg cm^{-1}
(iii) for manganese ferrite (Dillon and Earl 1959)	$A = 0{\cdot}14 \times 10^{-6}$ erg cm^{-1}

and the ferrites containing manganese appear to have lower values of A.

Using the value of A thus calculated, it is possible to estimate the energy γ and thickness δ of domain boundary walls in the material.

In a material with [111]-type easy directions, 71°, 109°, and 180° walls can occur. The thickness of 180° domain walls is determined to a large extent by the magnetostriction of the material. Ferroxcube D.1 has a low magnetostriction and it can be shown using Lilley's analysis (Lilley 1950, equation 5.14) that 180° walls can be expected to form only in (112) planes: 180° domain walls in a (110) plane do not have a finite thickness.

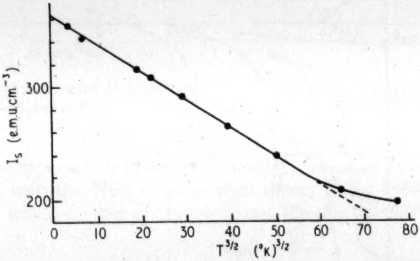

Figure 4. Saturation magnetization in Ferroxcube D.1 plotted against $T^{3/2}$.

The (112)–180° walls then have a thickness $\delta = 7{\cdot}91(A/K)^{1/2}$ and energy $\gamma = 2(KA)^{1/2}$. Substituting the room temperature value $K = 5{\cdot}1 \times 10^4$ and A as above, we obtain $\gamma = 0{\cdot}2$ erg cm^{-1} and $\delta = 1{\cdot}6 \times 10^{-5}$ cm. These values will be fairly representative over the whole temperature range as $\sqrt{K}$ varies by a relatively small amount.

90°-type walls will have thicknesses of one quarter to a half of that given above, and energies about a half.

§ 4. COERCIVITY OF FERROXCUBE D.1

Goodenough (1954) suggested that the main process causing reversal of magnetization in 'square-loop' materials is the nucleation of domains of reversed magnetization at grain boundaries. Having been created, these domains expand without impedance to the motion of their walls, and hence give rise to a definite shoulder on the hysteresis loop. In a theory which should be applicable to all materials which reverse their magnetization through the movement of domain boundary walls, Goodenough defined two critical fields: (i) the field required to create domains of reverse magnetization H_n, and (ii) the field required to move domain walls through the material H_w. The relative magnitudes of H_n and H_w then determine the shape of the hysteresis loop. The sense of H_n is positive or negative depending upon whether domains of reversed magnetization are apparent at remanence, or whether they are created in a reverse field, i.e. a field with the same sense as coercivity. The expressions Goodenough obtained can be summarized in the following:

$$H_c I_s = g\sqrt{K} + f I_s^2 \qquad (6)$$

in which g and f are constants. The first term on the right represents the energy required to move domain walls through the material and the second the energy required to create domains of reversed magnetization. The constant f on this basis could take positive or negative values depending upon the conditions outlined above.

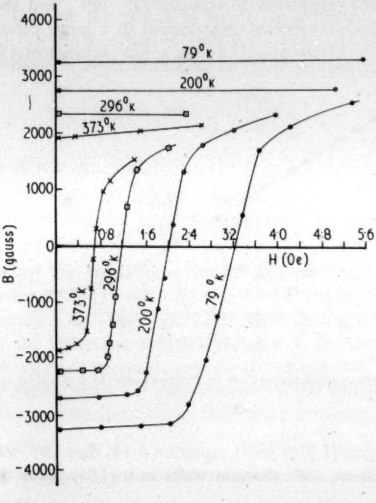

Figure 5. Hysteresis loops of Ferroxcube D.1 at different temperatures.

Hysteresis loops of Ferroxcube D.1 were determined at the four temperatures used in the previous experiment. These are given in figure 5. The shape of these loops is initially independent of temperature from 79 to 300 °K. The loop taken at the higher temperature does not have quite such a marked 'shoulder', and retentivity I_R/I_s is 0·72 instead of 0·75 in other cases. This would tend to indicate that similar processes are giving rise to reversal of magnetization over most, and possibly the whole, of the temperature range employed.

In figure 6 the parameter $H_c I_s$ is plotted against $\sqrt{K}$. Attempts were made to fit equation (6) to the curve in figure 6 without any success. The general indication was that an equation of this type would fit only very minor portions of the curve. It was thus necessary to conclude that reverse domain creation as envisaged by Goodenough does not cause the reversal of magnetization in this material.

It must be noted that in this material, the ratio $2K/I_s \sim 400$ Oe, which is much too large for the possibility of rotations of magnetization vectors to be responsible for the reversal of magnetization.

Micrographic studies of cleaved and polished surfaces of the specimen revealed many pores. These had a diameter of the order of 2×10^{-4} cm. The diameter quoted is a factor of ten larger than the width of domain boundary walls in the material, so the pores may be expected to influence coercivity. It hence seemed pertinent to compare the results with the Néel disperse field theory (Néel 1949). In its approximate form the theory would predict the following relationship for the coercivity:

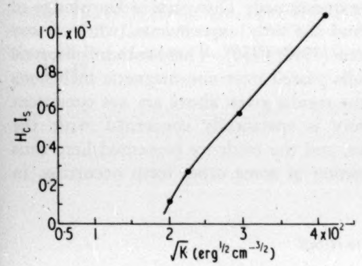

Figure 6. The parameter H_cI_s plotted against $\sqrt{K}$.

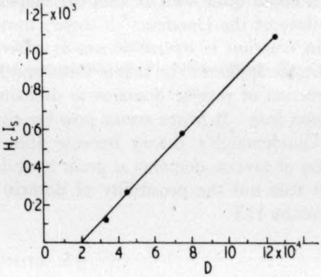

Figure 7. Graph showing variation of H_cI_s with D (see text).

$$H_c' \simeq \tfrac{1}{4}v\frac{\lambda^2\sigma_1^2}{KI_s}+\frac{Kv'}{I_m}. \tag{7}$$

In this equation the first term represents the contribution to the coercive force from islands of free poles, of total fractional volume v, which result from the presence of non-uniform stress in the material. The second term is due to the presence of free poles caused by non-magnetic inclusions of fractional volume v'. Here I_m is the mean magnetization over magnetic and non-magnetic material. Using values $I_m \sim I_s = 240$ e.m.u. cm^{-3}, $\lambda = 2\times10^{-7}$, $K = 5\times10^4$ erg cm^{-3} and $\sigma_1 \sim 3\times10^9$ dyn cm^{-2}, we obtain

$$H_c' \simeq 2\times10^{-2}v + 2{\cdot}1\times10^2 v'$$

from which it is obvious that the second term is the dominant one, and on this basis the effect of the pores on the coercivity would be expected to be much larger than any effects of stress.

The complete relationship given by Néel for the case of non-magnetic inclusions is

$$H_c' = \frac{2Kv'}{\pi I_m}\left[0{\cdot}386+\ln\left(\frac{2\pi I_m^2}{K}\right)^{1/2}\right]. \tag{8}$$

In figure 7 H_cI_s is plotted against

$$D = \left(\frac{2K}{\pi}\left[0{\cdot}386+\ln\left(\frac{2\pi I_s^2}{K}\right)^{1/2}\right]\right).$$

The resulting straight line has a gradient of 10^{-2} and an intercept $D_0 \simeq 2 \times 10^4$. The porosity of the material given by the manufacturers is 2–5%. The gradient is hence reasonably near this value, but the intercept cannot be justified by equation (8). Hence the Néel theory is not obeyed in Ferroxcube D.1.

The reversal of magnetization in a material like Ferroxcube D.1 is expected to occur by some process which gives rise to a very small distribution of coercivities within the material, and in this case one might not expect the Néel theory to apply. However, a process of domain creation appears much more attractive in this respect, since it could quite well explain the shapes of the hysteresis loops, and the reasons for the failure of the Goodenough theory must be questioned. Our present knowledge of domain creation is by no means extensive, and the only experimental work of any significance appears to be that of Bates and Martin (1953, 1956). These authors observed the creation of reverse domains as domain walls passed over non-magnetic inclusions in silicon iron. It hence seems possible that the results given above are not consistent with Goodenough's theory because this theory is specifically concerned with the creation of reverse domains at grain boundaries, and the evidence presented here thus cannot rule out the possibility of domain creation of some other form occurring in Ferroxcube D.1.

§ 5. CONCLUSIONS

It has been found possible to determine the magnetocrystalline anisotropy in a 'square-loop' ferrite by measurements of the approach to saturation in a polycrystalline specimen. The results presented in a linear form of the theoretical equation allow K to be calculated from a gradient and an intercept. The two values obtained in this way were found consistent at the four temperatures used and the method hence appears valid.

The exchange energy constant A in the same material was determined from measurements of the saturation magnetization at low temperatures. Along with the values of K found above, this gave the thickness and energy of domain boundary walls in the material to be $1{\cdot}6 \times 10^{-5}$ cm and $0{\cdot}2$ erg cm^{-2} respectively.

Comparison of measured values of coercivity at different temperatures with the relevant parameters determined experimentally shows that the Goodenough theory of domain creation is not applicable to this material. Pores of important size were observed in the material, but the experimental results are not consistent with the Néel disperse field theory.

ACKNOWLEDGMENTS

The author is indebted to his supervisor, Dr. R. Street, for his advice and encouragement. This work was carried out under contract with the Ministry of Supply, and the provision of a maintenance grant is gratefully ackowledged. Specimens of Ferroxcube D.1 were kindly supplied by Dr. K. Hoselitz of Mullard Research Laboratories.

A Temperature Dependent Relaxation in a Square Loop Ferrite

By J. R. CHAMBERLAIN

Department of Physics, The University, Sheffield 10†

Communicated by W. Sucksmith; MS. received 11*th May* 1961, *in revised form* 18*th July* 1961

Abstract. Measurements of the initial permeability of a commercial square-loop ferrite (Ferroxcube D.1) as a function of frequency and temperature are reported. These show the presence of a relaxation, which is due to the damping of domain boundary walls in the material by a process of electron diffusion. It is found that all the domain walls in the material are not affected by this process. The presence of the relaxation does not allow the dynamic characteristics of the domain walls, important in conventional pulsed-reversal experiments, to be determined by the method employed here.

MEASUREMENTS have been made of the initial reversible permeability of a square-loop ferrite material (Ferroxcube D.1), as a function of frequency and temperature, using an impedance bridge method. The bridge used was a modification of the Owen inductance bridge (Wilde 1952), in which the specimen is used as the former of a mutual inductance. The impedance presented to the circuit by this inductance is measured in terms of variable air condensers and small carbon resistors.

Figure 1 shows the variation of the real part of the permeability μ' as a function of frequency at room temperature. A similar plot of the imaginary part of the permeability μ'' and the loss angle $\tan\delta$ (μ''/μ') are also given. These have the form of dispersion curves typical of a relaxation phenomenon. However they do not follow normal relaxation curves because of an apparent distribution in the characteristic frequency f_c. This has the effect of broadening the curves over a large frequency range and decreasing

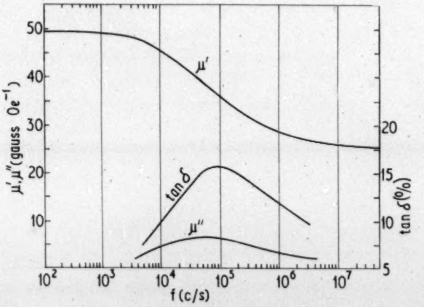

Figure 1. The frequency dependence of the initial permeability in Ferroxcube D.1. at room temperature.

---

† Now at the National Research Council, Ottawa, Ontario, Canada.

the maximum in μ''. Ignoring any effect of a distribution in f_c, a curve of the form

$$\mu' - 1 = \frac{\mu_f}{1+(f/f_c)^2} + \mu_R \tag{1}$$

could be reasonably fitted to figure 1 with f_c taken as the frequency at which μ'' is a maximum. In this equation μ_R represents a frequency independent component of the permeability, and $\mu_R + \mu_f = \mu_0 - 1$ where μ_0 is the d.c. initial permeability. In figure 1 $\mu_R = 26$ gauss Oe^{-1} and $\mu_f = 22$ gauss Oe^{-1}.

Following Wijn (1953) tan δ was determined as a function of temperature at fixed frequencies. The results of these measurements are given in figure 2. For a given frequency the loss angle reaches a maximum at a temperature $T_{\max}$. Plotting $\log f_c$ against $1/T_{\max}$ gave a straight line which indicated the law of the form

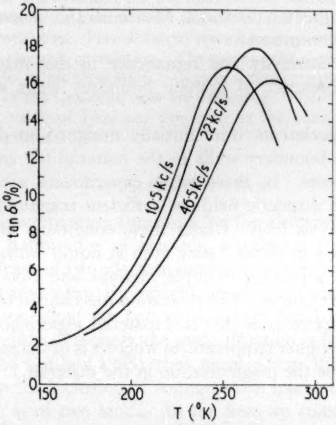

Figure 2. The temperature dependence of the loss angle tan δ at frequencies 10·5 kc/s, 22 kc/s and 46·5 kc/s.

$$f_c = f_\infty \exp(-E/kT)$$

and for the relaxation time $\tau = \tau_0 \exp(E/kT)$. From the results the activation energy $E = 0{\cdot}37$ ev and the characteristic time $\tau_0 = 5 \times 10^{-12}$ sec were calculated. These values compare with similar results obtained in other ferrites (e.g. Wijn 1953, Galt 1954, Gibbons 1959). The usual explanation is that the relaxation is due to the diffusion of electrons between ions of different valency on similar lattice sites.

The contribution to the initial permeability from rotational processes (Street and Lewis 1958) is

$$\mu_{\text{rot}} = 1 + \frac{2\pi I_s{}^2}{K} \tag{2}$$

where I_s is the saturation magnetization and K the magnetocrystalline anisotropy constant. For Ferroxcube D.1 at room temperature $K = 5{\cdot}03 \times 10^4$ erg cm^{-3} and $I_s = 240$ e.m.u. cm^{-3} (Chamberlain 1961), so that $\mu_{\text{rot}} = 8{\cdot}2$ gauss Oe^{-1}. The contribution to the initial permeability from domain wall motion is hence 39·8 gauss Oe^{-1}.

The effect of electron diffusion in ferrites has been considered by Clogston (1955). In this analysis the diffusing electrons are regarded as free, and are considered to arrange themselves so as to minimize the total free energy of the lattice. This rearrangement causes extra torques which resist changes in the direction of magnetization. The diffusion hence causes an increase in the magnetocrystalline anisotropy constant K, and gives a contribution to the domain wall damping parameter β (see, for example, Kittel and Galt 1956). Both of these effects cause a decrease in μ' with frequency. On the basis of Clogston's theory the changes in the rotational contribution to the permeability are less than 1% of μ_{rot}. The fractional change in μ' from this cause is hence negligible. This means that the decrease in permeability is due solely to the damping of domain walls. The residual permeability μ_{R} (equation (1)) is 26 gauss Oe^{-1}. This is a factor of three greater than μ_{rot}. Hence all the domain boundary walls are not affected by the diffusion process.

The permeability at coercivity and remanence in this material also show a dispersion, indicating the presence of domain boundary walls at these points on the hysteresis loop.

The permeability experiments were initially designed to determine the dynamic characteristics of domain boundary walls in the material for comparison with pulsed remagnetization experiments. In these latter experiments a core of the material is subjected to step-function magnetic fields of sufficient magnitude to take the material around a complete hysteresis loop. Under these conditions the material is observed to reverse its magnetization in about 1 μsec even at liquid nitrogen temperatures, and the switching coefficient S_{w} (see for example Menuyk and Goodenough 1955) is fairly insensitive to temperature changes. The relaxation mechanism observed above is hence unimportant in the fast flux reversal that this material experiences in computer applications, except perhaps at higher temperatures where τ is of the same order of magnitude as the time taken to reverse the magnetization in the material.

ACKNOWLEDGMENTS

The author would like to thank Dr. R. Street for his encouragement and Mr. A. C. Lynch for several discussions, and his helpful suggestions on the construction of the bridge network. The work was carried out under contract to the Ministry of Supply and a maintenance grant is gratefully acknowledged. Specimens of Ferroxcube D.1 were kindly supplied by Dr. K. Hoselitz of Mullard Research Laboratories.

Electron Correlation in the Ground State of Helium

By C. A. COULSON and A. H. NEILSON

Mathematical Institute, Oxford

MS. received 19*th June* 1961

Abstract. Formulae are obtained for the distribution function $f(r_{12})$ of the interelectronic distance r_{12} in the ground state of helium, and for the mean value of any positive integral power of r_{12}. Five different wave functions are considered, showing varying degrees of electron correlation. The greater the degree of correlation the larger is the mean electronic separation. Curves of $f(r_{12})$ are plotted, and from them the size and depth of the Coulomb hole are evaluated. There is a close correlation between the mean value of $1/r_{12}$ and the error in the energy as calculated with these five wave functions.

§ 1. INTRODUCTION

RECENT STUDIES using accurate wave functions for the electrons in atoms and molecules have shown the great importance of electron correlation (for a modern survey see Löwdin 1959). In the case of two-electron atoms the mean value of the interelectronic separation $\langle r_{12} \rangle$ is increased when, by introducing electron correlation into a previously uncorrelated function, we allow the two electrons to avoid being near to each other more frequently than before. Precisely the same situation is found for the two-electron molecule H_2 (Barnett and Coulson 1958) when we pass from the uncorrelated molecular-orbital wave function to the inclusion of configuration interaction.

Electron correlation is of two kinds. In the first we consider electrons of parallel spin. Here the Pauli principle keeps the electrons apart and leads to the Fermi hole. In the case of atoms some calculations of the shape and size of this Fermi hole have been made by Maslen (1956). With metals, however, much more work has been done, and no calculation of cohesive energy is of very great value which does not take explicit account of it. But the second type of correlation involves electrons of different spin, where the Pauli principle exerts no direct influence, and where the effect is due to the classical Coulomb repulsion between the electrons. We may therefore speak of a Coulomb hole.

Practically no numerical calculations have been made of the size of this Coulomb hole. It is, of course, related to the distribution function for the interelectronic distance —which we shall write $f(r_{12})$, and normalize so that

$$\int_0^\infty f(r_{12})\, dr_{12} = 1.$$

Any approximate wave function $\psi(1, 2)$ will lead to a corresponding $f(r_{12})$. We shall define the Coulomb hole as the difference between the values of $f(r_{12})$ when the function f is derived (*a*) from the true wave function, or our best approximation to it, and (*b*) from the best uncorrelated wave function, i.e. the Hartree–Fock wave function. This definition of the Coulomb hole is entirely analogous to that of the correlation energy, which is the corresponding difference in energy for the same two wave functions. In order to gain information about the Coulomb hole, we have made calculations for the ground state of helium. The advantages of this choice are several—it is the simplest situation where the hole exists; there is a wide variety of available wave functions embodying varying degrees of electron correlation; and we are not involved in any consideration of the Fermi hole, since our two electrons have opposed spins. In the course of this work it was necessary to evaluate the distribution function $f(r_{12})$ for the same set of approximate wave functions. We were unable to find in the literature any account of this function, and therefore report what we ourselves have done. We hope, in a later paper, to extend this type of discussion to other atoms, having more electrons.

§ 2. THE DISTRIBUTION FUNCTION $f(r_{12})$

In the ground state of the helium atom our wave function will be of the form

$$\psi(1, 2)\{\alpha(1)\beta(2)-\beta(1)\alpha(2)\}/\sqrt{2}.$$

The spin part is totally irrelevant for our analysis, and so we drop it, using only the space part $\psi(1, 2)$ normalized so that $\int \psi^2(1, 2)\, d\tau_1\, d\tau_2 = 1$. In our case it is known that $\psi(1, 2)$ involves only the three distances r_1, r_2, r_{12} (see figure 1). Then, from the probability interpretation of $\psi^2(1, 2)$ we have

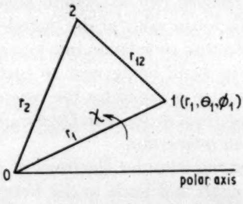

Figure 1. Notation. Numerals 1 and 2 denote the electrons, 0 is the nucleus.

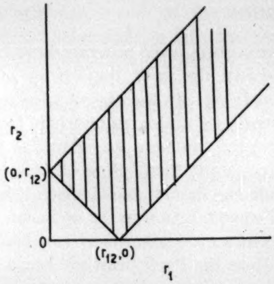

Figure 2. Shaded area represents range of integration in equation (2).

$$f(r_{12})\, dr_{12} = \int \psi^2(1, 2)\, d\tau_1 d\tau_2 \tag{1}$$

where the integration is taken over all positions of the two electrons such that the interelectronic distance lies between r_{12} and $r_{12}+dr_{12}$. Now if we define the direction of 01 by polar angles θ_1, ϕ_1, and if χ denotes an angle of rotation of the plane 012 around 01, then

$$d\tau_1 d\tau_2 = r_1 r_2 r_{12} \sin\theta_1\, dr_1 dr_2 dr_{12} d\theta_1 d\phi_1 d\chi.$$

Thus in (1) the integrations over the angles are immediate, and

$$f(r_{12}) = 8\pi^2 r_{12} \iint \psi^2(1, 2) r_1 r_2\, dr_1 dr_2, \tag{2}$$

r_1 and r_2 being allowed all values compatible with any given r_{12}. This is the shaded region in figure 2. Thus (2) may be written

$$f(r_{12}) = 8\pi^2 r_{12}\left\{\int_{r_{12}}^{\infty} r_1\,dr_1 \int_{r_1-r_{12}}^{r_1+r_{12}} r_2\psi^2(1,2)\,dr_2 + \int_0^{r_{12}} r_1\,dr_1 \int_{r_{12}-r_1}^{r_{12}+r_1} r_2\psi^2(1,2)\,dr_2\right\}. \tag{3}$$

The mean value of r_{12}^n is given by

$$\langle r_{12}^n \rangle = \int_0^{\infty} r_{12}^n f(r_{12})\,dr_{12}. \tag{4}$$

It is often convenient to obtain these mean values from the generating function

$$G(\gamma) = \sum \frac{(-\gamma)^n}{n!}\langle r_{12}^n \rangle = \int_0^{\infty} \exp(-\gamma r_{12}) f(r_{12})\,dr_{12} \tag{5}$$

which yields $\langle r_{12}^n \rangle$ for all positive integral n. By combining (2) and (5) we have

$$G(\gamma) = 8\pi^2 \int \exp(-\gamma r_{12})\psi^2(1,2) r_1 r_2\,dr_1 dr_2 dr_{12}. \tag{6}$$

For states other than the ^{1}S states there will be certain angular terms in the integrations in (2)–(6).

When evaluating the integrals in (2) and (6) it is often convenient to use the Hylleraas variables $s = r_1+r_2$, $t = r_2-r_1$, $u = r_{12}$, for which $-u \leqslant t \leqslant u \leqslant s \leqslant \infty$, and $dr_1 dr_2$ may be replaced by $\frac{1}{2}\,ds dt$. Equation (2) then becomes

$$f(r_{12}) = \pi^2 r_{12} \int_{r_{12}}^{\infty} ds \int_{-r_{12}}^{+r_{12}} dt(s^2-t^2)\psi^2(1,2). \tag{7}$$

With most of the wave functions that we shall use, this leads very simply to an expansion of $f(r_{12})$ in terms of the A_n and B_n functions defined by

$$A_n(\alpha) = \int_1^{\infty} s^n \exp(-\alpha s)\,ds$$

$$B_n(\alpha) = \int_{-1}^{1} t^n \exp(-\alpha t)\,dt = (-1)^n B_n(-\alpha).$$

Numerical values of A_n and B_n are tabulated by Flodmark (1957).

Similarly, when evaluating (6) it is often convenient to work in terms of the perimetric coordinates used by Pekeris (1958). These are

$$x = r_1+r_2-r_{12}, \qquad y = r_2+r_{12}-r_1, \qquad z = r_{12}+r_1-r_2$$

and the volume element $d\tau_1 d\tau_2$ becomes (for wave functions involving only r_1, r_2, r_{12})

$$d\tau_1 d\tau_2 = \tfrac{1}{4}\pi^2(x+y)(y+z)(z+x)\,dxdydz.$$

The triangular relations implied in figure 1 are now such that all three variables x, y, z range from 0 to ∞ independently.

One small simplification is worth mentioning. If additional correlation is introduced into a function $\psi(1,2)$ by a factor $g(r_{12})$ so that

$$\psi = \psi(1,2)g(r_{12})$$

then (2) shows that the new distribution function $f(r_{12})$ is obtained from the old one by a simple multiplication by $\{g(r_{12})\}^2$.

§ 3. WAVE FUNCTIONS USED

We shall be concerned with five distinct wave functions. These are:

I. The Eckart–Kellner function $N\exp\{-c(r_1+r_2)\}$, where N is a normalizing factor (here c^3/π) and c is given the 'best' value $c = 2-5/16 = 27/16$. This is a completely uncorrelated function.

II. The Eckart–Hylleraas function $N\{\exp(-ar_1-br_2)+\exp(-br_1-ar_2)\}$. This allows for 'in–out' correlation since the two electrons may be supposed to be in distinct orbitals. The inner orbital has $a = 2{\cdot}18$, and the outer orbital has $b = 1{\cdot}19$.

III. The partly-correlated function $N\exp\{-c(r_1+r_2)\}\{1+\alpha r_{12}\}$ where the presence of the term in brackets tends to increase the weight of those situations where r_{12} is large and so the electrons are well separated.

IV. The Hylleraas function

$$\sum c_{lmn}(r_1+r_2)^l(r_1-r_2)^{2m}r_{12}{}^n \exp\{-c(r_1+r_2)\}$$

which generalizes (III) and may be made as accurate as we wish by including a sufficient number of terms in the summation. This function has been scaled to satisfy the virial theorem with $2c = 3{\cdot}636$ and in this case r_1, r_2, r_{12} are written for the transformed vectors $2cr_1$, $2cr_2$, $2cr_{12}$; the new normalization constant is obtained from the unscaled one by multiplying by $(2c)^3$. In order to avoid undue numerical complexity, which is not justified for our present purpose, we considered the compromise function with six terms. For all practical purposes, however, this may be regarded as giving the exact $f(r_{12})$.

V. The Hartree–Fock function $F(r_1)F(r_2)$. This is the best possible uncorrelated function. The original calculations of $F(r)$ due to Wilson and Lindsay gave $F(r)$ as a numerical table. This is inconvenient. We have therefore used the analytical representation provided by Roothaan, Sachs and Weiss (1960). This is

$$F(r) = \sum_{n,\xi} c_{n,\xi} r^{n-1}\exp(-\xi r)$$

where $n = 1$, 2 and $\xi = 1{\cdot}40$, $3{\cdot}00$. This four-term function reproduces the self-consistent field function to within 2 or 3 parts in 10^4, and gives an energy value differing from the full Hartree–Fock value by less than 1 part in 10^5.

We shall refer to these wave functions by their numbers I–V. More detailed comparison of most of them, together with suitable references, may be found in a paper by Roothaan and Weiss (1960).

§ 4. RESULTS OF CALCULATIONS

In general the expressions for $f(r_{12})$ are too clumsy to be worth transcribing. But the following three formulae are sufficiently simple. (We have used r instead of r_{12} for convenience.)

Wave function I

$$f(r) = \frac{c^3}{6}(3r^2+6cr^3+4c^2r^4)\exp(-2cr) \tag{8}$$

Wave function III

$$f(r) = \frac{4c^5(3r^2+6cr^3+4c^2r^4)(1+\alpha r)^2 \exp(-2cr)}{24c^2+105\alpha c+144\alpha^2} \tag{9}$$

Wave function IV

$$f(r) = \exp(-2cr) \sum_{p=2}^{8} a_p r^p \tag{10}$$

where the a_p are products of the coefficients c_{lmn} in the original wave function. We have shown, in figure 3, curves to represent the variations of $f(r)$ for the functions I, IV and V. The remaining curves are related to these three in a way that follows (see later) from the numerical values in the table.

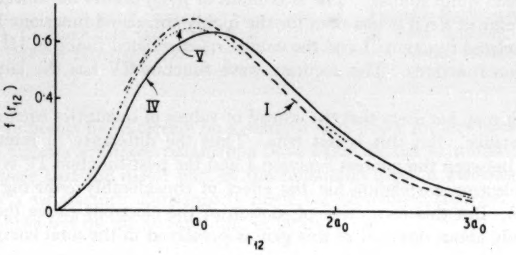

Figure 3. Distribution curves $f(r_{12})$. I Eckart–Kellner wave function, IV Hylleraas 6-term function, V self-consistent field function.

The two following generating functions $G(\gamma)$ are simple enough to be listed.

Wave function I

$$G(\gamma) = \frac{1}{8}\left(1+\frac{\gamma}{2c}\right)^{-3} + \frac{3}{8}\left(1+\frac{\gamma}{2c}\right)^{-4} + \frac{1}{2}\left(1+\frac{\gamma}{2c}\right)^{-5} \tag{11}$$

Wave function IV

$$G(\gamma) = \sum_{p=2}^{8} p!\,a_p(\gamma+2c)^{-(p+1)}, \tag{12}$$

where the notation is the same as in (10).

From the information in (8)–(12), and similar equations for the other wave functions, it is possible to compute the numerical values in the table. All the distances are measured in Bohr radii (a_0). We have verified that in every case except (V)

$$\int_0^\infty f(r_{12})\,dr_{12} = 1.$$

In the case of (V) our calculations were not sufficiently extensive for this purpose.

Comparison of Wave Functions for Helium

Wave function	I	II	III	IV	V
$\langle r_{12}\rangle$	1·296	1·394	1·372	1·420	1·311
$\langle 1/r_{12}\rangle$	1·055	0·993	0·974	0·946	1·026
$-E$(A.U.)	2·8476	2·8754	2·8912	2·9032	2·8617
r_{12} at peak of curve	1·0	1·0	1·1	1·1	1·0
$f(r_{12})$ at peak of curve	0·672	0·625	0·649	0·625	0·632
$f(r_{12})$ at r_{12} = 1·0	0·672	0·625	0·644	0·616	0·632
2·0	0·258	0·285	0·295	0·311	0·274
3·0	0·039	0·059	0·039	0·058	0·049

Functions I and V have no electron correlation, and their values for $\langle r_{12}\rangle$ are the smallest, and indeed quite similar. The maximum of $f(r_{12})$ occurs for smaller r_{12}, and at large r_{12} the value of $f(r_{12})$ is less than for the highly correlated functions II and IV. The 'in–out' correlated function II and the simple r_{12}-correlated function III give very similar distribution functions. The accurate wave function IV has the largest mean separation $\langle r_{12}\rangle$.

At first sight it may not seem that the spread of values of quantities such as $\langle 1/r_{12}\rangle$ is of great importance. But this is not true. Thus the difference in interelectronic repulsion energy between the poorest function I and the best function IV is 0·11 A.U., i.e. 3 ev. Thus electron correlation has the effect of considerably reducing electron–electron repulsion. But this restriction of motion of the electrons raises their kinetic energy, so that only about one-half of this gain is preserved in the total energy E.

§ 5. THE COULOMB HOLE

We are now in a position to draw the shape of the Coulomb hole. This has been defined in §1 as the difference between $f(r_{12})$ for the true function and the best uncorrelated Hartree–Fock function. In figure 4 we have plotted $\Delta(r_{12})$ as a function of r_{12}, where

$$\Delta(r_{12}) = f(r_{12})_{\text{Hylleraas}} - f(r_{12})_{\text{Hartree–Fock}}. \tag{13}$$

It is clear from the normalization conditions of $f(r)$ that the total area under the Δ-curve is zero. This curve shows that the probability of the two electrons lying anywhere within a distance 1·1 a_0 from each other is less than it would be without correlation, and correspondingly the probability that the electrons are separated by more than 1·1 a_0 is greater. We could say that 1·1 a_0 was the radius of the Coulomb hole. The greatest value of $\Delta(r_{12})$ occurs at $r_{12} = 0·52\,a_0$, a value which may be compared with the distance (0·59 a_0) from the nucleus at which the radial charge density is maximum. Thus the Coulomb hole is approximately of the same size as the charge-cloud itself. It would be interesting to know whether this occurs with other atoms and other orbitals. Finally the total amount of charge which is moved by the Coulomb hole is equal to the area of the curve in figure 4 between $r_{12} = 0$ and $r_{12} = 1·1\,a_0$. This turns out to be only 0·047e, i.e. approximately one-twentieth of an electron. In this we see how much smaller is the Coulomb hole than the Fermi hole, since in this latter the charge involved is 1·0e.

In conclusion we would like to draw attention to a curious, but simple, result which is implied in the table. In figure 5 we have plotted the error ΔE in the energy calculated for the five wave functions of § 3 against the mean value $\langle 1/r_{12}\rangle$. It is surprising to see

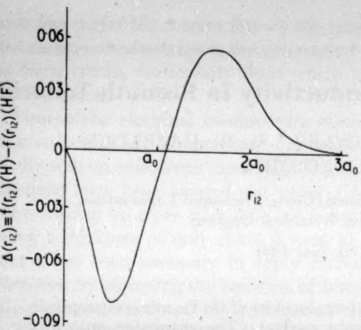

Figure 4. Coulomb hole. (H) = Hylleraas; (HF) = Hartree–Fock.

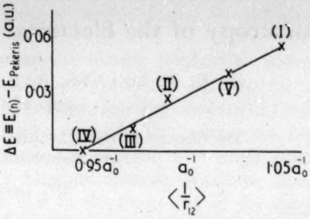

Figure 5. Relation between error in wave function energy and mean value of $1/r_{12}$.

that all five points lie so closely on a straight line. Now for any chosen function, when once the various arbitrary parameters have been chosen to minimize the energy, we may suppose that the major part of the remaining error is associated with the extent to which a satisfactory allowance is made for electron-correlation. This is precisely what is borne out by the straight line in figure 5.

Anisotropy of the Electrical Conductivity in Bismuth Telluride

BY R. T. DELVES, A. E. BOWLEY,† D. W. HAZELDEN
AND H. J. GOLDSMID

Hirst Research Centre, Wembley, England

MS. received 7th June 1961

Abstract. The anisotropy of the electrical conductivity of Bi_2Te_3 at room temperature has been determined by a four-probe method. The anisotropy ratio for undoped p-type material is close to 3·0; for iodine-doped n-type material it is appreciably higher and increases with the impurity concentration. Measurements of the galvanomagnetic effects in highly doped n-type Bi_2Te_3 have shown that the observed variation of the anisotropy ratio can be interpreted in terms of a change of shape of the equi-energy surfaces in momentum space with increasing density of charge carriers.

§ 1. INTRODUCTION

IN SPITE of the intense study of the semiconductor Bi_2Te_3 during the last few years there have been comparatively few measurements of the anisotropy of its transport parameters. This is due to the fact that such measurements require good single crystals of reasonable size. While it is relatively easy to grow single crystal sheets with dimensions which are large in the plane of the *a* axes, it is difficult to find samples which have any great thickness in the *c* direction. Furthermore, many single crystals, which appear at first sight to be perfectly sound, in fact contain deep cracks which are revealed upon etching. Such cracks can give rise to an apparently very large anisotropy ratio for the electrical conductivity and this may explain some of the results reported by Konorov (1956).

Previous measurements of the anisotropy of the electrical conductivity in these laboratories have been confined to a single sample of each conductivity type at room temperature (Goldsmid 1957) and two p-type samples at liquid nitrogen temperatures (Drabble 1958). It was, therefore, thought to be worth while extending these measurements over a wider range of material. Unfortunately all the single crystal p-type material has been undoped and the new observations on such material have merely served to confirm the earlier results. However, n-type crystals of Bi_2Te_3 with differing iodine concentrations have also become available and experiments on these specimens to determine the dependence of the anisotropy ratio on the density of the charge carriers have been carried out.

§ 2. DETERMINATION OF THE ANISOTROPY RATIO BY THE FOUR-PROBE METHOD

The conventional method for measuring the electrical conductivity of a semiconductor requires the application of two large-area current contacts and two intermediate potential probes to a regularly-shaped sample. While such a method can be applied to Bi_2Te_3 without difficulty when current flows along the cleavage planes, it is much less useful for current flow in the perpendicular direction. In the latter case the most serious disadvantage is the uncertainty as to whether or not the sample is entirely free from cracks, particularly those which may form or deepen during the application of the contacts.

---

† Now at the Physics Department, Medical School, Guy's Hospital, London, S.E.1.

Four-probe electrical conductivity measurements are usually confined to isotropic semiconductors but Airapetyants and Bresler (1959) have shown that they can be used equally well on anisotropic materials. Thus all the present electrical conductivity determinations have been carried out using a four-probe method. By making the inter-probe spacing no more than 0·08 cm it has been possible to work with single crystals having a thickness of only about 0·4 cm in the *c* direction, though, of course, in such cases it has been necessary to apply corrections due to the finite size of the sample. Moreover, by observing the variation of inter-probe voltage with orientation it has been a simple matter to detect the presence of cracks.

The apparatus will be described in detail elsewhere. It consists essentially of four equally-spaced probes which can be brought into contact with the surface of a crystal of Bi_2Te_3, as shown in figure 1, so that the line joining the probes can make any selected angle ψ with the cleavage planes. So as to avoid errors due to thermoelectric effects, the direction of the current, which is passed between the two outer probes, is periodically reversed. The voltage appearing between the two inner probes is converted to a single polarity so that it can be measured by a d.c. potentiometer.

Figure 1. Four-probe arrangement for determining the anisotropy of the electrical conductivity in bismuth telluride.

The theory of the four-probe method as applied to isotropic conductors has been given by Valdes (1954). The same theory may be used for anisotropic conductors provided that distances measured along each of the principal axes are suitably scaled. The current density **J** must satisfy the equations

$$\left.\begin{aligned} J_i &= -\sigma_{ii}\frac{\delta V}{\delta x_i} \\ \operatorname{div} \mathbf{J} &= 0 \end{aligned}\right\} \qquad (1)$$

where V is potential and σ_{ii} is the conductivity tensor component along the *i*th principal axis. Equations (1) take the same form as for an isotropic conductor of conductivity σ, equal to $(\sigma_{11}\,\sigma_{22}\,\sigma_{33})^{1/3}$, if one uses new coordinates X_i such that

$$X_i = \left(\frac{\sigma}{\sigma_{ii}}\right)^{1/2} x_i. \tag{2}$$

In applying this principle to Bi_2Te_3, which belongs to the crystal class $\bar{3}$m, it should be noted that $\sigma_{11} = \sigma_{22}$ if direction 3 is taken to be parallel to the c axis. Thus, when the probes are brought down on a plane which is perpendicular to the cleavage planes, the inter-probe spacing s must be transformed to S in the new coordinate system where

$$S = \sigma^{1/2} s\left(\frac{\cos^2\psi}{\sigma_{11}} + \frac{\sin^2\psi}{\sigma_{33}}\right)^{1/2}. \tag{3}$$

Substituting in Valdes' formula,

$$\frac{V_{\mathrm{I}}}{J_{\mathrm{O}}} = \frac{1}{2\pi\sigma S}$$

where V_{I} is the voltage between the inner probes and J_{O} is the current between the outer probes, one finds that

$$\frac{V_{\mathrm{I}}}{J_{\mathrm{O}}} = \frac{(r^{-1}\cos^2\psi + \sin^2\psi)}{2\pi\sigma_{11} s} \tag{4}$$

r being the anisotropy ratio σ_{11}/σ_{33}. If one defines an inter-probe resistance R as being equal to the ratio $V_{\mathrm{I}}/J_{\mathrm{O}}$ for any given angle ψ, then

$$\frac{R}{R_{\mathrm{a}}} = (\cos^2\psi + r\sin^2\psi)^{-1/2} \tag{5}$$

where R_{a} is the inter-probe resistance for $\psi = 0$.

Equations (4) and (5) apply strictly only for infinitely large specimens. Valdes showed how corrections could be applied to take into account the close proximity of the probes to the boundaries of the sample. The correction terms for anisotropic media take exactly the same form as given by Valdes provided that effective distances, as defined by equation (2), are employed.

§ 3. RESULTS OF ANISOTROPY MEASUREMENTS AT ROOM TEMPERATURE

Two typical sets of experimental results are shown in figure 2. For the p-type sample all the dimensions were very large compared with the inter-probe spacing and the variation of the inter-probe resistance R with angle ψ followed the form of equation (5) very closely. On the other hand, for the n-type sample, the c dimension was only about 6 times the inter-probe spacing. Thus in this case the variation of R with ψ was found to be appreciably different from that predicted by equation (5).

In figure 3 the measured anisotropy ratio at room temperature is plotted against the electrical conductivity σ_{11} along the cleavage planes. For the p-type samples the mean value of r is 2·95. This is about 10% higher than the value obtained previously at 20 °C (Goldsmid 1957), but agrees quite well with the figure given by Drabble (1958) for 77 °K. The range covered by the p-type samples is too small to allow one to draw any conclusions about the possible variation of anisotropy ratio with carrier concentration.

The observations on iodine-doped n-type samples confirmed the previous determination of the anisotropy ratio r where σ_{11} is equal to 2×10^3 ohm^{-1} cm^{-1}. However, they also showed quite clearly that the anisotropy ratio rises with σ_{11} and, for the most heavily doped sample, a value of r equal to 6 is reached. It is suggested that the anisotropy ratio depends on the carrier concentration because of a variation in the shape of the equi-energy surfaces in momentum space. To test the validity of this suggestion, galvanomagnetic measurements have been made on heavily doped n-type Bi_2Te_3.

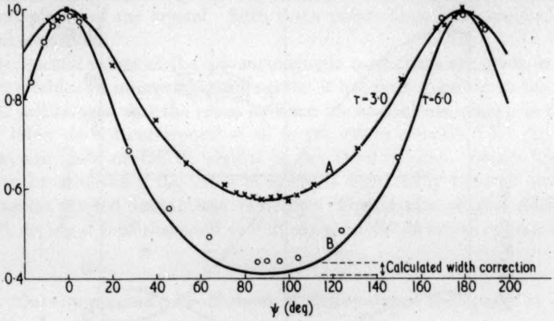

Figure 2. Variation of inter-probe resistance with orientation: A, p-type, $r = 3{\cdot}0$, large sample; B, n-type, $r = 6{\cdot}0$, short c dimension; full lines, theoretical curves, $R/R_a = (\cos^2\psi + r\sin^2\psi)^{-1/2}$.

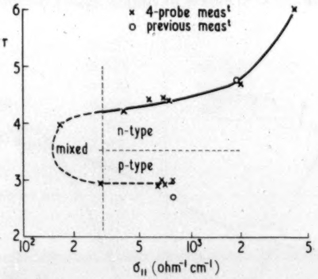

Figure 3. Anisotropy ratio as a function of electrical conductivity measurements at 20 °c.

§ 4. GALVANOMAGNETIC EFFECTS IN HIGHLY DOPED N-TYPE Bi_2Te_3

Galvanomagnetic measurements on n-type Bi_2Te_3, carried out by Drabble, Groves and Wolfe (1958, to be referred to as DGW), indicated the validity of a 6-valley band structure and gave a precise description of the shape and orientation of the equi-energy surfaces, assuming the relaxation time to be a function only of energy. The resistivity ρ_{11} for the material mentioned in DGW at 77 °K was given as $1{\cdot}46\times10^{-4}$ ohm cm.

The measurements reported here were carried out on single crystal material containing nominally 0·4% by weight of iodine and with a value of $6{\cdot}57 \times 10^{-5}$ ohm cm for ρ_{11} at 77 °K. The experimental procedure followed that described in DGW.

The variation of Hall and magnetoresistance effects with orientation of the magnetic field was found for two different experimental arrangements. In case I, shown in figure 4, the magnetic field lay parallel to the cleavage planes. In case II, shown in figure 5, the plane containing the magnetic field lay perpendicular to the cleavage planes. Figures 4 and 5 show that the observed behaviour agreed very well with that expected theoretically from the equations,

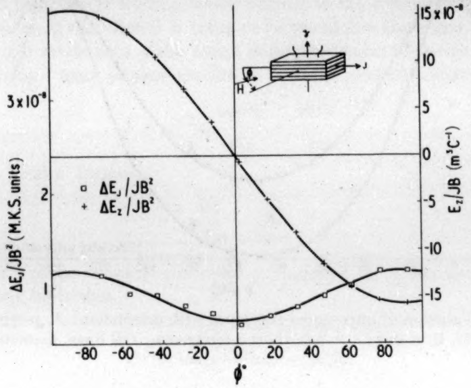

Figure 4. Galvanomagnetic effects in highly doped n-type Bi_2Te_3—Case I.

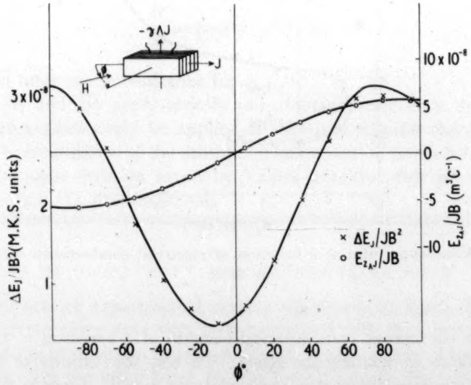

Figure 5. Galvanomagnetic effects in highly doped n-type Bi_2Te_3—Case II.

$$\text{case I}\begin{cases}\Delta E_J/JB^2 = \rho_{1111}\cos^2\phi + \rho_{1122}\sin^2\phi & (5a)\\ E_z/JB = -\rho_{312}\sin\phi & (5b)\end{cases}$$

$$\text{case II}\begin{cases}\Delta E_J/JB^2 = \rho_{1111}\cos^2\phi+\rho_{1133}\sin^2\phi+\rho_{1131}\sin 2\phi & (6a)\\ E_{z\wedge J}/JB = \rho_{123}\sin\phi. & (6b)\end{cases}$$

The same terminology as that of DGW has been used and it has been assumed that the Hall effect is linear in magnetic field and that the current flow is parallel to one of the three rotation planes of the crystal. Both these points have been checked under the experimental conditions.

The experimental values of the galvanomagnetic coefficients are given in the second column of the table. In interpreting the results it has been possible to use degenerate statistics. It will be seen that the ratios between the coefficients, shown in the last four rows of the table, do not correspond at all to the values calculated for the parameters m_1/m_2, m_3/m_2 and $\cos^2\theta$ of DGW, shown in the third column. Much better correspondence can be achieved if the value of m_3/m_2 is appreciably reduced and the other band parameters altered rather less radically. The results of the calculations for $m_1/m_2 = 1{\cdot}0$, $m_3/m_2 = 0{\cdot}05$ and $\cos^2\theta = 0{\cdot}06$ are given in the fourth column of the table.

Galvanomagnetic Coefficients of Highly-doped Bi₂Te₃ at 77 °K

The band parameters (*a*) in the third column satisfy the measurements of DGW on lightly-doped n-type Bi₂Te₃. The parameters (*b*) in the fourth column give a better fit to the present measurements.

Coefficient	Exptl value	Calculated values (*a*)	Calculated values (*b*)
ρ_{11}(ohm m) × 10⁶	0·657		
ρ_{123}(m³ c⁻¹) × 10⁶	0·058	$m_1/m_2 = 1{\cdot}21$	$m_1/m_2 = 1{\cdot}0$
ρ_{312}(m³ c⁻¹) × 10⁶	0·156	$m_3/m_2 = 0{\cdot}093$	$m_3/m_2 = 0{\cdot}05$
ρ_{1111}(m.k.s. units) × 10⁸	0·66	$\cos^2\theta = 0{\cdot}0546$	$\cos^2\theta = 0{\cdot}06$
ρ_{1122}	1·18		
ρ_{1133}	3·03		
ρ_{1131}	0·51		
$\rho_{123}^2/\rho_{11}\rho_{1111}$	0·78	1·67	0·70
$\rho_{123}^2/\rho_{11}\rho_{1122}$	0·43	1·04	0·39
$\rho_{123}^2/\rho_{11}\rho_{1133}$	0·17	0·48	0·23
ρ_{312}/ρ_{123}	2·69	2·06	2·70

It must be emphasized that it is impossible to choose a set of band parameters which gives really good agreement with the experimental results. This is in marked contrast to the extremely close correspondence between experiment and theory in DGW. It is thought that the heavy doping of Bi₂Te₃ has not merely made the equi-energy surfaces more prolate; it has also warped them so that they are no longer perfectly ellipsoidal.

The warping of the energy surfaces makes any exact interpretation of their change of shape impossible. However, it seems reasonable to use the band parameters given in the fourth column of the table to make some qualitative predictions about the effect of heavy doping.

In the first place, the anisotropy ratio σ_{11}/σ_{33} corresponding to the new parameters is 4·6 compared with a value of 4·1 obtained by DGW. In other words, the galvanomagnetic measurements on heavily doped material indicate a change in band structure which tends to increase the anisotropy ratio.

Secondly, for the set of band parameters given above, the carrier concentration is given by $n = 0{\cdot}192/e\rho_{123}$. This formula leads to an electron density of $2{\cdot}07 \times 10^{19}$ cm^{-3} and a mobility along the cleavage planes at 77 °K of 4600 cm^2 v^{-1} sec^{-1}. For the less heavily doped material of DGW the electron mobility was found to be 8900 cm^2 v^{-1} sec^{-1}.

The Seebeck coefficients at 77 °K for the material of DGW and the highly doped material are -80 and -22 μv deg^{-1} respectively. Supposing that the same scattering law is applicable in both cases, as suggested by magneto-thermoelectric measurements (Bowley, Delves and Goldsmid 1958), the change in Seebeck coefficient represents a 3·6 : 1 change in the Fermi energy ζ. If the relaxation time for the electrons is a function only of their energy $\mathscr{E}$, being proportional to $\mathscr{E}^{-\lambda}$ where λ is assumed to be a constant, then the mobility μ obeys the law $\mu \propto \zeta^{-\lambda}$. Thus, on the basis of these assumptions, one would expect the mobility of the heavily doped Bi_2Te_3 to be $3{\cdot}6^{-\lambda}$ times that of the DGW material. The change of mobility observed experimentally corresponds to a value for λ of 0·52, the figure for acoustic-mode lattice scattering being 0·5. It may be objected that a consideration of the change in mobility in the perpendicular direction would give a different result (in fact, the calculated value of λ in this case is 0·61). However, in spite of the uncertainty due to the suspected warping of the energy surfaces, it seems clear that, at the temperature of measurement, acoustic-mode lattice scattering is predominant even for the heavily doped sample.

§ 5. CONCLUSIONS

Four-probe measurements at room temperature have shown that the anisotropy ratio for the electrical conductivity is greater for n-type Bi_2Te_3 than for p-type material. They have also shown that the anisotropy ratio in the n-type case rises with the level of doping with iodine.

Studies of the Hall and magnetoresistance effects at liquid nitrogen temperature have shown that increased doping of n-type Bi_2Te_3 compresses the equi-energy surfaces more strongly in a direction nearly parallel to the three-fold rotation axis of the crystal. Such a change in the band structure tends to increase the anisotropy ratio of the electrical conductivity and, thus, provides a qualitative interpretation of the results of the four-probe measurements.

The galvanomagnetic measurements have supported the hypothesis that acoustic-mode lattice scattering is predominant in Bi_2Te_3 even at high doping levels.

The Electron Voltaic Effects in Silicon and Selenium Elements†

By E. W. BILLINGTON AND W. EHRENBERG

Department of Physics, Birkbeck College, London

MS. received 12th January 1961, *in revised form 1st June* 1961

Abstract. The electron and photovoltaic effects in silicon and selenium elements are studied experimentally. It is shown that the response to cathode rays is closely related to their penetration into the cells, and indicates data such as the depth of the barrier and the diffusion length of minority carriers. In particular, it is shown that electrons in grey selenium are mobile, with a diffusion length of about 8 microns.

A brief description is given of some fatigue effects encountered.

§ 1. INTRODUCTION

THE ENERGY of cathode rays impinging on a solid surface is largely dissipated by the production of pairs of electrons and holes within a well-defined distance from the surface. The distance increases rapidly with the voltage of the cathode rays. The Thomson–Whiddington law is a well-known expression for it, but more accurate relations are now available. Cathode rays are easily and within wide limits controlled with respect to energy, duration and intensity, and thus provide a means of studying the effect of ionizing different portions of a semiconductor barrier. This leads to information about the location of the barrier and about the contributions to the voltaic effects (the generation of a circulating current and an e.m.f. by incident radiation) of the carriers generated in different regions.

Studies of this electron voltaic effect were first reported by Becker and Kruppke (1937) for selenium photoelements; by Ehrenberg, Lang and West (1951) and Ehrenberg and Lang (1954) for selenium and copper oxide, and by Rappaport, Loferski and Linder (1956) for germanium barriers. In these papers the basic facts were established. It was found, for example, that in selenium elements, where the barrier is known to be near the surface, the electron voltaic effect commences at very low cathode-ray energies, whereas in copper oxide no effect was observed until the energy was raised to perhaps 70 kev, after some of the surface had been ground off. This confirmed that in copper oxide rectifiers the barrier is situated at the copper–copper oxide interface. But a detailed examination and analysis of the variation of the electron voltaic effect with energy of the cathode rays has not previously been carried out. It is the object of this paper to show, from measurements carried out on silicon and selenium cells, that significant results can be obtained by using cathode rays to prove barriers layers.

§ 2. INSTRUMENTATION

In order to examine the effect of cathode rays, the elements (without protective lacquer!) were placed in a demountable cathode-ray tube of conventional design. Attention was given, however, to minimizing the light coming from the filamentary cathode (and allowing for it). By mildly focusing the beam to a circle of about 1 cm diameter it was assured that it fell within the sensitive region of the elements of 1 in. diameter. By biasing the electron gun, the beam current could be set to any desired value, or it could be pulsed with on and off periods in the millisecond range. The output of the elements could be connected to a galvanometer or to a cathode-ray oscilloscope. The load resistance could be varied over a wide range, and a bias could be applied, but the results obtained with applied bias did not throw new light on the electron voltaic effect.

---

† This paper is based on a Ph.D. thesis submitted by E. W. Billington and accepted by the University of London. Some of its contents were presented at the International Conference on Semiconductors (Praha 1960); an abstract is being published in the conference reports.

Measurements with light were carried out using a Philips projection lamp type 13113 C/01 as a source, placed behind a cell through which a copper sulphate solution circulated. Spectral regions were selected by means of Wratten filters. The duration and the intensity of the illumination were controlled by a photographic shutter and by varying the separation of lamp and element. The illumination was measured by substituting a Schwartz thermopile for the element. The calibration provided by the makers (Hilger and Watts Ltd.) was accepted; allowance was made of course for the difference in area of the elements and the pile. The error in the absolute values of the light flux is estimated to 20%.

In measuring the voltaic effects special attention must be given to the load resistance of the elements. According to the elementary theory, the carriers generated in, or diffusing into, the region of changing electric potential drift in the field of the barrier and produce thus a current I in the direction of blocked flow. If the external resistance is sufficiently low, the carriers swept by the field across the barrier constitute the circulating current. I is therefore found by reducing the load to a minimum or by extrapolating to zero load the actual currents i measured at finite load. If the load is not negligible, the current I causes, across the external resistance r, a voltage V in the polarity of easy flow. As all rectifying junctions should satisfy a voltage–current relation of the form $i = i_0[e^{V/b}-1]$, the net circulating current becomes

$$i = I - i_0[e^{V/b}-1] \tag{1}$$

where i_0 and b are constants characteristic of the junction, and $V = ir$.

§ 3. SILICON SOLAR CELLS

The silicon 'solar' photovoltaic cell used in our experiments is a disk of p-type silicon, about 25 mm diameter and 0·5 mm thick, with a highly doped n-layer made by diffusion near one of the flat surfaces. In the normal use and in all our experiments, radiation is incident on to the n-type surface. A comprehensive survey of these elements has been given by Kleinman (1961).

For electron bombardment, $I = i_p g(V_p)$; V_p is the energy of the electrons in electron volts and i_p is the current carried by the incident electrons, which in our experiments varied between 4×10^{-10} and 10^{-5} amp; the 'gain' $g(V_p)$ is shown in figure 1. $g(V_p)$ is independent of i_p, and has the same value for steady and pulsed bombardment. Below about 20 kv the gain is small; above, it rises linearly, somewhat less than 5 ev (gross) being required for the creation of a pair.

The ranges of cathode rays in silicon have not been measured, but they should be identical with those in aluminium, if allowance is made for the difference in density. Ranges in aluminium measured by Schonland (1925), Lane and Zaffarano (1954), Young (1956), Holliday and Sternglass (1959) have recently been correlated by King (1960). The corresponding ranges in silicon are also given in figure 1. With increasing voltage an increasing proportion of the total electron energy is converted into pairs in layers more remote from the surface.

Now in this cell, the barrier is 2·5 μ behind the surface (personal communication by Mr. A. Bardsley, of Ferranti Ltd.), and so the interesting fact emerges that the n-layer is contributing very little to the voltaic effect. This may well be due to a high rate of surface recombination of carriers at the front surface. It has been reported by Harten (1959) that the sensitivity of photoelements can be varied over wide limits by changing the rate of surface recombination. Surface recombination in silicon elements has also been discussed by Kleinman (1961).

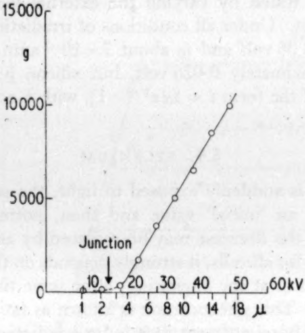

Figure 1. Electron voltaic effect in silicon; gain as function of the energy of the cathode rays and of their penetration. The position of the junction is marked by an arrow.

At about 20 kv, pair production in the bulk sets in, and at higher accelerating voltages most of the pair production takes place in the p-type silicon.

Electrons can reach the barrier by diffusion if they are generated within a diffusion length from the barrier. It must be concluded that the increase of gain with voltage shown in figure 1 will terminate when the range of electrons exceeds the diffusion length, or, alternatively, the thickness of the cell. The optical analogue of this has been analysed by Harten and Schultz (1955). Here, the accelerating voltage available was not high enough to show this effect.

It is of some interest to compare the electron data with corresponding data for the photovoltaic effect.

Under irradiation with visible light, I is found proportional to the intensity B of illumination, $I = CB$, up to about 10 milliwatts, the highest illumination available after filtering; table 1 gives in the second column observed gross values of C.

Table 1

$\lambda(\mu)$	C (A mw^{-1})	Quantum efficiency
0·44	$5{\cdot}7\times10^{-5}$	0·23
0·53	$11{\cdot}6\times10^{-5}$	0·40
0·60	$26{\cdot}5\times10^{-5}$	0·74

The corresponding values for the quantum efficiency in column 3 are corrected for reflection losses, using the expression for the reflectivities given by Moss (1952).

The values for the quantum efficiency appear to be closely related to the low gain observed with slow electrons; for, according to Dash and Newman (1955), the penetration (reciprocal absorption coefficient) of blue, green and red light is 0·43, 1·2 and 2 microns. The quantum efficiency thus appears to approach unity as the radiation tends to penetrate the n-layer, or at least, penetrates the surface region of high recombination.

Equation (1) has been tested by varying the external load at constant irradiation with cathode rays and light. Under all conditions of irradiation equation (1) was found to be satisfied with $b = 0{\cdot}06$ volt and i_0 about 7×10^{-7} amp. For thin junctions b is calculated to kT/e, approximately 0·026 volt, but silicon junctions normally obey a current–voltage relation of the form $i = i_0[e^{V/b} - 1]$, with $b \simeq 0{\cdot}05$ volt.

§ 4. SELENIUM

When a selenium cell is suddenly exposed to light, the photovoltaic effect rises in perhaps a millisecond to an 'initial' value and then, normally, decreases, although under extreme conditions the decrease may be replaced by an increase. The extent of this change is not the same for all cells, it strongly depends on the intensity of irradiation. The rate of change is highest at the beginning; after some time it has become a small fraction of its initial value. This phenomenon is known as fatigue, or creep. It is quite as marked for cathode-ray bombardment as it is for irradiation with visible light. The older observations on the electron voltaic effect referred to in the introduction were carried out by exposing the cells to a steady beam of electrons and observing the response of the cells on a galvanometer so that at least a few seconds had lapsed between the commencement of the exposure and the readings. The readings were therefore, to a varying extent, reduced by fatigue.

The fatigue can, however, be completely suppressed if the cathode rays are applied in short pulses. The results given below were accordingly obtained with 6 millisecond square pulses interrupted by 54 msec off periods. Observation of the output on a cathode-ray oscilloscope showed that the rise time of the response is short compared with 6 milliseconds, and the response curve follows closely the primary current pulse; after starting pulsed bombardment no change in the size of subsequent pulses is observed, for the conditions stated. Also, the output current measured by a galvanometer is exactly the mean value of the current measured by the cathode-ray oscilloscope, i.e. 0·1 of the value during the pulse.

For all cells, families of curves were obtained such as are shown in figure 2. The gain I/i_p decreases with increasing electron current. Except for a rather small initial region it increases linearly with voltage up to a critical voltage V_c which depends on the current density, and remains constant for higher electron energies. The penetration of the primary electrons marked on the abscissa is calculated by extrapolating values given by King (1960).

Consider first the curve for $i_p = 10^{-10}$ amp of figure 2. It is the response one would expect to find for a junction situated close to the surface, if the diffusion length of minority carriers in the bulk is about 5 microns. At very low accelerating voltages the ionization is restricted to a very thin layer near the top electrode; the current gain is low because incident electrons carry little energy. As the accelerating voltage increases the primary electrons produce proportionally more pairs, but also the centre of pair production moves away from the front into the junction (which occupies about

0·5 μ) and beyond. If the electrons in the bulk selenium were immobile, the gain would then cease to increase with increasing penetration because no contribution to the current would arise from the p-type selenium where the additional carriers are generated. From the observation that the gain still increases with cathode-ray energy, it must be concluded that the electrons released in the bulk diffuse into the junction and thus contribute to the current, just as the minority carriers contribute in the silicon cells. But the gain does cease to increase when at the cathode-ray energy eV_c the ionization commences to extend to a depth from which electrons cannot reach the junction by diffusion, i.e. beyond one diffusion length from it. Recent studies by Ehrenberg and King (not yet published) have shown that the ionization caused by cathode rays does not, in the region penetrated, vary much with cathode-ray energy in the range shown in figure 2. This explains why the gain remains approximately constant at energies above eV_c.

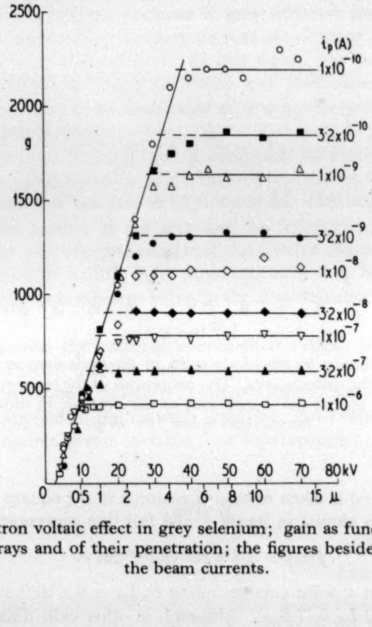

Figure 2. Electron voltaic effect in grey selenium; gain as function of the energy of the cathode rays and of their penetration; the figures beside the curves denote the beam currents.

The depth of penetration of primary electrons of energy eV_c gives therefore the diffusion length L of the minority carriers. At 10^{-10} amp, the diffusion length L is seen to be about 5 microns. It decreases with increasing density of cathode rays.

In order to extrapolate the diffusion length to zero primary current, consider that the lifetime τ of the carriers should be related to the lifetime τ_0 at zero excitation by

$$\frac{1}{\tau} = \frac{1}{\tau_0} + \frac{1}{\tau_1} \tag{2}$$

where τ_1 would be the lifetime if irradiation were the only cause of decay. Relation (2) is equivalent to

$$\frac{1}{L^2} = \frac{1}{L_0^2} + f(i_p). \tag{3}$$

By trial and error it was found that the values of V_c or L respectively given in figure 2 (and corresponding sets of values for all other cells examined) satisfy equation (3) closely

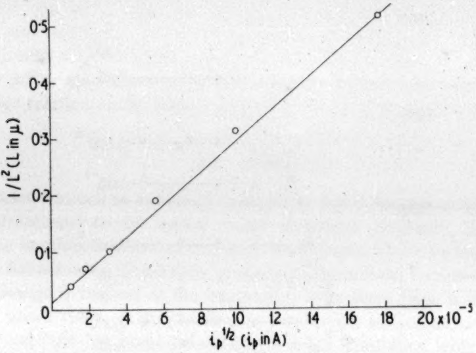

Figure 3. The diffusion length of electrons in grey selenium as a functionofthe current carried by the cathode rays. The reciprocals of the squares of the diffusion length are plotted against the square root of the current, in units of 10^{-10} amp, for currents below 10^{-7} amp.

if $f(i_p)$ (and therefore $1/\tau_1$) is taken to be proportional to the square root of the primary current density. This is shown in figure 3, the full line representing

$$f(i_p) = 2{\cdot}8 \times 10^{11} (i_p)^{1/2}\ \text{cm}^{-2}.$$

The line cuts the axis at a point corresponding to $L_0 = 9 \times 10^{-4}$ cm (calculated by the method of least squares, $L_0 = 7{\cdot}5\ \mu$). Although in other cells different values of gain and of change of gain with primary current are found, L_0 is always close to $8\ \mu$.

Diffusion length L, mobility w and lifetime τ are generally related by

$$L^2 = \frac{wkT}{e}\tau \tag{4}$$

and at 300 °K, $kT/e = 2{\cdot}5 \times 10^{-2}$ volt. This relation can be used to estimate the effective mobility of electrons in grey selenium. An idea of the lifetime of the electrons can be obtained from photoconductivity data. Zworykin and Ramberg (1949) have discussed the variation of photoconductive response of microcrystalline grey selenium with frequency of light pulses. This has one relaxation time of about 0·01 sec and another one of less than 3×10^{-4} sec. If we interpret the longer time as the *total* lifetime τ of the minority carriers, and assume that these data apply to our material we obtain from (4) with $L = L_0 = 8 \times 10^{-4}$ cm for the effective mobility of electrons in grey selenium a value $2{\cdot}5 \times 10^{-3}\ \text{cm}^2\ \text{v}^{-1}\ \text{sec}^{-1}$, which is in rather surprising agreement with that given by Spear (1957), viz. $5 \times 10^{-3}\ \text{cm}^2\ \text{v}^{-1}\ \text{sec}^{-1}$ for electrons in *amorphous* selenium.

According to this interpretation, an electron may undergo many cycles of trapping and release before it finally recombines with a hole or has found its way, by diffusion, into the field of the barrier. The decrease of diffusion lengths with cathode-ray currents indicates a corresponding decrease of total lifetime. It is known that lifetimes can decrease with increasing level of ionization (Hall 1959, 1960, Many and Bray 1958). The relation $\tau_1 \propto i_p^{-1/2}$ may in this connection be of considerable interest.

The numerical values given carry of course a considerable uncertainty. But the consistency of the above results leaves no doubt that the electron voltaic effect brings to light the important fact that the electrons in grey selenium are mobile, and that this mobility plays an important rolé in the performance of selenium barriers and a decisive role at least in the electron voltaic effect. In this respect the present studies support the view first put forward by Poganski (1953) and Hoffman and Rose (1953) that selenium barriers might have to be considered as p–n junctions rather than as unipolar Schottky barriers (Schottky 1941).

It can also be seen from figure 2, and is confirmed by many other measurements, that for selenium I is proportional to the bombarding current for low voltages up to about 10 kv, but it increases less fast at high voltages. This suggests that the rate of recombination near the surface is not increased by irradiation; this agrees with the well-known fact that at zero external resistance the current generated by visible light is proportional to its intensity; visible light penetrates only very little into selenium, the reciprocal of the absorption coefficient being in the neighbourhood of 0·5 micron (Gilles 1951).

If for given irradiation the external resistance is varied, equation (1) has always been found to account fairly well for the voltage–current relation, but the parameters i_0 and b depend on irradiation; equation (1) appears also to hold for unilluminated cells for external voltages applied in the forward direction. An examination of a number of cells suggested the figures given in table 2 as representative. The values refer to a surface of 3 cm².

Table 2

	i_0(A)	b(V)	I(A)
Dark cell	7×10^{-7}	0·06	
Cells illuminated with visible light (ft candles)			
(a) 40	3×10^{-6}	0·065	65×10^{-6}
100	$4{\cdot}5\times10^{-6}$	0·08	154×10^{-6}
(*b*) 75	$4{\cdot}4\times10^{-6}$	0·10	190×10^{-6}
160	16×10^{-6}	0·135	400×10^{-6}
Cathode rays of 30 kv			
Beam current (A)			
7×10^{-9}	$3{\cdot}3\times10^{-6}$	0·07	$0{\cdot}4\times10^{-5}$
3×10^{-8}	$5{\cdot}6\times10^{-6}$	0·077	$1{\cdot}4\times10^{-5}$
$1{\cdot}6\times10^{-7}$	34×10^{-6}	0·12	$5{\cdot}9\times10^{-5}$
6×10^{-7}	44×10^{-6}	0·14	11×10^{-5}
$1{\cdot}2\times10^{-6}$	64×10^{-6}	0·16	16×10^{-5}

In the dark and at low levels of illumination i_0 is near to 10^{-6} A cm^{-2} and b is near 0·06 volt. But these parameters increase rapidly with intensity of irradiation. It is an obvious conjecture that the increase of the value of the parameters is due to increased recombination.

§ 5. SOME REMARKS ABOUT FATIGUE

The intriguing and varied phenomena of fatigue have never been satisfactorily explained. Nor have our own quite extensive studies (Billington 1960) led to very definite conclusions. A few aspects may, however, be worth mentioning.

A measure of the fatigue was established as follows. When the irradiation commences, the voltage as observed on a cathode-ray oscilloscope rises rapidly to the initial voltage V_i and then decreases slowly, the rate of change becoming very small after a few seconds. The change of voltage ΔV in 6 seconds is therefore taken as the measure of the fatigue. It was found convenient to measure the incident radiation in terms of V_i, and typical curves showing ΔV as function of V_i (external resistance 1 MΩ) are shown in figure 4 for a number of selenium cells which show the effect strongly. The shapes of the curves are essentially the same for cathode rays and light. For cathode rays ΔV increases for a given value of V_i with increasing accelerating voltage; for light the fatigue could not be influenced by varying the humidity of the ambient air. The fatigue decreases slightly from blue to red, i.e. with increasing penetration. An *increase* of fatigue with wavelengths was observed by Preston (1944, 1946). His studies of fatigue refer, however, to fatigue relaxing within minutes or hours, so that possibly the effects studied previously are not connected with the effect noticed here.

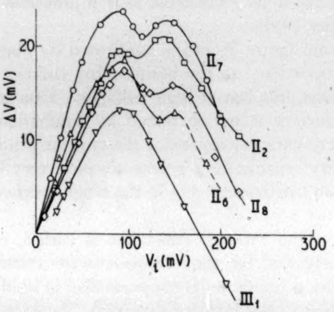

Figure 4. Fatigue of selenium cells under bombardment with 30kv cathode rays. The abscissa is the initial e.m.f., the ordinate the loss in e.m.f. in the first six seconds. Five different cells are represented.

It does not seem possible to explain the shapes of the curves shown in figure 4 by a simple model. But the absence of an ambient effect, and the increase of the effect with increasing penetration of the radiation suggests that the source of the fatigue lies in the interior of the cells, and could be connected with slow surface states situated at grain boundaries.

The silicon cells, as mentioned above, do not fatigue under electron bombardment; nor do they fatigue under illumination if they are kept *in vacuo*. A fatigue develops, however, if the (unvarnished) front is exposed to the atmosphere. The fatigue curves are then similar to those shown in figure 3 with a single broad maximum for $V_i = 275$ mv (at 1 MΩ load).

Harten (1959) has studied the effect of surface recombination on the sensitivity of silicon cells. The comparison with our cells is not straightforward as Harten illuminated his cells from the face opposite the junction. Also he did not look out for fatigue effects. But Harten did observe large changes in sensitivity on exposing the illuminated surfaces to water vapour, nitrogen or oxygen, and also changes in sensitivity with ambient illumination. The same surface states may be responsible for both Harten's effects and the fatigue we observed.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the receipt of a grant given to one of them (E.W.B.) by the Department of Scientific and Industrial Research. We also wish to thank Messrs. Ferranti Ltd. for letting us have some solar cells, and Messrs. Evans Electric for the supply of selenium elements.

Electrical Properties of Organic Insulating Liquids Containing Fluorescent Solutes

BY M. DARVENIZA† AND H. TROPPER‡

† Queensland University
‡ Queen Mary College, London

MS. received 15*th Decemer* 1960, *in revised form* 7*th July* 1961

Abstract. A new phenomenon is reported which is concerned with the excitation of fluorescent solutes in organic liquid dielectrics when high electric fields are applied. The characteristics of the emitted light have been studied and related to the pre-breakdown conduction current and the electric strength. Dielectric liquids showing this effect have been synthesized by dissolving known concentrations of fluorescent materials in simple organic liquids. These have confirmed the exeprimental results obtained with more complex transformer oil. Also, experiments are described which show that even highly degassed liquids exhibit a pressure dependence of electric strength if brought into a state of super-saturation by applying tension to the liquid.

§ 1. INTRODUCTION

PREVIOUS WORK in the study of electric breakdown processes in liquids has been fully reviewed elsewhere (Lewis 1959, Darveniza 1959). However, a brief review of relevant luminescence phenomena will be given here, since the reported experimental results link directly for the first time the two fields of electric breakdown and luminescence.

Organic solutions are widely used for the scintillation detection of energetic radiations (Birks 1953). Small amounts of fluorescent materials such as anthracene are dissolved in suitable organic liquids such as benzene, toluene, etc. These solvents absorb the incident radiation and the energy is re-emitted as fluorescence, characteristic of the solute (Kallmann 1950). Various mechanisms for the efficient solvent–solute transfer of energy have been proposed (Northrop and Simpson 1956, Kallmann and Furst 1951, 1954, 1956).

Several workers (Destriau 1947, Payne, Mager and Jerome 1950) have shown that electric fields may produce luminescence when applied to certain inorganic phosphors. Piper and Williams (1955) and Alfrey and Taylor (1955) have made detailed studies of electroluminscence in single crystals of zinc sulphide. A general relationship between the light output L and the applied voltage V has resulted from the experimental work: $L = A \exp(-BV^{-1/2})$ where A and B are constants.

Piper and Williams have considered various mechanisms for electroluminescence and it is generally agreed that the luminescent centres are excited by field-accelerated electrons. All experimental evidence points to the formation of sufficiently high electric fields in localized spots such as fluorescent centres.

§ 2. EXPERIMENTAL APPARATUS

2.1. *Test Apparatus*

Most of the results described below were obtained with industrial transformer oil conforming to the British Standards Specification B.S. 148: 1951. The oil was of

Peruvian origin and its physical properties may be summarized as follows: colour, pale yellow, slight blue fluorescence; specific gravity, 0·88 at 20 °c; dielectric constant, 2·16 at 20 °c; molecular weight, 310.

The only information available of its chemical properties is the result of an 'm–d–M' analysis: % carbon in aromatics, 8·5; aromatic rings per molecule, 0·3 mean; % carbon in naphthenics, 37·5; naphthenic rings per molecule, 1·8 mean; % carbon in paraffins, 53·7; aromatic compounds, 15% by mass; sulphur compounds, 1·07%, formation unknown; oxygen compounds, traces present, formation unknown.

The impurities which affect the electric strength of insulating liquids are solid particles, moisture and dissolved or entrained air. The oil was purified in a molecular still which utilized a form of flash distillation at reduced pressure and at a temperature sufficiently low to avoid thermal degradation. The still and the test cell formed parts of a totally enclosed all-glass system. Solid particles were removed by filtration through a sintered glass filter of one micron maximum pore size. All parts of the system could be evacuated to a pressure of less than 10^{-4} mm Hg. The distillation technique (Darveniza 1960) enabled the oil to be completely distilled in an atmosphere of air or of nitrogen at pressures between 10^{-2} and 5 mm Hg. Separation of the various fractions of the oil was possible by distillation at suitable temperature and the results are shown in figure 1. It was found that at temperatures approximately 70 °c below that required for complete distillation, only a small fraction of the oil (less than 1%) was not distilled. This consisted mainly of the colouring components of the oil and its separation left the remainder of the oil comparatively clear in appearance.

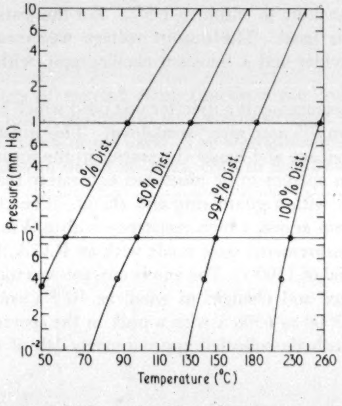

Figure 1. Fractionation of oil as a function of temperature and ambient pressure.

Experiments were also made using the simple organic liquids hexane and benzene, to which known concentrations of fluorescent materials were added. Spectroscopic grades of these liquids were filtered several times through a fine sintered glass filter under vacuum. After dissolving the fluorescent material the prepared samples were again passed through a filter into the test cell.

The test cell was designed to keep the volume to a minimum. Electrical measurements were made between 1 cm diameter nickel spheres mounted horizontally in the test cell. The gap spacing could be varied from 50 to 500 microns with an estimated error between ± 1·5%. Before each test, the electrodes were prepared by mechanical polishing with soft mops and a suitable grease as adopted by Hancox and Tropper (1958). Buffing was continued until no scratches or pits were visible when examined under a metallurgical microscope, magnification 100.

For the variation of the hydrostatic pressure applied to the test liquid two extra-sensitive metal bellows were used. By means of these it was possible to apply tensions equivalent to 350 mm Hg to the test liquid and positive pressures up to 760 mm Hg.

2.2. *Electrical Equipment*

Direct voltages varying between 600 v and 20 kv were obtained from a stabilized source which incorporated a radio-frequency generator. The measurement of this voltage was considered accurate to within ± 1·5%. For the tests with impulse voltages a six-stage generator was used. The output voltage was measured by means of a resistance–capacitance divider and a transient oscillograph, with an estimated error of ± 3%.

During breakdown measurements a diverter was used which by-passed the discharge current in a time less than 0·5 μsec after breakdown. This greatly reduced breakdown products and electrode damage and hence the scatter in the measurements.

To permit conduction current to be measured accurately the low voltage electrode of the test cell was fitted with a guard ring and shield. The current was determined by measuring the volt drop across a high resistance with a 'Vibron' electrometer.

Quantitative light measurements were made with an R.C.A. 931–A photomultiplier operated at a total potential of 1100 v. The anode current was measured with a resistive shunt and an electrometer and changes as small as 10^{-9} A could be detected. The spectral range was from 3000 to 6500 Å with a peak in the spectral response at 4000 Å. It is estimated that the cathode collected approximately $\frac{1}{7}$th of the total light emitted from the test cell.

§ 3. EXPERIMENTAL RESULTS

3.1. *Factors affecting Measurements of Electric Strength and Conduction Current*

The breakdown strength of the oil before purification was found to be 380 kv cm^{-1} with a coefficient of variation of 8%. After distilling the oil in an atmosphere of nitrogen at a pressure of 10^{-2} mm Hg the strength increased to 1120 kv cm^{-1} and the coefficient of variation was reduced to 4·7%. A marked conditioning process was observed, i.e. an increase in strength with successive breakdowns, and at least 10 conditioning discharges were necessary before a stable electric strength was achieved. Retaining the electrodes but changing the oil sample required a further but much smaller conditioning process and this was also necessary when the liquid in the test cell was allowed to stand undisturbed for periods in excess of twenty-four hours.

The consistency of the breakdown measurements can be seen from table 1 which shows the results of 4 different tests. Before each test the electrodes were freshly prepared by mechanical polishing and degassed in the test cell for at least 12 hours before submersion in the test liquid. It was found that the measurements were independent of the rate of rise of the applied test voltage and of the time interval between successive voltage applications, provided the rate of rise was less than 250 v sec^{-1} and the interval between shots was greater than one minute.

It is well known that electric strength measurements made with short duration impulse voltages are critically dependent on the electrode surface conditions (Hancox and Tropper 1958). The dependence is considered to be due to the time-dependent process of electron emission from the cathode. It was eliminated by brushing the electrodes with grade 2/0 emery cloth. Subsequent impulse strength measurements with voltage wave-shapes of varying ramp functions (i.e. voltages increasing linearly with time at different rates) resulted in an electric strength independent of time, for times to breakdown in excess of 0·5 μsec. The strength measured in this manner was similar to that obtained with direct voltages, both in magnitude and scatter.

Table 1

Consistency of Breakdown Measurements

Test	First breakdown (kv cm^{-1})	No. of conditioning shots	Final breakdown strength (kv cm^{-1})
A	650	13	1120
B	740	7	1180
C	690	10	1030
D	690	12	1060

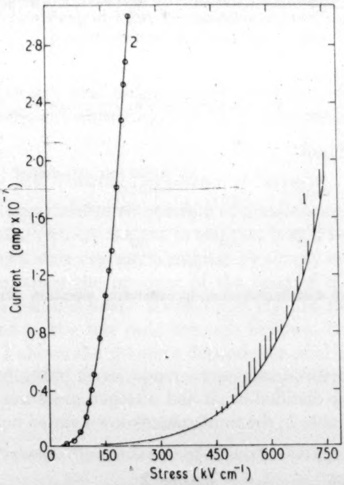

Figure 2. Effect of conditioning on conduction current. Curve 1, before breakdown; curve 2, after spark conditioning of electrodes.

Since most experimental breakdown results were obtained with spark-conditioned electrodes, measurements of pre-breakdown processes were made also with such electrodes. Typical current–electric stress curves for fresh electrodes and spark-conditioned electrodes are shown in figure 2. As with other pre-breakdown processes the conduction current was much more stable with spark-conditioned electrodes, although the magnitude was at least two orders higher.

In all results of breakdown measurements and of pre-breakdown processes given below, spark-conditioned electrodes were used and only the parameters of the test liquid were varied.

3.2. *Dependence of Strength on Gas Content*

Breakdown measurements were made on samples of oil distilled in air and in nitrogen at pressures between 10^{-3} and 5 mm Hg of residual gas. When the gas in use was changed, the oil was flushed with the new gas for at least forty-eight hours. Before each distillation, the oil was allowed to settle into rough equilibrium with the intended still pressure before leaving the gas bubbling chamber. The results obtained are shown in figure 3, the vertical lines indicating the standard deviation. It was found that variation of the nitrogen gas content had no significant effect on the electric strength in the range considered. The electric strength of the oil rose significantly as the partial pressure of air held in solution was raised from 10^{-2} to 1 mm Hg. This result confirms the work reported by Khambanonda (1958).

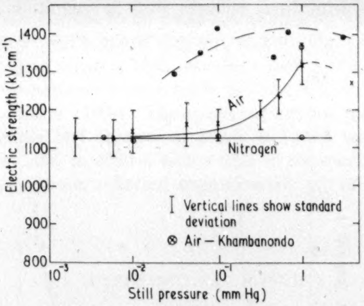

Figure 3. Effect of distillation (i.e. hydrostatic) pressure on electric strength.

Impulse voltage measurements were made, with ramp voltages and scratched electrodes, on oil samples distilled in air and nitrogen pressures of 10^{-2} and 1 mm Hg. The results are given in table 2; the time to breakdown varied between 0·5 and 1·0 μsec.

Table 2

Electric Strength for Impulse Voltages

Still atmosphere (mm Hg)	Electric strength (kv cm⁻¹)	Coefficient of variation (%)
Nitrogen, 10^{-2}	1140	5
Nitrogen, 1	1170	4·8
Air, 10^{-2}	1080	6·9
Air, 1	1520	6·7

3.3. *Strength of Various Oil Fractions*

Samples of oil were distilled at various temperatures in nitrogen at a pressure of 10^{-1} mm Hg and the breakdown results are plotted in figure 4. The electric strength rose as the still temperature was decreased from 210 to 145 °c and thereafter no significant change was observed. Referring to figure 1 it can be seen that the increase in strength is associated with the removal of colouring matter from the oil. The colouring matter was also separated from the oil in a still atmosphere of 1 mm Hg of air and again a significant rise in electric strength was observed.

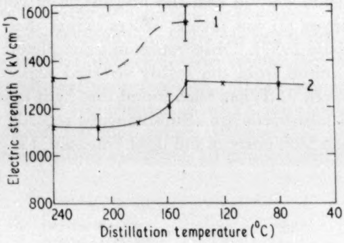

Figure 4. Electric strength of different oil fractions obtained by varying distillation temperature. Curve 1, with air at 1 mm Hg maintained in still; curve 2, with N_2 at a pressure of 10^{-1} mm Hg.

A similar rise in strength was observed with impulse voltages. A strength of 1420 kv cm^{-1} with a coefficient of variation of 7·2% was recorded for oil distilled at 140 °c in nitrogen.

3.4. *Pressure Dependence of Strength*

It is generally agreed that the electric strength of transformer oil shows little dependence on hydrostatic pressure unless the gas in solution is in a state of super-saturation. For highly degassed oil this state cannot be reached by simply reducing the gas pressure above the liquid surface, since the pressure of the head of oil necessary to immerse the electrodes cannot be reduced below about 1 mm Hg. In this work, tensions up to 350 mm Hg were applied to the test fluid through bellows, thus achieving a state of supersaturation. Table 3 shows the pressure dependence of electric strength for highly degassed oil and for oil distilled in nitrogen at a pressure of 1 mm Hg.

Table 3

Pressure Dependence of Electric Strength

Oil sample	Pressure (mm Hg)	Electric strength (kv cm^{-1})
Nitrogen (1 mm Hg)	+300	1120
	+ 50	1120
	−100	1100
	−225	1045
	−350	910
Highly degassed oil, 3×10^{-3} mm Hg	+300	1130
	+ 50	1130
	−350	935

The results show a significant reduction in strength when a tension of 350 mm Hg was applied to the test liquid. No significant pressure dependence was observed in the range of 1 to 760 mm Hg of hydrostatic pressure. A similar reduction of electric strength with tension was observed with oil samples distilled in air at 1 mm Hg and oil samples with the colouring fraction removed.

No significant variation in electric strength with tension or pressure was observed with impulse voltages.

3.5. *Light Emission and Conduction Current*

Preliminary experiments showed that the magnitude of conduction current and of pulse activity in transformer oil was several orders higher than that reported of simple hydrocarbon liquids (House 1957). Observation in a completely darkened room showed that visible light was emitted from the highly stressed region of the oil gap for d.c. fields in excess of 600 kv cm^{-1}. It has been found that light emission may be correlated with electric breakdown measurements. Simultaneous records were therefore obtained of electric strength, conduction current and light emission, for each set of experimental conditions.

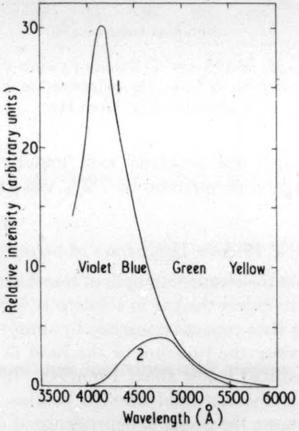

Figure 5. Fluorescence spectrum of transformer oil. Curve 1, emission spectrum; curve 2, eye response to emission spectrum.

The light emitted was blue and similar in appearance to the blue fluorescence obtained by excitation with ultra-violet radiation. The glow appeared if either the voltage across a fixed gap was increased, or if a fixed voltage of 12 kv was applied and the gap decreased from 500 to 100 microns. This showed that the glow was a true high field effect, and that it was not due to spurious corona effects. The fluorescence spectrum of the oil when excited with an ultra-violet source (mercury lamp, OX I filter) was determined and is shown as figure 5. Also shown is the spectrum weighted by the spectral response of the eye. Thus, when viewed by eye, the fluorescence of oil has a peak in the blue region (4800 Å). An Adam Hilger wavelength spectrometer was used to resolve the spectrum of the light emitted due to high electric fields, but this was very difficult because of the small amount of light emitted. At all stresses, the spectrum appeared to be diffuse. At a stress of 900 kv cm^{-1}, the point of maximum intensity was at 5300 Å with a visible spread from 4580 to 5600 Å. The point of peak intensity in the spectrum shifted to shorter wavelengths as the stress increased. At 1300 kv cm^{-1}, the peak appeared at 4800 Å, which corresponds to the peak of fluorescence spectrum as observed by eye (figure 5).

A travelling telescope with a maximum magnification ×80 was used to examine the glow. This appeared to result from filamentary luminous channels which completely bridged the gap from cathode to anode, with no apparent change in intensity along their length. The intensity of light varied from channel to channel, and also with time in each channel, each having a 'flickering' appearance. The filamentary channels occupied a diameter of about three to four times the gap width. As the stress increased above 1100 kv cm^{-1}, the light output became more intense and more diffuse in a localized region about one to two gap widths in diameter. There was some evidence to suggest that it was possible to predict the channel in which final breakdown would occur by choosing the brightest channel at high stress. Photography of the light emission was attempted but even with exposures exceeding 10 minutes and the fastest available film, no record was obtained.

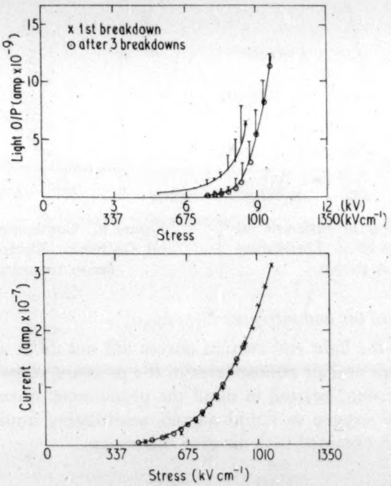

Figure 6. Effect of liquid conditioning on light emission and conduction current. Electrode gap 89μ, oil distilled at 160 °C.

3.5.1. *Effect of conditioning of test liquid.*

Simultaneous conduction current and light output measurements were made on freshly distilled oil and on the same oil after three breakdowns. As can be seen from figure 6, there is no significant change in current in the two cases, but the light intensity over the same range of stress is lower after the three breakdowns. Since the electrodes in both cases were spark-conditioned before the test it must be assumed that a conditioning of the liquid took place during the three breakdowns which had no effect on the conduction current, but resulted in a reduction of light output. This was a general observation and whenever the test liquid was changed the first few low breakdowns were always preceded by a light output which decreased after subsequent breakdowns as the liquid conditioning proceeded.

3.5.2. *Effect of various oil fractions.*

Light and current measurements for the various fractions of the oil are given in figures 7 and 8. No breakdowns occurred in the test cell during these tests. The still temperatures were chosen to remove the colouring fraction in steps, and it was found that the light output and the current decreased as more of the colouring fraction was removed. At temperatures below 140 °c, no further significant reduction resulted.

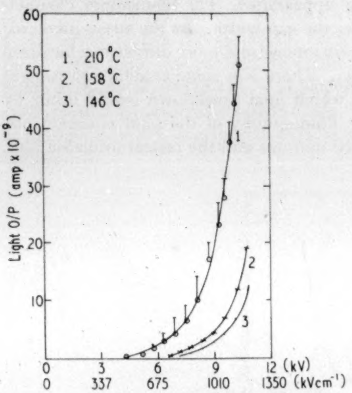

Figure 7. Light emission of different oil fractions. Electrode gap 89 μ. Distillation temperatures as shown.

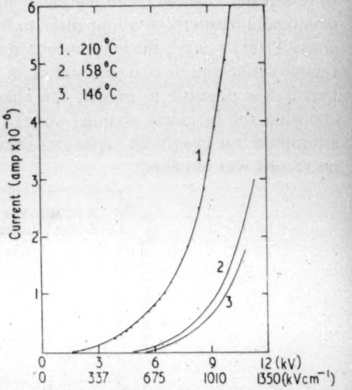

Figure 8. Conduction current of different oil fractions. Electrode gap 89 μ. Distillation temperatures as shown.

3.5.3. *Effect of dissolved air and nitrogen.*

It was found that the light and current curves did not differ significantly between oils distilled in nitrogen and air atmospheres in the pressure range 10^{-2} and 1 mm Hg. This result was surprising, bearing in mind the pronounced quenching effect (Cohen and Weinreb 1956) of oxygen in liquid organic scintillating liquids, and the marked rise in electric strength obtained with air over this range.

3.5.4. *Pressure dependence.*

The pressure dependence of light emission and conduction current was determined using an oil sample distilled in air at a pressure of 1 mm Hg. A stress of 1040 kv cm^{-1} was applied to a 89 micron gap. Fifty alternate readings at +760 mm Hg pressure and −350 mm Hg tension were taken. The averages of the readings are given in table 4.

Table 4

Effect of Pressure on Light Output and Conduction Current

Pressure (mm Hg)	+760	−350
Light output ($\text{A} \times 10^{-9}$)	5·1	5·1
Conduction current ($\text{A} \times 10^{-7}$)	4·41	4·46

With current a slight increase (1%) was often recorded when tension was applied. This effect is not significant as the conduction current fluctuation during the test was several per cent.

3.5.5. *Confirmatory experiments with hexane and benzene.*

The fluorescence of transformer oil is due to unsaturated polycyclic aromatic compounds dissolved in the oil. If these materials cause light emission under the action of high electric fields, it should be possible to synthesize a dielectric which would also emit light. The simple organic liquids, *n*-hexane and benzene were investigated, using spark-conditioned electrodes.

With purified *n*-hexane no visible light was observed at stresses up to 1100 kv cm^{-1}. The hexane was then doped with 1 g l^{-1} of scintillation grade anthracene. Light emission characteristic of anthracene in solution was observed. The electric strength was 610 kv cm^{-1} on the first application of voltage, and increased with succeeding conditioning breakdowns, until an average strength of 955 kv cm^{-1} was obtained. The decrease of light intensity with increase in electric strength is shown in figure 9, but the effect was more pronounced than with transformer oil (figure 8). Samples of hexane were also doped with scintillation grade *p*-terphenyl and again light, characteristic of the fluorescent solute, was emitted when an electric stress was applied.

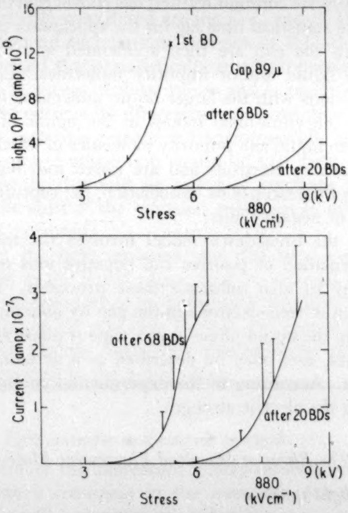

Figure 9. Conduction current and light output of hexane containing 1 g l^{-1} anthracene, after different numbers of breakdowns. Electrode gap 89 μ.

Commercially pure benzene (extra-pure for molecular weight determination) was filtered and tested without the addition of a fluorescent impurity. Very intense blue light was observed at relatively low electric fields, which was accompanied by a large conduction current. A similar trend of increasing electric strength and decreasing light emission was observed with conditioning breakdown.

Microscopic examination of these samples showed that the filamentary channels were similar to those found in transformer oil, apart from the greatly increased intensity observed in benzene.

§ 4. DISCUSSION OF RESULTS

4.1. *A General Model for Events Leading to Beakdown*

With liquids of high physical purity, the breakdown process is, at least in part, electronic in nature. The events leading to breakdown may be conveniently considered as three separate processes: (i) the production of free electrons in the gap, (ii) the subsequent acceleration of the electrons by the electric field, and their retardation by collisions with liquid or impurity molecules, (iii) the multiplication of charge carriers leading to instability and to final breakdown.

Most workers consider that free electrons are emitted from the cathode and considerable evidence, both experimental and theoretical, indicates that this is so for electric fields of the order 10^5 and 10^6 v cm^{-1}. House (1957) proposed that the dominant process for direct voltages is a Schottky field-aided thermionic emission. For pulse voltages, the availability of free electrons dominates the subsequent breakdown process, although Bickley (1958, private communication) has shown that brushing electrodes with emery greatly reduces the statistical time lag for the appearance of an initiating electron.

The free electrons in the gap are then accelerated and are involved in various collision processes with liquid and/or impurity molecules. Loss of energy may be due to: (*a*) inelastic collisions with the larger liquid molecules, (*b*) electrons of suitable energy interacting with the vibrational modes in the bonds of the liquid molecules, (*c*) excitation collision with liquid and impurity molecules in which the excited molecules absorb the energy of the free electrons and are raised into higher electronic excited states which may lead to fluorescence or dissociation, (*d*) capture of electrons by molecules and the formation of negative ions.

The last process in the breakdown model involves the multiplication of charge carriers in the gap. Formation of positive and negative ions may result from earlier processes and these may in turn influence these processes. However, the decisive event is the multiplication of free electrons in the gap by ionizing collisions. Ionization of molecules is possible in the liquid phase or in a vapour phase such as a micro-bubble.

Of the three processes, each may be described as a necessary but not a sufficient condition for breakdown. According to the experimental conditions, any one may be dominant in determining the electric strength.

4.2. *The Effect of Dissolved Fluorescent Materials*

4.2.1. *Characteristics of light emission.*

The results in § 3.5 show that the light intensity increased in an exponential manner with increasing field, that the intensity of emitted light was associated with the electric strength, and that the spectrum of the light emitted was characteristic of the fluorescent solute. It is significant that these experimental characteristics are similar in nature to the electroluminescence characteristics reported for solid inorganic phosphors. With hexane, known concentrations of anthracene and *p*-terphenyl were introduced; in transformer oil, the constituents which produce the fluorescence are largely unknown. Jezl, Stuard and Ross (1958) have shown that tricyclic and polycyclic aromatics are present in the oil and may constitute up to 1% of the 15% by mass of aromatics present. It is probable that these molecules contribute most to the blue fluorescence and to the yellow colour of the liquid.

The various possible mechanisms for electroluminescence in solid fluorescent materials have been discussed in § 1. A further possibility must be considered here, chemiluminescence due to photochemical action between the dissolved oxygen and fluorescent materials. Chemiluminescence may contribute to the light emission in the doped hexane, but this possibility must be excluded for tests in transformer oil which was highly degassed in the purification system. As in the study of electroluminescence in solid fluorescent materials, it is likely that the fluorescence observed in organic liquids is due to the excitation of the fluorescent materials by electrons accelerated by the high electric field. Since the fluorescent components in transformer oil are largely unknown, no quantitative estimate of the electron energies required for excitation may be made. However, the absorption spectra of anthracene and *p*-terphenyl in dilute solutions are well known. The lower limit of absorption of anthracene is 3800 Å, and this corresponds to a minimum quantum energy of 3·25 ev required for excitation. It is suggested that the emission of light characteristic of the fluorescent material is experimental evidence that free electrons with energies in excess of 3 ev are present in the gap at electric fields below breakdown.

Lewis (1956) and Adamczewski (1957) have demonstrated that the majority of free electrons in the gap are retarded by vibrational collisions with the atomic bonds in the molecule. The bonds usually considered are the C–C and C–H bond, and their vibrational frequencies correspond to quantum energies of 0·11–0·14 ev and 0·36–0·37 ev respectively. It is suggested that a statistically small proportion of the electron population achieves energies in excess of these values and is accelerated by the electric field until excitation collisions occur with fluorescent components of the liquid. Because of the range of fluorescent materials present in transformer oil, it would be expected that materials with lower limits of absorption would be first excited, and that as the field increased the absorption limit would be raised as electrons gained higher energies. This is confirmed by the shift of the emission spectrum in oil to shorter wavelengths as the electric field was increased.

The possibility that the light emission was due to micro-discharges in the oil, rather than to excitation in the liquid phase, may be rejected because the intensity of light emission showed no dependence on hydrostatic pressure, from positive pressures of 760 mm Hg to tensions of 350 mm Hg. Further, fracture of the liquid under tension did not occur with high electric fields, and this indicates that the excitation of the fluorescent materials occurred in the liquid phase.

4.2.2. *Relation between light emission and electric strength.*

Removal, or reduction, of the fluorescent solutes resulted in a marked rise in electric strength, associated with a reduction in the intensity of light emission. Fractional distillation of transformer oil, separating the colouring components, raised the strength from 1100 to 1300 kv cm^{-1} and reduced the light output by one order. Similarly, the electric strength of hexane was lowered from 1050 kv cm^{-1} to 700 kv cm^{-1} by the addition of fluorescent materials, which resulted in light emission.

This relationship between light output and electric strength was also observed during the conditioning of the test liquid. It was found that the strength was low and the light output was high if the oil in the gap was changed. Both were returned to normal by several conditioning sparks. The higher strength after conditioning appears to result from a lower concentration of fluorescent materials in the high stress region. These are probably ionized in the breakdown spark and are swept away to the electrodes by the next application of voltage. It is significant that liquid conditioning was lost if the oil was allowed to stand undisturbed for long periods, presumably due to the diffusion of the fluorescent materials back into the gap, thus restoring the equilibrium of the solution.

Measurements made with short duration impulses again showed the effect of fluorescent materials on the electric strength of transformer oil. This indicates that these materials affect electronic processes leading to electric breakdown, and that the processes involved are not time-dependent in the range of one microsecond to steady state. Three possibilities are suggested to explain why the presence of these materials and light emission causes a reduction in electric strength: (i) their dissociation gives rise to positive ions which increase electron emission from the cathode as proposed by Green (1956), (ii) photoelectric emission from the cathode due to energetic photons released by the fluorescent process, (iii) the lifetime of an excited fluorescent molecule is about 10^{-8} sec in these liquids, and a definite probability exists for interaction between such a molecule and a low energy electron, with the transfer of the excitation energy to the electron. The chance of such an interaction occurring is greatly increased by the fact that energy transfer may take place between excited fluorescent molecules with a transit time of 10^{-12} sec (Kallmann and Furst 1951, 1954, 1956). Thus, it is possible for electrons to achieve high energies by a mechanism unaffected by vibrational barriers due to liquid molecules. This may be similar to the mechanism outlined by Fröhlich (1939) for ionic crystals containing impurity or imperfection energy levels near the conduction band. It has been shown that if the imperfections are sufficiently numerous to interact with each other the strength will be lowered (von Hippel and Lee 1941).

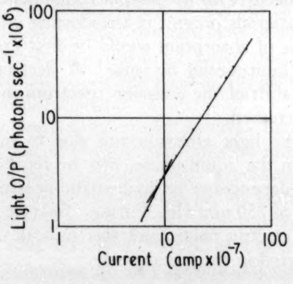

Figure 10. Relation between light output and conduction current.

4.2.3. *Light emission, conduction current and stress relationships.*

The total light output from the test cell has been plotted against conduction current flowing for transformer oil in figure 10. It shows a linear increase of light output with current, within the limits of observed fluctuations (values were taken from the best curve drawn through the experimental results). A similar relationship was observed for all simultaneous light and current measurements in transformer oil, doped hexane and benzene. It may be shown that the proportion of the total energy absorbed in the gap from the electric field ($V \times I$) which is released by light emission is $1/(3 \cdot 3 \times 10^9)$. Replotting the light–stress curve for transformer oil in the manner log L against $E^{1/2}$ gave a straight line. It is significant that the Schottky plots of conduction current and stress reported by House (1957) in *n*-hexane are also linear, and the light output due to electroluminescence in solid inorganic phosphors also follows a similar relation with electric stress.

The experimental results show that fluorescent materials greatly increase the conduction current flowing through the gap at high electric fields. It is well known that the higher molecular weight components of transformer oil (including the colouring fractions) dissociate under the action of daylight, which is sufficiently actinic to produce a noticeable change in the acidity of the oil over a long period. Under the influence of high electric fields, these molecules are dissociated into ions as a result of excitation by energetic electrons moving in the gap, resulting in an increase of charge carriers and so an increase in current.

4.3. *Pressure Dependence*

Since the light emission and conduction current were unaffected by changes in pressure it is concluded that the first two breakdown processes, outlined above, are not pressure dependent. However, a significant reduction in electric strength measured with direct voltages was observed with the liquid in a state of super-saturation due to the application of tension up to 350 mm Hg. This suggests that the last process, the multiplication of free electrons in the gap by ionization, is affected by hydrostatic pressure. A reduction of electric strength between 12 and 19% due to a change of pressure in this range cannot be explained by a change in density, since the change in volume due to a pressure change of this order is less than $1/10^6$. This suggests that ionization and multiplication of free electrons occurs in a gaseous phase such as a bubble and that it is affected by hydrostatic forces prevailing on the bubble. The fact that no pressure dependence was observed with impulses of short duration indicates that this mechanism is time dependent. This is in agreement with the theory proposed by Seitz (1958) for the growth of bubbles in a supersaturated solution subjected to ionizing radiations.

4.4. *Influence of Dissolved Gases*

The experimental results show a significant rise in the electric strength of oil with air in solution at an equilibrium pressure of 1 mm Hg. This is in agreement with the results of Sletten (1959) and Khambanonda (1958). This increase is present for direct voltages and impulses of short duration, and it would appear that the air in solution affects electronic processes in the gap. Since nitrogen plays no part, it must be concluded that the effect is due to the presence of oxygen. It is well known (von Hippel and Lee 1941) that oxygen, an electronegative gas, can remove electrons from a discharge by resonance capture of electrons of suitable energy. The mechanism by which oxygen may contribute to the electric strength has been discussed qualitatively elsewhere (Darveniza 1959). Whatever the nature of the liquid state (and there is no generally accepted model), it would be reasonable to expect that dissolved oxygen molecules would be positioned at preferred sites such as holes or vacancies, and that electron acceleration would also be most favoured at these sites. These holes or vacancies are essential to the fluidity of the liquid, making up its free volume. It is suggested that oxygen influences the free electron density in the gap, and so the electric strength, to a degree out of all proportion to its concentration, because the dissolved gas molecules are generally to be found in the very sites in the liquid most suitable for electron acceleration.

§ 5. CONCLUSIONS

It may be concluded from experimental work that dissolved fluorescent materials, such as anthracene, which absorb energy by resonance of electron orbitals into higher states, may be excited in the liquid state by the application of high d.c. electric fields to organic insulating liquids. Experimental evidence indicates that the presence of these materials and the resultant light emission influences the electric strength of these liquids, both for direct and for impulse voltages. These results suggest that electronic processes involved in the breakdown mechanism are influenced by this excitation. Removal of the fluorescent materials was found to decrease the light output, and to increase the strength of the liquid.

The reduction of electric strength, by placing highly degassed liquids in a state of supersaturation by the application of tension, indicates that the breakdown processes must involve, at least in part, a vapour phase which is subject to hydrostatic forces.

ACKNOWLEDGMENTS

Acknowledgments are made to Professor M. W. Humphrey Davies for the provision of facilities, and to colleagues of the dielectrics team at Queen Mary College for encouragement and discussion. The authors wish to thank Professor G. F. J. Garlick of Hull University for the determination of fluorescence spectra.

Finally, one of the authors (M.D.) acknowledges the award in 1956 of a Travelling Research Fellowship by the University of Queensland, Australia.

Temperature Effects in Domain Patterns from Single Crystals of Haematite (α-Fe_2O_3)

By G. KAYE†

Department of Physics, Imperial College, London

Communicatd by M. Blackman; *MS. received* 17*th March* 1961

Abstract. Electron shadow patterns have been used to study the configuration of domains present in single crystals of haematite (α-Fe_2O_3) in the temperature range 0 to 700 °c. The observations were made using a furnace designed to fit into the specimen chamber of the electron diffraction camera.

It has been found that once a crystal has been heated to above its Curie temperature the configuration of domains present in the specimen at room temperature is partially stable. Repeated heat treatment of the crystal to above its Curie point leads to a partial 'memory effect' similar to that described by Blackman, Haigh and Lisgarten in 1957 for the low temperature transition in haematite.

A study of the variation with temperature of the sizes of features in the shadow patterns provides a method of determining the Curie temperature of haematite crystals with an accuracy to 2 to 3 degrees. In this way Curie temperatures between 643 and 688 °c have been observed for crystals from different origins.

Finally an attempt has been made to correlate the Curie temperature of various crystals with their lattice parameters as determined by x-ray powder photographs.

§ 1. INTRODUCTORY REMARKS

THE EXISTENCE of ferromagnetic domains in natural single crystals of haematite was first demonstrated by Blackman, Haigh and Lisgarten (1957) by means of electron shadow patterns. Their results, obtained at room temperature, were consistent with average domain sizes of about $\frac{1}{10}$ mm or more. These observations were later verified by Williams, Sherwood and Rameika (1958). The latter used artificially produced crystals and, employing the magnetic Kerr effect, found domains of a similar size. Part of the present work is concerned with studying the appearance of the electron shadow patterns of the surfaces of natural single crystals of haematite from various localities as the crystals are heated to temperatures above their Curie points and then cooled. In this way information has been gained about the behaviour of ferromagnetic domains in the temperature range 0 to 700 °c.

In addition, it has been known for some time that, under suitable conditions, titanium may be substituted for some of the iron in the haematite crystal lattice. The resulting solid solution series that can be prepared has as its end members haematite and ilmenite ($FeTiO_3$), so that a typical member of this series can be written

$$x\mathrm{FeTiO_3}(1-x)\mathrm{Fe_2O_3}$$

(where x is the molecular proportion of ilmenite in haematite). The properties of the haematite–ilmenite series have been the subject of many investigations; some of the more important of these investigations being by Pouillard (1950), Basta (1953), Ishikawa and Akimoto (1957), Uyeda (1957) and Cox (1958). In all of these cases chemically prepared powders were used. Uyeda's results, which are similar to those of other workers, showed that the Curie temperature and lattice parameters of the prepared powders varied almost linearly with composition (i.e. x value).

---

† Now at the Morgan Crucible Co., Wandsworth, London.

The present investigations are also concerned with examining the effect of titanium, present as an impurity in natural crystals of haematite, on the Curie temperature and lattice parameters of the crystals.

§ 2. APPARATUS

In order that shadow patterns could be observed at temperatures up to, say, 700 °c (i.e. above the Curie point of pure haematite) it was necessary to construct a specimen heating unit which could be situated inside the specimen chamber of an electron diffraction camera. This heating unit is shown in detail in figure 1. It is constructed in three parts, the specimen holder, the heating unit and the supports. All parts heated to more than 400 °c are made of stainless steel or 'Pyrophylite'. The latter has good electrical and heat insulating properties. The specimen is seated on a small hollow stainless steel cap B. The cap is clamped to the end of a solid Pyrophylite rod C by means of a chuck. The Pyrophylite rod is itself clamped by another chuck to the end of a hollow brass rod A. The brass rod passes through a brass plate, a vacuum seal being formed between the rod and the plate by a Neoprene O-ring. The plate is connected to a similar plate by means of the flexible metal bellows D. The latter plate is in contact with another O-ring and is bolted on to the sides of the specimen chamber F. When this plate is in position, the specimen is situated at the centre of the specimen chamber. Loss of heat by conduction from the heated steel cap to the walls of the diffraction camera is minimized by the insertion of the Pyrophylite section in the rod supporting the specimen.

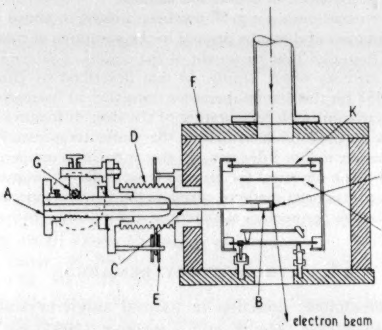

Figure 1. Specimen heating unit (some detail omitted for the sake of clarity).

It is possible to vary the glancing angle of incidence of the electron beam with respect to the specimen, using the tilting mechanism E, by about 5° on either side of the position of zero glancing angle. It is also possible to rotate the specimen and hence vary the azimuthal angle through 360°. The specimen can be moved in and out of the beam by means of the mechanism G. The heating unit consists of two coaxial cylinders, the inner one H made of silica, the outer one K (the radiation shield) made of stainless steel. Nichrome wire is wound to and fro along the length of the outer surface of the inner cylinder and along the length of the inner surface of the radiation shield. The heating unit is mounted inside the specimen chamber, the supports being constructed principally of Pyrophylite. The specimen L can be heated to temperatures up to 800 °c. The temperature of the specimen is measured by a chromel–alumel thermocouple (in the form of 'Thermocoax' wire) incorporated in the specimen holder with the hot junction placed immediately behind the specimen. The results of various preliminary experiments showed that the thermocouple recorded the actual temperature of the surface of the specimen.

§ 3. EXPERIMENTAL DETAILS

The experimental arrangement for producing electron shadow patterns of the crystals is similar to that used by Blackman, Haigh and Lisgarten (1959). The electron beam is accelerated in most cases to 40 kv and focused just above the specimen to be examined. In addition, the focus is caused to oscillate at mains frequency by a pair of coils carrying alternating current. The divergent band of electrons so formed is intercepted by the edge of the crystal producing an electron shadow of the surface of the crystal which can be observed on a fluorescent screen or recorded on photographic film. These shadow patterns have been studied as the specimens were heated to temperatures up to 800 °c and then cooled, all experiments being conducted in the earth's magnetic field. In most cases the crystals used had well-formed smooth (00.1) faces. In the case of crystals from Elba and Etna, the faces which were used were the (10.1), (22.3) and (01.4) planes (using hexagonal crystal axes). The specimens were covered with a layer of colloidal graphite, to avoid the possibility of electrostatic charging of inclusions (such as quartz) in the crystals, by the electron beam.

§ 4. RESULTS

4.1. *The Effect of Temperature on the Domain Configurations observed in various Haematite Crystals*

Figure 2 shows a series of shadow patterns of the surface of a typical previously unheated single crystal of haematite from Elba, as the crystal was heated to 700 °c and then cooled in the earth's magnetic field. In these experiments it was found useful to study the variation with temperature of the sizes (denoted by W) of prominent features in the observed shadow patterns. For example figure 3 shows the variation of W with temperature for several prominent features observable in figure 2 as the crystal is heated and then cooled. The experimental results shown in figures 2 and 3 indicate:

(i) That as the crystal is heated the positions of the prominent features in the shadow patterns remain unchanged although their sizes vary; in some cases, however, a few additional features appear as the crystal is heated.

(ii) That the sizes of these features are almost constant up to about 600 °c; from 600 to 680 °c there is a rapid decrease in their sizes, the shadow edge becoming straight at about 688 °c (that is, the shadow is of a purely geometrical nature). This is associated with the disappearance of the ferromagnetism and hence of the magnetic leakage field as the Curie temperature of the crystal is reached.

(iii) That as far as can be estimated from measurements based on the sizes of prominent features, the sizes of all the features in the shadow pattern appear to become zero at the same temperature (see figure 3). These features also appear to vary with temperature in approximately the same way.

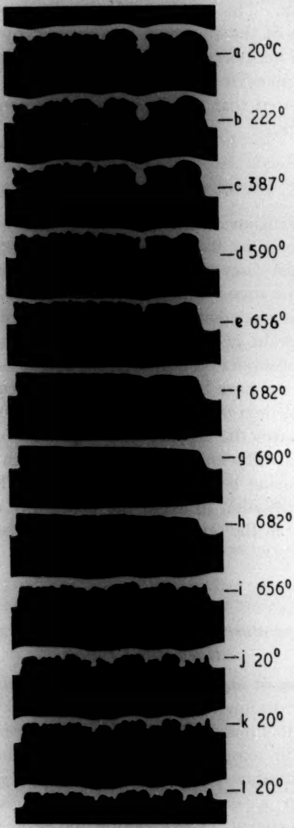

Figure 2. The effect of temperature on the shadow pattern of the surface of a single crystal of haematite, origin Elba. The length of the crystal in the direction perpendicular to the electron beam is 7 mm.

(iv) *That, as far as the initial heating of the specimen is concerned*, the detail in the shadow pattern observable at room temperature after the crystal has been cooled from above its Curie temperature does not show any similarity to that present in the pattern before the crystal is heated (compare figures 2(*a*) and (*j*)). The sizes of the feature in these two patterns are, however, of the same order of magnitude. This can be seen from figure 3 which also shows, for a few features, the variations of feature size with temperature which appear on cooling the crystal from above its Curie point.

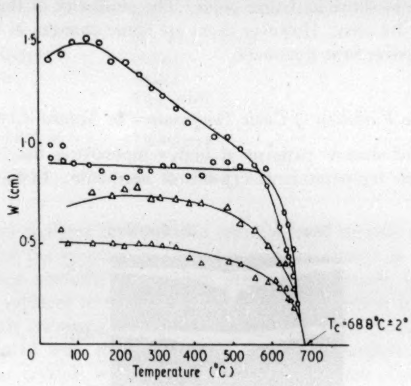

Figure 3. Variation of feature size *W* with temperature for two prominent features. The lower two curves were obtained during the cooling of the crystal from above the Curie point, the upper curves during heating through the Curie point.

Further experiments in which single crystals of haematite from various localities have been used have shown the following:

(i) The sizes of the features observable in the shadow patterns of different haematite crystals seem to be of the same order of magnitude. Further, these patterns do not appear to be dependent on the type of surface examined (i.e. (00.1), (10.4) etc.).

(ii) When crystals, instead of being heated to their Curie temperature, are heated to, say, 10 °c below this temperature and allowed to cool it is found that the shadow patterns observable before and after heating are identical. The results from an experiment of this type are shown in figure 4.

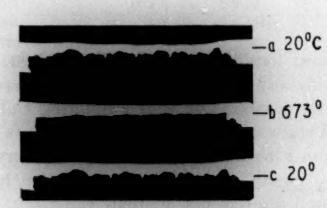

Figure 4. Shadow patterns of a haematite crystal (origin Brazil): (*a*) at room temperature, (*b*) at 673 °c (10 deg c below the Curie temperature of 683 °c), (*c*) at room temperature after the crystal has cooled. The length of the crystal in the direction perpendicular to the electron beam is 7 mm.

(iii) *After the initial heating of the specimen* (to above its Curie point) the shadow patterns which can be seen at room temperature before and after further repeated heating of the specimen showed marked similarities to one another as regards the details. This is also illustrated in figure 2. The crystal of haematite (origin Elba) was heated four times to above its Curie point. The similarity of the details in figures 2(*j*) to (*l*) can clearly be seen. However there are some changes in the detail of these patterns during successive heat treatment.

4.2. *The Variation of Curie Temperature in Natural Crystals*

The observation of shadow patterns at high temperatures has been used in § 4.1 to determine the Curie temperature of crystals of haematite. In figure 5 two crystals of haematite from different localities (namely Elba and St. Gotthard, Switzerland) were mounted side by side and their shadow patterns observed as the crystals were heated towards their Curie points. The widely differing Curie points of the crystals is clearly seen; a detailed study of the shadow patterns shows these Curie points to be 688 °c for the crystal from Elba and 643° c for the other crystal from St. Gotthard. In this way it was found possible to differentiate between haematite crystals having Curie temperatures within 3 deg c of one another.

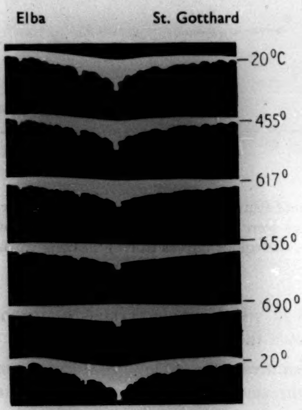

Figure 5. Comparison of the shadow patterns of two natural single crystals of haematite having widely differing Curie points—one (origin Elba) having a Curie point of 688 °c, the other (origin St. Gotthard) having a Curie point of 643 °c. The length of each of the crystals in the direction perpendicular to the electron beam is 4 mm.

Experiments of the type illustrated in figure 5 have been performed using crystals from many different localities. Table 1 indicates the range of Curie temperatures obtained from the various crystals which have been examined. In no case has a Curie temperature of less than 643 °c been observed.

Table 1

Curie Temperatures of Natural Haematite Crystals from Various Sources

Specimen No.	Origin	Curie Temp. (°c)
E–H(H)1	Elba	688 ± 2
Et . –H	Mt. Etna, Sicily	688 ± 3
S–H(G–B)D1	Brazil	685 ± 2
S–H(B)20	Brazil	684 ± 2
S–H(E)	Unknown	673 ± 3
S–H(A)1	Unknown	660 ± 3

Spectrochemical analyses of haematite crystals from various localities have shown (see Kaye 1960) that the variation in Curie temperature shown in table 1 is due, principally, to the various amounts of titanium present as impurity in the crystals. This titanium, when it replaces iron in the haematite crystal lattice, lowers the Curie temperature and slightly increases the size of the unit cell. The change in the lattice parameters was associated with the variation in the Curie temperature in the following way. A number of crystals were first examined by electron shadow pattern methods outlined in § 4.1 to determine their Curie temperatures. A quantity of powder was obtained from each crystal by grinding the surface previously examined. A portion of the powder was analysed by spectrochemical methods, the remainder being used for a determination of the lattice parameters by standard x-ray powder methods.

The information gained in this way for five natural crystals of haematite is shown in table 2, and will be discussed in § 5.

Table 2

Variation of the Lattice Parameters of Haematite Crystals (from various localities) with the Volume of the Hexagonal Unit Cell

Specimen No.	Origin	Major Impurities	Lattice Parameters			Curie Temp. (°c)
			A_H(Å)	C_H(Å)	V_H(Å^3)	
E–H(H)1	Elba	None	5·0348	13·751	301·87	688
S–H(E)	Unknown	0·3% Ti	5·0357	13·758	302·14	673
S–H(G–B)C1	Unknown	1% Ti	5·0356	13·756	302·08	661
S–H(S–G)A1	St. Gotthard, Switz.	2·5% Ti	5·0362	13·758	302·20	656
S–H(S–G)B1	St. Gotthard, Switz.	3% Ti	5·0362	13·761	302·26	643

V_H is the volume of the hexagonal unit cell. The errors in A_H and C_H are ±0·0005 and 0·002 respectively; the error in V_H is ±0·13.

§ 5. DISCUSSION

The interpretation of electron shadow patterns of haematite crystals in terms of the existence of an arrangement of ferromagnetic domains in the crystals is now fairly well established. On this basis one can infer the following from the results described in § 4.1.

The fact that the features in the shadow patterns change very little as the temperature of the crystal is increased to the Curie temperature, implies that the boundaries between the ferromagnetic domains (i.e. the Bloch walls) are, in the main, stable at temperatures below the Curie temperature. The small changes that occur are consistent with the formation of additional domain walls (i.e. the sub-division of large domains).

The variation with temperature of the sizes of the features (figure 3) makes the observation of shadow patterns at high temperatures a reasonably accurate method for the determination of the Curie temperature of haematite crystals. It is possible to measure the Curie point by this method with an accuracy to about 3 deg c.

It should be noted that this Curie point is defined by the vanishing of the magnetic field. This will be higher than the value obtained from the point of inflection of the curve of magnetization against temperature. The latter method gives 675 °c.

The initial heating of a specimen to above its Curie temperature leads, on cooling to room temperature, to an arrangement of domains which is completely different from the original configuration. The new domain boundaries are seen to be at least partially 'pinned down', since subsequent heating and cooling of the specimen produces domain arrangements which show similarities to the arrangement observed on cooling after the first heat treatment (see figures 2 (*j*) to (*l*)). There is, therefore, a partial 'memory' effect similar to the memory effect observed by Blackman, Haigh and Lisgarten (1959) for the low temperature transition in haematite. However, in the present case the 'memory' is not nearly so good as for the low temperature transition and appears to vary from specimen to specimen. The experiments in which crystals have been heated to just below the Curie temperature and then cooled show that the magnetic leakage field varies reversibly with temperature provided the Curie temperature is not exceeded.

The results of the present work described in § 4.2 have shown that the lowest Curie temperature observed in natural crystals from many different localities, is 643 °c (as compared with 688 °c for crystals from Elba). Deductions from the spectrochemical analyses of haematite crystals which have a Curie temperature in this region (see Kaye 1960) are consistent with $1\cdot5\%$ titanium at the most being incorporated into the crystal lattice ($x \simeq 0\cdot05$). It seems reasonable, therefore, to assume that this amount of titanium approximates closely to the maximum that can be so accommodated in the haematite lattice at room temperature. Any titanium in excess of the above amount at the time of the formation possibly exsolved out of the lattice as the crystal cooled slowly (assuming the haematite was formed at high temperature). The point is important in connection with the shape of the solvus curve for the haematite–ilmenite series. The present results suggest that the solvus curve should pass through the composition $x \simeq 0\cdot05$ at room temperature. This implies that the solvus relationship determined by Uyeda (1957) should be modified slightly.

The variation of the volume of the hexagonal unit cell with Curie temperature, shown in table 2, is linear to within experimental error. Other investigations of the haematite–ilmenite series, using chemically prepared powders, have not dealt in detail with the region considered in this work, $0 < x < 0\cdot1$, but generally with the entire series. It is not, therefore, possible to compare the results of the present work with those of other investigations.

ACKNOWLEDGMENTS

The author wishes to express his sincere thanks to Professor M. Blackman for suggesting the problem and to Dr. N. D. Lisgarten for his interest and useful discussions. The author is indebted to the Staff of the Woolwich Outstation Chemistry Department, Atomic Energy Research Establishment, Harwell, for the spectrographic analyses of the samples of haematite, and to Dr. R. G. Davis of the Mineralogy Department, Natural History Museum, for providing facilities for x-ray photographs of some specimens. He would also like to thank the Department of Scientific and Industrial Research for a maintenance grant.

Magnetothermal Measurements on Gadolinium

By L. F. BATES and A. J. PACEY

The University, Nottingham

MS. received 25th July 1961

Abstract. The small heat changes accompanying the magnetization of 99·9% pure gadolinium were measured on a rod specimen. The results are analysed, and the principal magnetization processes are identified. Domain wall movement which occurs in low fields is discussed in the light of a theory by Goodenough, and the coercivity which the theory predicts is found to agree fairly well with experiment. Comparison is made with earlier results for cobalt.

§ 1. INTRODUCTION

Reasonably pure metallic gadolinium was first prepared by Trombe in 1935. A few months later, Urbain, Weiss and Trombe (1935) showed that the metal was ferromagnetic below about 16 °c. Now, the modern theory (Stoner and Rhodes 1949) of magnetothermal effects is based on the assumption that measurements are made at temperatures well below the Curie point. It is evident, therefore, that magnetothermal measurements on gadolinium must be made at lower temperatures than are usual in such work.

Apart from arrangements for cooling the specimen down to 100 °K, the present experiment followed standard practice (Bates and Sherry 1955). The specimen was in the form of a rod, 20 cm long and 0·31 cm in diameter, and was obtained from Johnson, Matthey and Co. Ltd. It contained less than 0·1% impurities, of which the principal were silicon, aluminium, manganese and iron. Ten thermocouples were tied to the specimen, and it was placed inside the magnetizing solenoid. The magnetic field was changed by successive increments ΔH and the corresponding thermal changes $\Delta Q'$, total and reversible, were measured. By convention, the thermal energy of the system was taken to be zero in the maximum (negative) field used, and a plot of Q' against H for half a cycle was obtained by summing the individual increments of field and thermal energy (figures 1 and 2).

The results were calibrated by making use of the expression

$$(\partial Q'/\partial H)_S = -T(\partial I/\partial T)_H.$$

Values of $-T(\partial I/\partial T)_H$ at $H = 600$ Oe were obtained from the (I, H) measurements over the whole range of temperatures. These were plotted against temperature (figure 3) and the measured deflections which gave $(\partial Q'/\partial H)_S$ were fitted to this graph. It will be seen from figure 3 that $(\partial Q'/\partial H)_S$ is very small at low temperatures, but increases to a high value near the Curie point; above the Curie point, it falls rapidly to a small value.

§ 2. EXPERIMENTAL ERRORS

Following the Stoner and Rhodes theory, the first stage in the analysis of the experimental results is to calculate values of b'', using the expression,

$$\left[\frac{(\partial Q'_{\mathrm{R}}/\partial H)_S - aI}{H(\partial I_{\mathrm{R}}/\partial H)_T}\right] - a$$

where $a = -(T/I_0)(dI_0/dT)$ and $\partial I_{\mathrm{R}}/\partial H$ is the reversible susceptibility.

Two sources of error in the values of b'' might have been important as a result of taking measurements at reduced temperatures. The first of these was the effect of the instability of the system at low temperatures, which meant that low sensitivities had to be used. To estimate this error, it was assumed that the (I, H) measurements were perfectly accurate, the error being entirely in $(\partial Q'/\partial H)_S$, and of magnitude of about 30 erg cm^{-3}Oe^{-1}. This represents a 30% error at 100 °K, but only 2% error at 223 °K, where $(\partial Q'/\partial H)$ was larger. It will be seen from the expression for b'' that the error in b'' depends on the error in the expression $(\partial Q'/\partial H) - aI$. At 100 °K, aI was much greater than $(\partial Q'/\partial H)$, so that the large error in the latter quantity did not have a proportionate effect on b''. The probable error in b'' was ±0·2 in all cases.

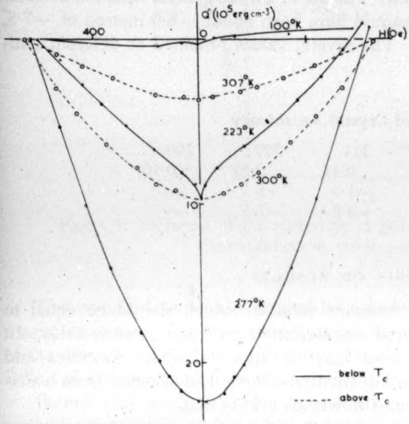

Figure 1. Thermal curves for gadolinium at stated temperatures, those above the Curie point indicated by dotted lines.

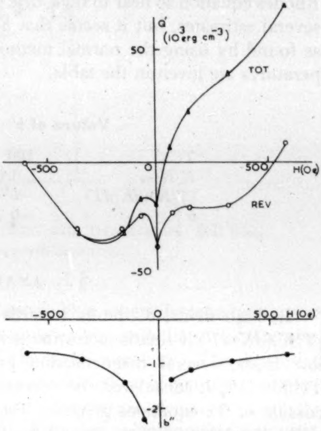

Figure 2. Q' and b'' curves for gadolinium at 100 °K.

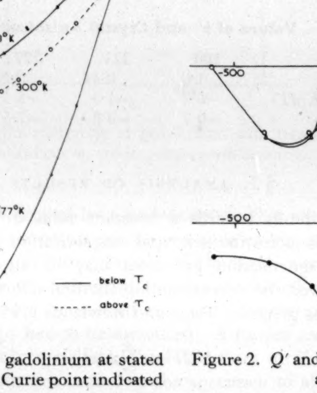

Figure 3. Graph of $-T(dI/dT)_H$ against temperature of the gadolinium specimen.

The second experimental error which may have been important occurs because the temperature at which the thermal measurements were made could not be exactly reproduced when the hysteresis cycle was observed. A Dewar flask which fitted inside the solenoid was arranged to hold liquid oxygen, solid carbon dioxide or ice and salt, as required. However, the specimen never quite reached the temperature of these materials because of the need to protect it from contact with them by means of a closed glass tube. But this precaution, necessary because of the active chemical nature of gadolinium, improved the thermal stability of the system. The effect was probably quite small at 100 °K and 277 °K, but it was estimated that the error was considerable when solid carbon dioxide was used.

Additional errors were to be expected at 277 °K as a result of using the Stoner and Rhodes equation so near to the Curie point. The use of a more general equation involves several estimates, but it seems that b'' should have been about $-8{\cdot}0$ instead of $-7{\cdot}5$, as found by using the normal method. The several values obtained at different temperatures are given in the table.

Values of b'' and Crystal Anisotropy

T(°K)	100	223	277	290
K/K_{100}	1·0	0·44	0·23	0·10
$(T/K)(dK/dT)$	−0·7	−1·3	−8·5	—
b''	−0·7	−0·8	−7·5	—

§ 3. ANALYSIS OF RESULTS

In high fields, b'' tends towards a constant value b_1 which should be equal to $(T/K)(dK/dT)$ if rotations are the principal magnetization processes in such fields. In low fields, several magnetization processes may be superimposed. Saunders and Tebble (1960) considered the corresponding thermal effects, and showed from a discussion of the equations given by Teale and Rowlands (1957) that

$$b''H = \sum_{n=1}^{N} b_n v_n$$

where v_n is the derivative of a free energy function with respect to magnetization, and b_n is a constant, analogous to b_1, for the nth magnetization process. It is of the form $(T/A_n)(dA_n/dT)$, so that, for example, rotations against strain anisotropy give b_n equal to $(T/\lambda_s)(d\lambda_s/dT)$.

The difficulty with this equation is that there is no way of calculating v_n. However, if only two magnetization processes are superimposed, it is possible to make certain assumptions about v_1 and v_2 which enable estimates of b_2 to be obtained, from both magnetothermal results and coercivity data. We have used the formula (cf. Bates and Pacey 1961†)

$$b_2 = \frac{T}{H_c}\frac{dH_c}{dT} + \frac{T}{I_0}\frac{dI_0}{dT},$$

where H_c is the coercivity. Estimates so obtained for gadolinium appeared to lie between $(T/\gamma)(d\gamma/dT)$ and $(2T/I_0)(dI_0/dT)$. This result suggested that the low field magnetization processes might be those described by Goodenough (1954), who gives an expression for the coercivity of the form

$$H_c \simeq \frac{a_1\gamma}{I_0} + a_2 I_0 \text{ with } \gamma = (AK)^{1/2},$$

where a_1 and a_2 are constants for a given material. In figure 4, the measured coercivity is compared with that predicted by Goodenough's theory. An absolute value for the value of K at 100 °K, K_{100}, could not be obtained, but it was estimated to be approximately 5×10^5 erg cm^{-3}. Using this value, the values of a_1 and a_2 which gave the best fit were, respectively, $1{\cdot}45 \times 10^4$ and 10^{-3}. The agreement is quite good, except that the theory does not give as big a trough at about 210 °K as the experimental points seem to indicate.

---

† *Proceedings of International Conference on Magnetism*, Kyoto, Japan.

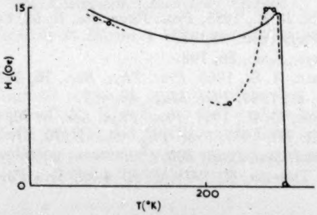

Figure 4. Variation of the coercivity of gadolinium with temperature: full line, theoretical curve; circles, experimental points.

The principal process envisaged by Goodenough is that when domains of reverse magnetization expand, they are controlled by free pole energy and the surface tension of the domain walls. This contributes roughly 13 Oe to the coercivity. The remaining 2 Oe can be accounted for on Goodenough's theory as the effect of grain boundaries.

Before this analysis could be carried out, the temperature dependence of the magnetocrystalline anisotropy had to be measured. A torque magnetometer was used, but as the specimen was polycrystalline, absolute values of K could not be obtained. However, there was sufficient orientation in the specimen to allow satisfactory values of $(T/K)(dK/dT)$ to be found. (As mentioned above, K lay between 10^5 and 10^6 erg cm^{-3} at 100 °K.) Values found for K are given in the table in terms of the value of K at 100 °K. The differences which were found between the measured values of b_1 and $(T/K)(dK/dT)$ were all within the limits of the error suggested in § 2.

Cobalt has a hexagonal crystal structure and a large crystal anisotropy, so that it should behave very much like gadolinium. Data obtained for polycrystalline cobalt by Bates and Sherry (1955) and Tebble and Teale (1957) were examined, and values of b_2 which lay between $(T/\gamma)(d\gamma/dT)$ and $(T/K)(dK/dT)$ were obtained. These specimens were partially annealed and had coercivities of 28 Oe and 34 Oe, respectively. However, Samuel (1928) gives coercivity data for a specimen which was more completely annealed, and from which an estimate of b_2 was obtained in good agreement with $(T/\gamma)(d\gamma/dT)$. The coercivity of this specimen, 11 Oe, was of the order of magnitude predicted by Goodenough's formula.

§ 4. CONCLUSIONS

The magnetothermal measurements described here provided data from which the magnetization processes in polycrystalline gadolinium have been identified. In high fields, the principal magnetization process is rotation against crystal anisotropy. Below about 100 Oe the growth of domains of reverse magnetization, as envisaged by Goodenough, becomes more important. The magnetization processes in annealed, polycrystalline cobalt are substantially the same.

ACKNOWLEDGMENTS

We are indebted to Mr. J. K. Ackers for making the measurements of magneto-crystalline anisotropy. A. J. P. thanks the Department of Scientific and Industrial Research for a maintenance grant.

Paramagnetic Resonance of Manganese

By T. P. P. HALL, W. HAYES and F. I. B. WILLIAMS

The Clarendon Laboratory, Oxford

Communicated by B. Bleaney; MS. received 27th July 1961

Abstract. The paramagnetic resonance spectrum of divalent manganese has been investigated in the crystals CdF_2, $KMgF_3$ and CdTe which have cubic symmetry, and in the crystals ZnO, $MgCl_2$, and $CdCl_2$ which have axial symmetry. The measured cubic field splitting parameter *a* is compared with values predicted from recent theoretical work.

§ 1. INTRODUCTION

THE THEORY of Watanabe (1957, 1960) stimulated interest in the splitting of the energy levels of S-state ions by cubic crystal fields. He concluded that the crystal field parameter *a* should be determined entirely by even powers of the crystal potential *V* and hence should be positive for both positive and negative values of *Dq* (for a definition of *Dq* see McClure 1959). It was subsequently pointed out by Powell, Gabriel and Johnston (1960, 1961, to be referred to as I) that terms odd in *V* may contribute significantly to *a*. However, all previous measurements on MnIII ($3d^5, {}^6S_{5/2}$) and the isoelectronic FeIV in cubic environments with both positive *Dq* (octahedral co-ordination) and negative *Dq* (fourfold and eightfold co-ordination) have yielded positive values of *a*. (For a discussion of some recent measurements see Geschwind 1961). In environments with axial symmetry, terms *D* and *F* appear in the spin Hamiltonian for *d* electrons corresponding to axial fields of the second degree (V_2^0) and of the fourth degree (V_4^0). Crystal field mechanisms to account for the second-degree axial term have been proposed by Pryce (1950) and by Watanabe (1957), the first linear in *V*, and the second quadratic in *V* (for a review of crystal field theory see Low 1960). Kondo (1960) has extended the theory to include overlap and covalent effects in an attempt to explain observed *D* values for MnIII in NaCl and LiCl (Watkins 1959).

Because of the general interest in the spectra of S-state ions we have measured the spectra of MnIII present as a substitutional impurity in the cubic crystals CdF_2, $KMgF_3$ and CdTe and in the axial crystals $CdCl_2$, $MgCl_2$ and ZnO. CdF_2 has the fluorite structure and cleaves in (111) planes; each cadmium ion is bonded to eight fluorine ions at a distance of 2·33 Å. Crystals of $KMgF_3$ have the cubic perovskite structure and each magnesium ion is surrounded by six fluorine ions at a distance of 1·994 Å. The CdF_2 and $KMgF_3$ crystals were grown by the Stockbarger (1949) method. CdTe has the zinc blende structure and cleaves in (110) planes; each cadmium ion is bonded to four tellurium ions at a distance of 2·78 Å. X-ray examination of our CdTe crystals disclosed a high degree of mosaic structure.

$CdCl_2$ and $MgCl_2$ have similar structures with $R\bar{3}m$ symmetry and the unit cell dimensions (Wyckoff 1948), with the isomorphous $MnCl_2$ included for comparison, are given in table 1.

In $CdCl_2$ the metal ions and the chlorine ions form planes normal to the trigonal axis and the planes of metal ions are separated by two planes of chlorine ions. The bonding between the adjacent planes of chlorine ions is rather weak (Pauling 1960) and the crystals cleave easily along these planes. For $CdCl_2$, the Cd–Cl distance is 2·74 Å, the distance between chlorine ions in the same plane is 3·85 Å and the distance between nearest chlorine ions in neighbouring planes is 3·68 Å, implying a compression along the trigonal axis of the octahedron of chlorine ions surrounding each cadmium ion. From data given by Murray (1955) we find that in $MnCl_2$, the Mn–Cl distance is 2·53 Å and the Cl–Cl distance is 3·69 Å and here also we have a compression along the trigonal axis of the chlorine octahedron surrounding the manganese ion. Equivalent data on the atomic spacings in $MgCl_2$ are not available. The crystals of $CdCl_2$ and $MgCl_2$ were grown by dropping an evacuated silica capsule containing the anhydrous chloride powder mixed with 0·1% $MnCl_2$ through a sharp temperature gradient; they are strongly hygroscopic.

Table 1

	a_0(Å)	α
$CdCl_2$	6·23	36° 02′
$MnCl_2$	6·20	34° 35′
$MgCl_2$	6·22	33° 36′

The ZnO sample, which was kindly supplied to us by Dr. P. B. Dorain, was obtained from a naturally occurring deposit. It contained traces of manganese and was pink in colour due to continuous absorption in the blue region of the spectrum which, presumably, arises from charge transfer transitions associated with impurities. The sample showed the zincite symmetry, C6mc, in which the Zn ion is surrounded by a tetrahedron of oxygen ions. The Zn–O distance is 1·95 Å measured along the trigonal axis of the crystal and is 1·98 Å measured along the other axes of the tetrahedron, implying a slight compression of the tetrahedron along the unique axis. The hexagonal unit cell parameters are $a_0 = 3{\cdot}2426$ Å and $c_0 = 5{\cdot}1948$ Å (Wyckoff). There are two inequivalent ions in the magnetic unit cell. The measurements were carried out at X and K-band in spectrometers of the type described by Llewellyn (1957).

§ 2. EXPERIMENTAL RESULTS

2.1. *Crystals with Cubic Symmetry*

The spin Hamiltonian for Mnɪɪɪ in an environment with cubic symmetry may be written

$$\mathscr{H} = g\beta\mathbf{H}\,.\,\mathbf{S} + A\mathbf{I}\,.\,\mathbf{S} + \tfrac{1}{6}a[S_\xi^4 + S_\eta^4 + S_\zeta^4 - \tfrac{1}{5}S(S+1)(3S^2+3S-1)] + \sum_n \mathbf{I}^n\,.\,A^n\,.\,\mathbf{S}. \quad (1)$$

Neglecting the final term which describes the hyperfine interaction between the magnetic electrons and the nuclei of ligand ions, the positions of the resonance lines are given by

$$\begin{aligned} M &= \pm\tfrac{5}{2} \leftrightarrow \pm\tfrac{3}{2} & g\beta H &= g\beta H_0 \mp 2pa - Am_I - \alpha(\tfrac{35}{4} - m_I^2 \pm 4m_I) \\ M &= \pm\tfrac{3}{2} \leftrightarrow \pm\tfrac{1}{2} & g\beta H &= g\beta H_0 \pm \tfrac{5}{2}pa - Am_I - \alpha(\tfrac{35}{4} - m_I^2 \pm 2m_I) \quad (2) \\ M &= +\tfrac{1}{2} \leftrightarrow -\tfrac{1}{2} & g\beta H &= g\beta H_0 - Am_I - \alpha(\tfrac{35}{4} - m_I^2) \end{aligned}$$

where $\alpha = A^2/2g\beta H_0$, $p = 1 - 5\phi$, $\phi = l^2m^2 + m^2n^2 + n^2l^2$, and l, m, n are the direction cosines of the magnetic field relative to the principal cubic axes ξ, η, ζ.

In the spectrum of MnIII in CdF_2 the hyperfine interaction with the neighbouring fluorine nuclei may be separated into an isotropic part A_s and an anisotropic part A_p (Tinkham 1956). A_s is greater than the cubic field parameter a and the spectrum consists of six manganese hyperfine lines, characterized by m_I, each with a resolved fluorine hyperfine structure, and each of these fluorine lines has a five line fine structure due to the cubic crystal field. A careful investigation of the spectrum was made at X and K-band in the [100], [110] and [111] directions but, because of the great complexity of the spectrum, it was not possible to obtain a precise value for a. It was possible to assign an upper limit of 4×10^{-4} cm^{-1} to $|a|$ but a value less than half of this is more likely. A re-investigation of the spectrum of MnIII in CaF_2 suggested that the value of $a = +0{\cdot}6 \times 10^{-4}$ cm^{-1} given by Baker, Bleaney and Hayes (1958) should be replaced by an upper limit for $|a|$ similar to that given here for CdF_2. The measured constants of the spin Hamiltonian are given in table 2. Our measurements on $KMgF_3$:Mn were carried out at X-band only. Our results, which are given in table 2, are in agreement with the measurements of Ogawa (1960) within the quoted experimental errors.

Our measurements on CdTe, given in table 2, were carried out simultaneously with those by Lambe and Kikuchi (1960) and agree with theirs. We find, as they did, that the spin–lattice relaxation time is unusually short. The line width is 50 G at 300° K; at 90° the fine structure is resolved and the line width is 17 G; at 20° the line width is 3 G and an isotropic interaction A_s with the nearest neighbour cadmium nuclei is observed in the $M_S = +\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition. The mosaic structure found in all the available samples may explain the failure to resolve the cadmium hyperfine structure in the $M_S = \pm\frac{5}{2} \leftrightarrow \pm\frac{3}{2}$ and the $M_S = \pm\frac{3}{2} \leftrightarrow \pm\frac{1}{2}$ transitions. The resolution of a hyperfine interaction with the second nearest neighbours is an indication of the strongly covalent nature of this crystal which has a band gap of 1·5 ev.

The line width and the complexity of the electron spin resonance spectrum often combine to defeat one in trying to find small a values. In an effort to find an alternative method we have examined the relative merits of the electron nuclear double resonance (Feher 1956) and of the usual electron spin resonance techniques. When the magnetic field is not along a principal cubic axis, cross terms appear in the third and fourth order between the crystal field and the hyperfine structure to give a surprisingly large shift in the energy levels which is linear in the nuclear magnetic quantum number, but with rather a complex dependence on the electronic magnetic quantum number which enables it to be separated from the nuclear quadrupole and Zeeman terms. Bleaney and Rubins (1961) have calculated the effects of some of these cross terms between the hyperfine interaction and a second-degree crystal field with axial symmetry. Calculations are given here for a crystal field of general symmetry. We shall assume a spin Hamiltonian of the form

$$\mathscr{H} = g\beta \mathbf{H}\,.\,\mathbf{S} + A\mathbf{I}\,.\,\mathbf{S} + V - g_n\beta_n \mathbf{H}\,.\,\mathbf{I}$$

where V represents the crystal field and may be written (Baker, Bleaney and Hayes 1958)

$$V = \sum_{n,m} B_n{}^m O_n{}^m.$$

(The cubic field operator $\frac{1}{6}a[S_\xi{}^4 + S_\eta{}^4 + S_\zeta{}^4 - \frac{1}{5}S(S+1)(3S^2+3S-1)]$ of equation (1) becomes $B_4(O_4{}^0 + 5O_4{}^4)$ in the notation of Baker, Bleaney and Hayes and the second-degree axial field operator $D[S_z{}^2 - \frac{1}{3}S(S+1)]$ of equation (5) (see § 3) becomes $B_2{}^0O_2{}^0$ in the same notation). This general expression for V is much simplified along the symmetry axes of the crystal, but we shall retain the general form since the effect of aligning the magnetic field in a general direction will be considered, and it is more convenient to keep the Zeeman interaction diagonal. A discussion of the transformation of these crystal field operators under a general co-ordinate rotation may be found in Baker and Williams (1961). The positions of the electron nuclear double resonance lines are affected by the cubic crystal field through the following mechanisms, where the unperturbed Hamiltonian is $\mathscr{H}_0 = g\beta H_z S_z$

$$\text{(i)}\ |\langle M_S m_I|A\mathbf{I}.\mathbf{S}|M_S\pm 1\, m_I\mp 1\rangle|^2 \{\langle M_S\pm 1\, m_I\mp 1|V|M_S\pm 1\, m_I\mp 1\rangle - \langle M_S\, m_I|V|M_S\, m_I\rangle\}$$

$$\text{(ii)}\ |\langle M_S m_I|V|M_S+m\, m_I\rangle|^2\{\langle M_S+m\, m_I|A\mathbf{I}\cdot\mathbf{S}|M_S+m\, m_I\rangle - \langle M_S m_I|A\mathbf{I}.\mathbf{S}|M_S m_I\rangle\}$$

$$\text{(iii)}\ |\langle M_S m_I|V|M_S\pm 1\, m_I\rangle|^2|\langle M_S\pm 1\, m_I|A\mathbf{I}.\mathbf{S}|M_S\, m_I\pm 1\rangle|^2.$$

Mechanism (i) reflects the way in which the crystal field helps the Zeeman interaction to decouple the electronic and nuclear spins. Mechanism (ii) shows how the crystal field destroys S_z quantization and hence alters the expectation value of S_z. The last mechanism has been considered by Bleaney and Rubins. These mechanisms contribute to the energy level characterized by (M_S, m_I) as follows:

$$\text{(i)}\ \left(\frac{A}{2g\beta H}\right)^2 \sum_{\pm}\{S(S+1)-M_S(M_S\pm 1)\}\{I(I+1)-m_I(m_I\mp 1)\} \times\{\langle M_S\pm 1\, m_I|\sum_n B_n^0 O_n^0|M_S\pm 1\, m_I\rangle - \langle M_S m_I|\sum_n B_n^0 O_n^0|M_S m_I\rangle\}$$

$$\text{(ii)}\ Am_I\sum_{m\neq 0}\frac{|\langle M_S m_I|\sum_n B_n^{|m|}O_n^{|m|}|M_S+m\, m_I\rangle|^2}{m(g\beta H)^2}$$

$$\text{(iii)}\ Am_I\frac{|\langle M_S m_I|\sum_n B_n^1 O_n^0|M_S m_I\rangle|^2}{8M_S(g\beta H)^2}.$$

It is interesting to note that where $M_S = \pm S$, (ii) and (iii) exactly cancel one another for $m = 1$ in (ii).

A useful figure for comparing the effectiveness of two types of measurement for the determination of a parameter is afforded by the ratio of that parameter's contribution to some observed quantity to the probable error in the measurement of this quantity. To make this more definite, one may define a figure of merit F for an experiment to obtain the value of a parameter x_p by measurement of a quantity s, which is in general a function of all the parameters $x_1, \ldots x_p, \ldots x_n$ of the problem. We assume that we know the value of all these, except x_p, and that our values are in error by $\delta x_1, \ldots \delta x_{p-1}, \delta x_{p+1}, \ldots \delta x_n$. Finally let δs be the probable error in measuring s. Then we define F such that

$$F = x_p\frac{\partial s}{\partial x_p}\Big/\left(\delta s - \sum_{i\neq p}\frac{\partial s}{\partial x_i}\delta x_i\right). \tag{3}$$

It is assumed that the x_i are sufficiently accurately known to justify the neglect of the second term in the denominator of (3). Further, since δs is usually proportional to the line width, it will be replaced by the line width in the ensuing discussion.

Table 2

Parameters of the Spin Hamiltonian for MnII Ions in Cubic Crystals

$CdCl_2$	20	15	2·001$\underline{5}$ ±0·000$\underline{5}$	(−) 81·5 ±0·2	(+) 14·8 ±0·5	⩽0·$\underline{5}$

If in an electron nuclear double resonance experiment the line width Δ_N arises from mechanism (i), i.e. incomplete decoupling of the electronic and nuclear spins, it may be written (Bleaney 1958)

$$\Delta_N = \tfrac{1}{2}\left(\frac{A}{g\beta H}\right)^2 [S(S+1) - M_S(M_S+1) + 2M_S m_I]\Delta_E$$

if we neglect the nuclear Zeeman term.

The electronic line width Δ_E is assumed to be constant for all transitions, and to be independent of variation of the parameters being measured.

We shall consider measuring the cubic crystal field parameter of MnIII in a crystal with an axial distortion along a $\langle 100 \rangle$ direction. If we neglect the fourth degree axial crystal field term which is usually small then the Hamiltonian with the z axis along a $\langle 100 \rangle$ direction is

$$\mathscr{H} = g\beta \mathbf{H} . \mathbf{S} + A\mathbf{I} . \mathbf{S} + B_2^0 O_2^0 + B_4(O_4^0 + 5O_4^4) - g_n \beta_n \mathbf{H} . \mathbf{I}, \tag{4}$$

where $S = I = \frac{5}{2}$. We then find the most favourable figure of merit for an electron spin resonance determination by measuring the splitting of the $M_S = +\frac{5}{2} \leftrightarrow +\frac{3}{2}$ and the $M_S = -\frac{5}{2} \leftrightarrow -\frac{3}{2}$ lines is

$$F_{\text{ESR}} = \frac{5b_4}{\Delta_E} \quad \text{where} \quad b_4 = 60B_4.$$

The ratios of the above F_{ESR} to the figure of merit F_{ENDOR} for the mechanisms (i), (ii), and (iii) for the $M_S = +\frac{1}{2}$, $m_I = -\frac{3}{2} \leftrightarrow -\frac{5}{2}$ nuclear transition are

(i)

$$\frac{F_{\text{ENDOR}}}{F_{\text{ESR}}} = \frac{40}{13}$$

(ii) + (iii)

$$\frac{F_{\text{ENDOR}}}{F_{\text{ESR}}} = \frac{6}{65}\frac{b_4^1}{b_4^0}\frac{2b_2^1 - b_4^1}{A} \quad \text{for} \quad |m| = 1$$

where $b_4^m = 60B_4^m$ and $b_2^m = 2B_2^m$

(iii)

$$\frac{F_{\text{ENDOR}}}{F_{\text{ESR}}} = \frac{2}{65}\frac{b_4^2}{b_4^0}\frac{3b_2^2 - \frac{1}{5}b_4^2}{A} \quad \text{for} \quad |m| = 2.$$

The first expression does not depend on the parameters of the spin Hamiltonian (4) since we have assumed that the ENDOR line width arises from the same mechanism as this ENDOR shift. The last two expressions vanish if H is aligned in the [100] direction, but if, for example, it lies in a (100) plane at 22·5° to the [100] axis they become

$$\frac{F_{\text{ENDOR}}}{F_{\text{ESR}}} = \frac{6}{13}\frac{(\frac{5}{2}a - 2{\cdot}82D)}{A} \quad \text{for } |m| = 1$$

$$\frac{F_{\text{ENDOR}}}{F_{\text{ESR}}} = \frac{1}{13}\frac{(0{\cdot}45D - \frac{1}{4}a)}{A} \quad \text{for } |m| = 2$$

in the a and D notation.

It is apparent that the electron nuclear double resonance technique will begin to yield appreciably more accurate answers than electron spin resonance only when the crystal field splitting exceeds the hyperfine structure (a or $D \gg A$).

2.2. *Crystals with Axial Symmetry*

The experimental results, summarized in table 3, are interpreted in terms of the spin Hamiltonian (Bleaney and Trenam 1954)

$$\begin{aligned}\mathscr{H} &= g\beta \mathbf{H}\,.\,\mathbf{S}+A\mathbf{I}\,.\,\mathbf{S}+D[S_z^2-\tfrac{1}{3}S(S+1)]\\ &\quad+\left(\frac{a}{6}\right)[S_\xi^4+S_\eta^4+S_\zeta^4-\tfrac{1}{5}S(S+1)(3S^2+3S-1)]\\ &\quad+\left(\frac{F}{180}\right)[35S_z^4-30S(S+1)S_z^2+25S_z^2-6S(S+1)+3S^2(S+1)^2]. \qquad (5)\end{aligned}$$

The axes ξ, η, ζ are the principal axes of the cubic field and the [111] axis, referred to this basis, is the trigonal axis of the crystal and is labelled the z axis. In the case of $MgCl_2$ and $CdCl_2$ the hyperfine interaction with the neighbouring chlorine nuclei is not resolved but contributes to the observed line width (see table 3).

The axial terms add to (2) the following expressions for the line positions:

$$\begin{aligned}M &= \pm\tfrac{5}{2}\leftrightarrow\pm\tfrac{3}{2}, &&\mp[2D(3\cos^2\theta-1)+\tfrac{1}{8}Fq]-32\delta_1+4\delta_2\\ M &= \pm\tfrac{3}{2}\leftrightarrow\pm\tfrac{1}{2}, &&\mp\left[D(3\cos^2\theta-1)-\frac{5}{24}Fq\right]+4\delta_1+5\delta_2\\ M &= +\tfrac{1}{2}\leftrightarrow-\tfrac{1}{2}, &&16\delta_1-8\delta_2.\end{aligned}$$

Here θ is the angle between the z axis and the direction of the applied magnetic field, $q = (35\cos^4\theta-30\cos^2\theta+3)$ and the second-order terms due to the axial field are $\delta_1 = (D^2/g\beta H_0)\cos^2\theta\sin^2\theta$ and $\delta_2 = (D^2/4g\beta H_0)\sin^4\theta$.

When measurements are made with the magnetic field either along or perpendicular to the trigonal axis the term $a-F$ occurs in the expression for the line position and it is not possible to determine a and F separately. It is possible to distinguish the effects of the terms in a and F by making measurements in other directions, but the interpretation of the measurements depends on a knowledge of the position of the ξ, η, ζ axes.

In the investigation of Mniii in the hexagonal form of ZnS by Keller, Gelles and Smith (1958) the term in a was dropped from the spin Hamiltonian and a value of $F = -7{\cdot}5\times10^{-4}\,\mathrm{cm}^{-1}(-8{\cdot}1\,\mathrm{G})$ calculated from measurements made in directions parallel and perpendicular to the trigonal axis. From our discussion it would appear that their results indicate a value of $a-F = +7{\cdot}5\times10^{-4}\,\mathrm{cm}^{-1}$.

It was not possible to obtain a general orientation of $MgCl_2$ or of $CdCl_2$ crystals from the external morphology and x-ray methods were not successful because of the pronounced hygroscopic nature of the crystals. In the case of ZnO the polycrystalline nature of part of the sample imposed a similar limitation. With ZnO there is the further complication that the two ions in each unit cell are inequivalent, the directions of the axes ξ, η, ζ for one being related to ξ', η', ζ' for the other by a rotation of 60° about their common trigonal axis. This produces a doublet structure on the $M = \pm\frac{5}{2}\leftrightarrow\pm\frac{3}{2}$ and the $M = \pm\frac{3}{2}\leftrightarrow\pm\frac{1}{2}$ lines except in special directions for which the two spectra coincide. The smallness of a and the large line width of 18 G, which is due to the poor nature of the crystal, account adequately for our failure to observe this effect. We have made measurements at 90 °K and at 20 °K which are in agreement within the experimental error and the measurements at 20 °K are given in table 3. Dorain's (1958) definition of the cubic crystal field term differs from ours and his a values should be multiplied by -3 for comparison with our a values. We then find that his value of a for manganese in ZnO agrees with our value within the experimental error, though his D value does not.

In calculating the line positions for MnIII in $MgCl_2$ and ZnO it was found necessary to include third-order perturbations terms, e.g. terms proportional to A^2D and, in the perpendicular plane, to D^3. It was found that all significant third-order contributions were included by expressing the energy denominators in the second-order terms to first order in D and A in place of the zero-order energy differences proportional to $g\beta H_0$. In the perpendicular plane the separation of the extreme lines in the manganese spectrum is $(1/g\beta)[5A+4D+(a-F)]$ correct to second order in D and A: the third-order corrections are 3·5 G for $MgCl_2$ and 10 G for ZnO and are clearly significant in comparison with $(1/g\beta)(a-F)$. The large value of D made third-order corrections necessary for calculations on the measurements of the parallel spectrum in ZnO. The fortuitous overlapping of many of the lines in the parallel spectrum in $MgCl_2$ made it necessary to make use of measurements made in the perpendicular plane in order to obtain sufficient data to evaluate the parameters of the spin Hamiltonian.

Another consequence of the large axial terms, in the case of ZnO, was the appearance of 'forbidden' transitions, corresponding to $\Delta m_I = \pm 1$, of the type discussed by Bleaney and Rubins. These were observed along the parallel direction for which they are expected to vanish; their presence suggested, as was confirmed by X-ray examination, that a considerable proportion, perhaps as much as 20%, of the sample was composed of very small crystals with more or less random orientation.

In all of the crystals examined very weak low field spectra were observed but not measured; their position and appearance was consistent with their being 'forbidden' $\Delta M_S = \pm 2$ transitions. In $CdCl_2$ there was an additional weak spectrum with a value of D of about 330×10^{-4} cm^{-1} which is probably due to interstitial MnIII ions.

§ 3. DISCUSSION

If the ground state of MnIII were pure $^6S_{5/2}$ we would not expect an interaction with the crystal field since the crystal field has no direct interaction with the spin. However, spin–orbit coupling will admix other multiplets of the ground configuration, $3d^5$, into the ground state resulting in a small splitting of the $^6S_{5/2}$ manifold into a quartet Γ_8 and a doublet Γ_7 with a separation $3a$. Watanabe in his attempt to calculate this splitting considered the effect of the crystal field, spin–orbit interaction and spin–spin interaction on the sextet and quartet states of the ground configuration of the free ion. He treated the crystal field as a perturbation on the $\Sigma_{i\neq j}(e^2/r_{ij})$ term which describes the electrostatic interaction between the electrons on the MnIII ion. Powell *et al.* (I), who use the same Hamiltonian as Watanabe, point out, however, that the effect of the crystal field is comparable with this term and also show that consideration of the admixture of the doublets of the ground configuration into the ground state by the spin–orbit coupling is essential. Their method of calculating a does not require the crystal field to be small and they conclude that a is most sensitive to the spin–orbit coupling constant λ and to Dq and varies as $\lambda^4(Dq)^n$, where n varies from 3 to 6 over the range of Dq values 700 cm^{-1} to 1500 cm^{-1}. The theory may be applied to crystals with axial symmetry since the cubic and axial parts of the crystal field are separable.

In their initial calculations Powell *et al.* (1960) used a value of 400 cm^{-1} for λ but pointed out subsequently (Powell *et al.* 1961) that a value of about 250 cm^{-1} is more likely in solid environments. The value of λ for iron group ions in solids is found to be about 25% less than the free ion value (Owen 1955, Low 1958, Hall and Hayes 1960) due to screening effects of the ligand electrons (Marshall and Stuart 1961). Variations of λ with environment are therefore to be expected and will be significant since λ occurs to the fourth power in the expression for a.

Table 4 gives *a* values (kindly supplied to us by Dr. D. F. Johnston) calculated from the theory of Powell *et al.* over a range of *Dq* and λ values. These values were calculated assuming the Racah (1942) parameter $B = 1000\ \text{cm}^{-1}$ and $C = 3000\ \text{cm}^{-1}$; the values of B and C were arrived at by fitting the field independent $^4\Gamma_1$ level in the crystal at 25 000 cm^{-1} and assuming $C/B = 3$ as in the free ion.

Table 4

Calculated Values of *a*(in 10^{-4} cm^{-1}) for MnIII

Dq(cm^{-1})	λ = 300 cm^{-1}	λ = 270 cm^{-1}	λ = 240 cm^{-1}	λ = 210 cm^{-1}
300	0·14	0·12	0·09	0·06
400	0·47	0·33	0·23	0·15
500	0·93	0·67	0·43	0·29
780	3·40	2·37	1·57	1·00
830	4·17	2·90	1·93	1·23

Powell *et al.* (1960) predict very small negative *a* values but only for *Dq* values in the range 0 to +200 cm^{-1}. Previously measured *Dq* values for MnIII in crystals with sixfold co-ordination lie in the range +700 to +1000 cm^{-1} (see table 5) and negative *a* values are not expected. MnIII and FeIV in cubic crystal fields of positive and of negative *Dq* and with a variety of ligands have so far always yielded positive *a* values. It must be emphasized that in the measurements quoted in this paper and in many of the measurements reported in the literature the sign of *a* is determined relative to the sign of the hyperfine constant *A* which is assumed to be negative. The sign of *A* has been measured in some crystals (see, for example, Bleaney and Ingram) and found to be negative and it seems unlikely that environmental effects will change the sign. In the case of symmetries less than cubic, positive values of *a* have been reported except in KCl:MnIII where Watkins (1959) gives a tentative assignment of -1×10^{-4} cm^{-1} to *a*.

Table 5

***Dq* Values of MnIII in Crystal Environments with Sixfold Co-ordination**

Crystal	*Dq* (cm^{-1})	Reference
MnF_2	780	Stout (1959)
$KMnF_3$	780	Hrostowski (private communication via R. G. Shulman)
$MnCl_2$	830	Stout (1960) Pappalardo (1959, 1960)
$MnBr_2$	940	Stout (1960) Pappalardo (1959, 1960)
MnO	979	Pratt and Coelho (1959)

The optical absorption spectrum of $MnCl_2$ (table 5) gives $Dq = 830\ \text{cm}^{-1}$. From table 4 we predict a value of about 2×10^{-4} cm^{-1} for *a* if we assume $\lambda = 250\ \text{cm}^{-1}$. It would be interesting to compare this value of *a* with the *a* values in $CdCl_2$:Mn and

$MgCl_2$:Mn but we have been able to determine only values of $a-F$ for these salts. However, since a and F are both fourth-order crystal field terms, we expect F to be considerably smaller than a if it arises from a small perturbation of the cubic field. This is observed to be so in cases for which a and F have been separately determined (e.g. Bleaney and Trenam). If we then assume $a-F \simeq a$, we find that our measured values are smaller than the predicted value for $MnCl_2$. A measurement of Dq and a in the same crystal would be advantageous, but, since optical transitions within the ground configuration of MnIII are both spin and parity forbidden the investigation of the optical spectrum is difficult in specimens sufficiently dilute for electron spin resonance measurements. We attempted to grow crystals of $CdCl_2$:Mn in which it would be possible to measure both a and Dq but without success.

Powell *et al.* (1961) using optical data obtained from MnO(a_0 = 4·435 Å) (Pratt and Coelho 1959) find that their calculated value of a for MnIII in the ismorphous MgO(a_0 = 4·203 Å) is considerably smaller than the measured value (Low 1956) and suggest that the discrepancy may be due in part to the change in lattice parameter affecting Dq and in part to covalency effects. Since fluorine is the most electronegative of the elements, fluoride crystals might be expected to give a better check on the theory. The optical spectrum of MnF_2 (table 5) gives Dq = 780 cm^{-1} and the theory of I then predicts a value of about 2×10^{-4} cm^{-1} for a. The electron spin resonance spectrum of MnIII present as a trace impurity in the isomorphous ZnF_2 has been investigated (Tinkham 1956, Clogston *et al.* 1960) but no value was found for a because of the complexity of the spectrum. Dq in $KMnF_3$ is 780 cm^{-1}, predicting a value of a which is identical with that predicted for MnF_2. However, we find $a = 6{\cdot}5\times10^{-4}$ cm^{-1} for MnIII in the isomorphous $KMgF_3$. Both $KMgF_3$ and $KMnF_3$ have cubic symmetry and the lattice parameters are a_0 = 3·987 Å and a_0 = 4·190 Å respectively. The fact that the a value of manganese in $KMgF_3$ is greater than predicted from measurements in $KMnF_3$ supports the view of I that the smaller lattice spacing in the diamagnetic crystal may be partly responsible. This view is further strengthened by the fact that the a value of manganese in $CdCl_2$ is smaller than that predicted from optical measurements on $MnCl_2$ since in this case the cation–anion distance in the diamagnetic crystal is greater.

Optical data on MnIII bonded with four or eight ligands are scant. Data on other iron group ions are given in table 6 and it is apparent that the crystal field strengths

Table 6

***Dq* Values of Divalent Iron Group Ions with Fourfold and Eightfold Co-ordination**

Ion	Co-ordination	Dq(cm^{-1})	Reference
ZnO:Co	4	−390	Pappalardo (private communication) See also McClure (1957)
ZnO:Ni	4	−405	
ZnO:Cu	4	−500	
$CoCl_4^{2-}$	4	−375	Orgel (1955) See also Holm and Cotton (1959)
$CoBr_4^{2-}$	4	−360	
CoI_4^{2-}	4	−290	
CaF_2:Co	8	−340	Stahl-Brada and Low (1959)

are about half those observed with sixfold co-ordination (McClure 1959). We therefore expect a *Dq* value of about 400 cm^{-1} for MnIII with fourfold and eightfold co-ordination and, from table 4, an *a* value of about $0 \cdot 3 \times 10^{-4}$ cm^{-1}. We have not been able to put a firm upper limit on *a* in the eightfold co-ordinated CaF_2 and CdF_2 because of the fluorine hyperfine structure but Low and Rosenberger (1960) show that $a < 1 \times 10^{-4}$ cm^{-1} in the isomorphous $SrCl_2$. The agreement here is reasonable but gets worse as we go to the more covalent ZnO (table 3) and in the very covalent CdTe ($a = 27 \times 10^{-4}$ cm^{-1}) we find a discrepancy of almost two orders of magnitude indicating the inadequacy of the purely ionic model of I for covalent systems.

The values of *a* measured for FeIV are in general an order of magnitude larger than the values found for MnIII and Low (1956, 1957) finds in MgO that a(MnIII) $= +18 \cdot 61 \times 10^{-4}$ cm^{-1} and a(FeIV) $= +205 \times 10^{-4}$ cm^{-1}. A reliable value of λ for FeIV is not available but Kotani (1949) suggests that the λ value is only about 10% larger than that of MnIII and should not therefore contribute significantly to the increase in *a*. The values of *Dq* for triply charged iron group ions are about twice as large as the *Dq* values for divalent ions (Holmes and McClure 1957). In an investigation of the variation of *a* with pressure, Walsh (1961) finds evidence which indicates that *a* for MnIII and FeIV in MgO varies as $(Dq)^4$ in which case an increase of a factor of two in *Dq* in passing from MnIII to FeIV would more than account for the observed increase in *a*.

ACKNOWLEDGMENTS

We would like to thank Professor B. Bleaney and Dr. D. F. Johnston for their comments on the manuscript. We are indebted to Dr. R. W. H. Stevenson for the crystal of CdF_2, to Dr. P. B. Dorain for the crystal of ZnO and to Professor D. A. Wright and Dr. J. Woods for the crystal of CdTe. The crystal of $KMgF_3$ was supplied by Mervyn Instruments Ltd. This work was supported by the Board of Admiralty and the United States Air Force. One of us (F.I.B.W.) is indebted to the Rhodes Trust for a Scholarship.

Electron–Phonon Interaction by the Method of Pseudo-potentials

By L. J. SHAM

Cavendish Laboratory, University of Cambridge

Communicated by J. M. Ziman; *MS. received* 18*th August* 1961

Abstract. The matrix element is calculated (i) for orthogonalized plane waves assuming that the ion moves rigidly and (ii) for the equivalent plane waves on the assumption that the net effective potential (Hartree–Fock potential plus pseudo-potential) moves rigidly with the ion. It is shown that these two results are equivalent if the pseudo-potential operator can be treated as a localized potential.

§ 1. INTRODUCTION

It is very convenient to regard the conduction electrons in a metal or semiconductor as moving in an effective potential field consisting of the Hartree–Fock field and a repulsive potential. The latter arises from the need to orthogonalize the wave functions of the conduction electrons to the wave functions of the core-electrons. By virtue of the near cancellation of these two potentials the wave functions of the conduction electrons can be approximately represented by simple combinations of plane waves. This idea has been justified by Phillips and Kleinman (1959) and Cohen and Heine (1961) for the energy states in crystals. Ziman (1961) has suggested that each ion carries its effective potential around rigidly with it and that the electron–phonon interaction may be calculated as if this were true. We wish to prove this in the following sense. Consider a solid where the ions are slightly displaced from their equilibrium positions. This gives rise to small changes in the actual crystal potential. We can calculate the electron–phonon interaction from first principles by taking matrix elements for the change of potential between electron states of the unperturbed crystal expressed in terms of orthogonalized plane waves. On the other hand, we can let the effective potential take the place of the actual potential and calculate the matrix elements for the change of this potential between electron states, expressed now in *simple* plane waves. We shall show that if the non-local pseudo-potential operator (Cohen and Heine 1961) can be replaced by a local potential function, then these two calculations of the electron–phonon interaction matrix element yield equivalent results.

§ 2. ORTHOGONALIZED PLANE WAVES AND THE PSEUDO-POTENTIAL

We base the whole calculation on the orthogonalized plane-wave method. Consider a finite crystal of N cells, each with volume Ω_0. For simplicity, we restrict ourselves to one atom per unit cell. The Hamiltonian for one electron is

$$\mathscr{H} = -\nabla^2 + V(\mathbf{r}) \tag{1}$$

where we take the crystal potential in the form

$$V(\mathbf{r}) = \sum_{\mathbf{l}} U(\mathbf{r}-\mathbf{l}), \tag{2}$$

$\mathbf{l}$ running over the N lattice vectors and $U(\mathbf{r}) = U(r)$.

Following Heine (1957), we take the 'atomic' wave functions of the core-electrons, $\phi_t(\mathbf{r})$, as eigenfunctions satisfying

$$[-\nabla^2 + U(\mathbf{r})]\phi_t = \mathscr{E}_t\phi_t. \tag{3}$$

Throughout the calculation we shall assume that $\phi_t(\mathbf{r})$ is negligible outside the Wigner–Seitz cell centred at the origin.

By the tight-binding approximation, the 'crystal' wave functions of the core-electrons are

$$\psi_{t\mathbf{k}}(\mathbf{r}) = \frac{1}{\sqrt{N}}\sum_{\mathbf{l}} \exp(i\mathbf{k}\cdot\mathbf{l})\phi_t(\mathbf{r}-\mathbf{l}). \tag{4}$$

An orthogonalized plane wave of the form

$$\chi_{\mathbf{kg}}(\mathbf{r}) = \frac{1}{\sqrt{(N\Omega_0)}}\exp[i(\mathbf{k}+\mathbf{g})\cdot\mathbf{r}] - \sum_t b_{t\mathbf{kg}}\psi_{t\mathbf{k}} \tag{5}$$

where $\mathbf{g}$ is the reciprocal lattice vector and $b_{t\mathbf{kg}}$ the orthogonalizing constant given by

$$b_{t\mathbf{kg}} = \frac{1}{\sqrt{\Omega_0}}\int_{N\Omega_0} \exp[i(\mathbf{k}+\mathbf{g})\,.\,\mathbf{r}]\phi_t^*(\mathbf{r})\,d^3\mathbf{r}. \tag{6}$$

Expanding the wave function of a conduction electron in terms of orthogonalized plane waves, we get

$$\psi_{t\mathbf{k}}(\mathbf{r}) = \sum_{\mathbf{g}} C_{\mathbf{k}}\chi_{\mathbf{gkg}}(\mathbf{r}). \tag{7}$$

The clue to our method lies in the matrix element of the determinant, which fixes the energies in the orthogonalized plane wave expansion:

$$\begin{aligned}\langle\chi_{\mathbf{kg}'}|\mathscr{H}-\mathscr{E}I|\chi_{\mathbf{kg}}\rangle = {}&(\mathbf{k}+\mathbf{g})^2\delta_{\mathbf{gg}'} + \bar{V}(\mathbf{g}'-\mathbf{g})\\ &+\sum_t(\mathscr{E}-\mathscr{E}_t)b_{t\mathbf{kg}'}{}^*b_{t\mathbf{kg}} - \mathscr{E}\delta_{\mathbf{gg}'}\end{aligned} \tag{8}$$

where $\bar{V}(\mathbf{g})$ is a Fourier component of $V(\mathbf{r})$, that is,

$$\bar{V}(\mathbf{g}) = \frac{1}{N\Omega_0}\int_{N\Omega_0} V(\mathbf{r})\exp(-i\mathbf{g}\,.\,\mathbf{r})\,d^3\mathbf{r}. \tag{9}$$

If we define the transform

$$\begin{aligned}\bar{U}(\mathbf{k}) &= \frac{1}{\Omega_0}\int_{N\Omega} U(\mathbf{r})\exp(-i\mathbf{k}\,.\,\mathbf{r})\,d^3\mathbf{r}\\ &= \frac{4\pi}{\Omega_0}\int_0^\infty r^2U(r)j_0(kr)\,dr\end{aligned} \tag{10}$$

then

$$\bar{U}(\mathbf{g}) = \bar{V}(\mathbf{g}). \tag{11}$$

Now the effect of orthogonalization manifests itself in the term

$$\sum_t(\mathscr{E}-\mathscr{E}_t)b_{t\mathbf{kg}'}{}^*b_{t\mathbf{kg}}.$$

Suppose the effect can be simulated by a local potential $V_{\mathrm{R}}(\mathbf{r})$ taken in the form

$$V_{\mathrm{R}}(\mathbf{r}) = \sum_{\mathbf{l}} U_{\mathrm{R}}(|\mathbf{r}-\mathbf{l}|) \tag{12}$$

Then its Fourier components have to satisfy

$$\bar{U}_{\mathrm{R}}(|\mathbf{g}'-\mathbf{g}|) \simeq \sum_{t} (\mathscr{E}-\mathscr{E}_t) b_{t\mathbf{k}\mathbf{g}'}{}^{*} b_{t\mathbf{k}\mathbf{g}}. \tag{13}$$

For our purpose we need the extension

$$\sum_{t} (\mathscr{E}-\mathscr{E}_t) b_{t\mathbf{k}'\mathbf{g}'}{}^{*} b_{t\mathbf{k}\mathbf{g}} = \bar{U}_{\mathrm{R}}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g}) \tag{14}$$

where the two *b*'s do not belong to the same **k**-vector. Equation (14) follows from equation (13) if we take $U_{\mathrm{R}}(\mathbf{r}) = V_{\mathrm{R}}(\mathbf{r})$ inside the Wigner–Seitz cell and $U_{\mathrm{R}}(\mathbf{r}) = 0$ outside. Then

$$\bar{U}_{\mathrm{R}}(\mathbf{k}) = \sum_{\mathbf{g}} \bar{V}(\mathbf{g}) \frac{1}{\Omega_0} \int_{\Omega_0} \exp[i(\mathbf{g}-\mathbf{k}) . \mathbf{r}]\, d^3\mathbf{r}.$$

From the Fourier expansion

$$\exp[i(\mathbf{k}-\mathbf{k}') . \mathbf{r}] = \sum_{\mathbf{g}''} \exp(i\mathbf{g}'' . \mathbf{r}) \frac{1}{\Omega_0} \int_{\Omega_0} \exp[i(\mathbf{k}-\mathbf{k}'-\mathbf{g}'') . \mathbf{r}]\, d^3\mathbf{r}$$

valid inside the Wigner–Seitz cell, we obtain

$$b_{t\mathbf{k}\mathbf{g}} = \frac{1}{\sqrt{\Omega_0}} \int_{\Omega_0} \exp[i(\mathbf{k}+\mathbf{g}) . \mathbf{r}] \phi_t^{*}(\mathbf{r})\, d^3\mathbf{r}$$

$\phi_t(\mathbf{r})$ negligible outside the Wigner–Seitz cell,

$$= \sum_{\mathbf{g}''} b_{t\mathbf{k}'\mathbf{g}+\mathbf{g}''} \frac{1}{\Omega_0} \int_{\Omega_0} \exp[i(\mathbf{k}-\mathbf{k}'-\mathbf{g}'') . \mathbf{r}]\, d^3\mathbf{r}.$$

Hence

$$\begin{aligned}
&\sum_{t} (\mathscr{E}-\mathscr{E}_t) b_{t\mathbf{k}'\mathbf{g}'}{}^{*} b_{t\mathbf{k}\mathbf{g}} \\
&= \sum_{\mathbf{g}''} \frac{1}{\Omega_0} \int_{\Omega_0} \exp[i(\mathbf{k}-\mathbf{k}'-\mathbf{g}'') . \mathbf{r}]\, d^3\mathbf{r} \sum_{t} (\mathscr{E}-\mathscr{E}_t)) b_{t\mathbf{k}'\mathbf{g}'}{}^{*} b_{t\mathbf{k}'\mathbf{g}+\mathbf{g}''} \\
&= \sum_{\mathbf{g}''} \bar{U}_{\mathrm{R}}(\mathbf{g}'-\mathbf{g}-\mathbf{g}'') \frac{1}{\Omega_0} \int_{\Omega_0} \exp[i(\mathbf{k}-\mathbf{k}'-\mathbf{g}'') . \mathbf{r}]\, d^3\mathbf{r} \\
&= \bar{U}_{\mathrm{R}}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})
\end{aligned}$$

If we can interpolate the values of $\bar{U}_{\mathrm{R}}(\mathbf{k})$ from equation (13) or, better still, obtain the values from equation (14), we can get, by the Hankel inversion theorem (Sneddon 1951),

$$U_{\mathrm{R}}(\mathbf{r}) = \frac{\Omega_0}{2\pi^2} \int_0^{\infty} k^2 \bar{U}_{\mathrm{R}}(k) j_0(kr)\, dk. \tag{15}$$

This provides a practical method for constructing the pseudo-potential using the results of an orthogonalized plane-wave band-structure calculation.

From equations (8) and (13), we see that the matrix element on the left-hand side of equation (8) satisfies

$$\langle \chi_{\mathbf{kg}'} | \mathscr{H} - \mathscr{E} I | \chi_{\mathbf{kg}} \rangle = \langle \mathbf{k}+\mathbf{g}' | -\nabla^2 + V + V_{\mathrm{R}} - \mathscr{E} I | \mathbf{k}+\mathbf{g} \rangle \tag{16}$$

where $|\mathbf{k}+\mathbf{g}\rangle$ denotes the plane wave $(N\Omega_0)^{-1/2} \exp i(\mathbf{k}+\mathbf{g})\cdot\mathbf{r}$. The secular equation

$$\sum_{\mathbf{g}} \langle \chi_{\mathbf{kg}'} | \mathscr{H} - \mathscr{E} I | \chi_{\mathbf{kg}} \rangle C_{\mathbf{kg}} = 0 \tag{17}$$

is equivalent to

$$\sum_{\mathbf{g}} \langle \mathbf{k}+\mathbf{g}' | -\nabla^2 + V + V_{\mathrm{R}} - \mathscr{E} I | \mathbf{k}+\mathbf{g} \rangle C_{\mathbf{kg}} = 0. \tag{18}$$

This suggests that we may treat the conduction electrons as if they were moving in potential $V+V_{\mathrm{R}}$ and as if their wave functions were combinations of plane waves with the same coefficients as those of corresponding orthogonalized plane waves.

The assumption made in equation (13) can only be justified by a band-structure calculation for a specific metal using the orthogonalized plane-wave method. Note that for our purpose we have chosen the repulsive potential V_{R} so that (i) it does not involve the wave functions of the conduction electrons and (ii) it does not depend on $\mathbf{k}$ for a given energy.

§ 3. ELECTRON–PHONON INTERACTION FOR ORTHOGONALIZED PLANE WAVES

The next step is to show that the interaction matrix element $\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}')$ (Ziman 1960, p. 182) based on the rigid ion model is the same whether we calculate it from orthogonalized plane waves in potential V or plane waves in potential $V+V_{\mathrm{R}}$. The details are set out as follows.

We first calculate

$$\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}') = -N\mathbf{e}_{\mathbf{q}p} \cdot \int_{N\Omega_0} \psi_{\mathbf{k}'}{}^*(\nabla U)\psi_{\mathbf{k}}\, d^3\mathbf{r} \tag{19}$$

where

$$\int_{N\Omega_0} \psi_{\mathbf{k}}{}^*\psi_{\mathbf{k}}\, d^3\mathbf{r} = 1$$

and $\psi_{\mathbf{k}}$ is given by the expansion in orthogonalized plane waves, equation (7).

$$\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}') = -N\mathbf{e}_{\mathbf{q}p} \cdot \sum_{\mathbf{gg}'} C_{\mathbf{k}'\mathbf{g}'}{}^* C_{\mathbf{kg}} \int_{N\Omega_0} \chi_{\mathbf{k}'\mathbf{g}'}{}^*(\nabla U)\chi_{\mathbf{kg}}\, d^3\mathbf{r}. \tag{20}$$

Each term

$$\int_{N\Omega_0} \chi_{\mathbf{k}'\mathbf{g}'}{}^*(\nabla U)\chi_{\mathbf{kg}}\, d^3\mathbf{r}$$

$$= \int \Big[(N\Omega_0)^{-1/2} \exp[-i(\mathbf{k}'+\mathbf{g}')\,.\,\mathbf{r}] - \sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^* \psi_{t'\mathbf{k}'}{}^* \Big](\nabla U)$$

$$\times \Big[(N\Omega_0)^{-1/2} \exp[i(\mathbf{k}+\mathbf{g})\,.\,\mathbf{r}] - \sum_{t} b_{t\mathbf{kg}} \psi_{t\mathbf{k}} \Big]\, d^3\mathbf{r} \tag{21}$$

can be separated into four parts, I + II + III + IV, which we attack in turn.

$$\mathrm{I} = \int [(N\Omega_0)^{-1/2}\exp\{-i(\mathbf{k}'+\mathbf{g}').\mathbf{r}\}](\nabla U)[(N\Omega_0)^{-1/2}\exp\{i(\mathbf{k}+\mathbf{g}).\mathbf{r}\}]\,d^3\mathbf{r}$$

$$= \frac{i}{N\Omega_0}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})\int U\exp[i(\mathbf{k}+\mathbf{g}-\mathbf{k}'-\mathbf{g}').\mathbf{r}]\,d^3\mathbf{r}$$

$$= \frac{i}{N}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})\bar{U}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g}), \tag{22}$$

$\bar{U}$ denoting the Fourier transform of U as in (10).

$$-\mathrm{II} = \int\Big[\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^*\psi_{t'\mathbf{k}'}{}^*\Big](\nabla U)[(N\Omega_0)^{-1/2}\exp\{i(\mathbf{k}+\mathbf{g}).\mathbf{r}\}]\,d^3\mathbf{r}$$

$$\doteq \frac{1}{N\sqrt{\Omega_0}}\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^*\int\exp[i(\mathbf{k}+\mathbf{g}).\mathbf{r}](\nabla U)\phi_{t'}{}^*\,d^3\mathbf{r},$$

neglecting overlap terms like $\{\nabla U(r)\}\phi_{t'}(\mathbf{r}-\mathbf{l})$ with $\mathbf{l} \neq 0$. From equation (3),

$$(-\nabla^2+U)\phi_t{}^* = \mathscr{E}_t\phi_t{}^*$$

$$(-\nabla^2+U)\nabla\phi_t{}^*+(\nabla U)\phi_t{}^* = \mathscr{E}_t\nabla\phi_t{}^*. \tag{23}$$

Therefore

$$-\mathrm{II} = -\frac{i}{N}(\mathbf{k}+\mathbf{g})\sum_t \mathscr{E}_{t'}b_{t''\mathbf{k}\mathbf{g}'}{}^*b_{t'\mathbf{k}\mathbf{g}}+$$

$$+\frac{1}{N\sqrt{\Omega_0}}\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^*\int\exp[i(\mathbf{k}+\mathbf{g}).\mathbf{r}](\nabla^2-U)\nabla\phi_{t'}{}^*\,d^3\mathbf{r}. \tag{24}$$

Similarly,

$$-\mathrm{III} = \int[(N\Omega_0)^{-1/2}\exp\{-i(\mathbf{k}'+\mathbf{g}').\mathbf{r}\}](\nabla U)\Big[\sum_t b_{t\mathbf{k}\mathbf{g}}\psi_{t\mathbf{k}}\Big]\,d^3\mathbf{r}$$

$$= \frac{i}{N}(\mathbf{k}'+\mathbf{g}')\sum_t \mathscr{E}_t b_{t\mathbf{k}'\mathbf{g}'}{}^*b_{t\mathbf{k}\mathbf{g}}+$$

$$+\frac{1}{N\sqrt{\Omega_0}}\sum_t b_{t\mathbf{k}\mathbf{g}}\int\exp\{-i(\mathbf{k}'+\mathbf{g}').\mathbf{r}\}(\nabla^2-U)\nabla\phi_t\,d^3\mathbf{r}. \tag{25}$$

$$\mathrm{IV} = \int\Big[\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^*\psi_{t'\mathbf{k}'}{}^*\Big](\nabla U)\Big[\sum_t b_{t\mathbf{k}\mathbf{g}}\psi_{t\mathbf{k}}\Big]\,d^3\mathbf{r}$$

$$= \frac{1}{N}\sum_{t't} b_{t'\mathbf{k}'\mathbf{g}'}{}^*b_{t\mathbf{k}\mathbf{g}}\int\phi_{t'}{}^*(\nabla U)\phi_t\,d^3\mathbf{r}$$

by equation (4) and 'non-overlapping' assumption

$$= \frac{1}{N}\sum_{t't} b_{t'\mathbf{k}'\mathbf{g}'}{}^*b_{t\mathbf{k}\mathbf{g}}\int\phi_{t'}{}^*(\nabla^2-U+\mathscr{E}_t)\nabla\phi_t\,d^3\mathbf{r}$$

by equation (23)

$$= \frac{1}{N}\sum_{t't} b_{t'\mathbf{k}'\mathbf{g}'}{}^*b_{t\mathbf{k}\mathbf{g}}\Big[\int\phi_{t'}{}^*(\nabla^2-U)\nabla\phi_t\,d^3\mathbf{r}+\int(\nabla\phi_{t'}{}^*)(\nabla^2-U)\phi_t d^3\mathbf{r}\Big]. \tag{26}$$

Combining the second term of II and the second term of IV, we get

$$-\frac{1}{\sqrt{N}}\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}\int\Big[(N\Omega_0)^{-1/2}\exp\{i(\mathbf{k}+\mathbf{g})\,.\,\mathbf{r}\}-N^{-1/2}\sum_{t} b_{t\mathbf{k}\mathbf{g}}\phi_t\Big](\nabla^2-U)(\nabla\phi_{t'}{}^{*})\,d^3\mathbf{r}$$

$$=-\frac{1}{\sqrt{N}}\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}\int(\nabla\phi_{t'}{}^{*})(\nabla^2-U)\chi_{\mathbf{k}\mathbf{g}}\,d^3\mathbf{r}$$

by equation (5), which can be replaced by

$$-\frac{1}{\sqrt{N}}\sum_{t'} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}\int(\nabla\phi_{t'}{}^{*})(-\mathscr{E}_{\mathbf{k}})\chi_{\mathbf{k}\mathbf{g}}\,d^3\mathbf{r} \tag{27}$$

since

$$\sum_{\mathbf{g}} C_{\mathbf{k}\mathbf{g}}\int(\nabla\phi_{t'}{}^{*})(\nabla^2-U)\chi_{\mathbf{k}\mathbf{g}}\,d^3\mathbf{r}$$

$$=\int(\nabla\phi_{t'}{}^{*})(\nabla^2-U)\psi_{\mathbf{k}}\,d^3\mathbf{r}\qquad\text{by equation (7)}$$

$$=\int(\nabla\phi_{t'}{}^{*})(-\mathscr{E}_{\mathbf{k}})\psi_{\mathbf{k}}\,d^3\mathbf{r}$$

$$=\sum_{\mathbf{g}} C_{\mathbf{k}\mathbf{g}}\int(\nabla\phi_{t'}{}^{*})(-\mathscr{E}_{\mathbf{k}})\chi_{\mathbf{k}\mathbf{g}}\,d^3\mathbf{r}.$$

Similarly, the sum of the second term of III and the first term of IV is replaceable by

$$-\frac{1}{\sqrt{N}}\sum_{t} b_{t\mathbf{k}\mathbf{g}}\int\chi_{\mathbf{k}'\mathbf{g}'}{}^{*}(-\mathscr{E}_{\mathbf{k}'})(\nabla\phi_t)\,d^3\mathbf{r}. \tag{28}$$

Expression (27) can be further developed as

$$=\frac{\mathscr{E}_{\mathbf{k}}}{\sqrt{N}}\sum_{t} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}\int(\nabla\phi_{t'}{}^{*})\Big[(N\Omega_0)^{-1/2}\exp\{i(\mathbf{k}+\mathbf{g})\,.\,\mathbf{r}\}-N^{-1/2}\sum_{t} b_{t\mathbf{k}\mathbf{g}}\phi_t\Big]\,d^3\mathbf{r}$$

by equation (5)

$$=-\frac{\mathscr{E}_{\mathbf{k}}}{N}i(\mathbf{k}+\mathbf{g})\sum_{t} b_{t\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}-\frac{\mathscr{E}_{\mathbf{k}}}{N}\sum_{t't} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}\int(\nabla\phi_{t'}{}^{*})\phi_t\,d^3\mathbf{r} \tag{29}$$

by equation (6).
Similarly, expression (28) becomes

$$\frac{\mathscr{E}_{\mathbf{k}'}}{N}i(\mathbf{k}'+\mathbf{g}')\sum_{t} b_{t\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}-\frac{\mathscr{E}_{\mathbf{k}'}}{N}\sum_{t't} b_{t'\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}\int\phi_{t'}{}^{*}(\nabla\phi_t)\,d^3\mathbf{r}. \tag{30}$$

For elastic scattering $\mathscr{E}_{\mathbf{k}}\simeq\mathscr{E}_{\mathbf{k}'}$ (i.e. phonon energy is assumed negligible)

$$\mathrm{II}+\mathrm{III}+\mathrm{IV}=\frac{i}{N}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})\sum_{t}(\mathscr{E}_{\mathbf{k}}-\mathscr{E}_t)b_{t\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}, \tag{31}$$

making use of equations (24), (25) and (29), (30) and the fact that

$$\int(\nabla\phi_{t'}{}^{*})\phi_t\,d^3\mathbf{r}+\int\phi_{t'}{}^{*}(\nabla\phi_t)\,d^3\mathbf{r}=0.$$

Finally, from (21), we get

$$\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}') = -i\mathbf{e}_{\mathbf{q}p}\,.\sum_{\mathbf{g}\mathbf{g}'} C_{\mathbf{k}'\mathbf{g}'}{}^{*}C_{\mathbf{k}\mathbf{g}}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})$$

$$\times\Big[\bar{U}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})+\sum_{t}(\mathscr{E}_{\mathbf{k}}-\mathscr{E}_{t})b_{t\mathbf{k}'\mathbf{g}'}{}^{*}b_{t\mathbf{k}\mathbf{g}}\Big]. \qquad (32)$$

Notice that equation (32) is exact within the limitation of the orthogonalized plane-wave method and in its derivation the assumption for establishing the pseudo-potential, equation (13) has not been invoked. Observe that transverse phonons as well as longitudinal ones contribute to the scattering, even for N-processes (Collins 1961).

§ 4. ELECTRON–PHONON INTERACTION FOR THE EQUIVALENT PLANE WAVES

In the pseudo-potential model, we regard the ions as carrying around their effective potentials $U+U_{\mathrm{R}}$ so that the wave functions of the conduction electrons are given by

$$\phi_{\mathbf{k}} = \sum_{\mathbf{g}} C_{\mathbf{k}\mathbf{g}}(N\Omega_0)^{-1/2}\exp\{i(\mathbf{k}+\mathbf{g})\,.\,\mathbf{r}\} \qquad (33)$$

where $C_{\mathbf{k}\mathbf{g}}$ is given in equation (7). The matrix element is then

$$\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}') = -N\mathbf{e}_{\mathbf{q}p}\,.\int\phi_{\mathbf{k}'}{}^{*}\nabla(U+U_{\mathrm{R}})\phi_{\mathbf{k}}\,d^3\mathbf{r}$$

$$= -i\mathbf{e}_{\mathbf{q}p}\,.\sum_{\mathbf{g}\mathbf{g}'} C_{\mathbf{k}'\mathbf{g}'}{}^{*}C_{\mathbf{k}\mathbf{g}}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})$$

$$\times[\bar{U}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})+\bar{U}_{\mathrm{R}}(\mathbf{k}'+\mathbf{g}'-\mathbf{k}-\mathbf{g})], \qquad (34)$$

following steps similar to those leading to (22).

From equation (14) we conclude that equation (34) is equivalent to equation (32). Thus we have justified the use of the pseudo-potential model in calculating electron–phonon interaction matrix elements. Here it must be emphasized that the corresponding coefficients in the linear combinations of orthogonalized plane waves and plane waves must be the same, namely $C_{\mathbf{k}\mathbf{g}}$ in equation (7), so that when the wave function of the conduction electron is normalized in the expansion of orthogonalized plane waves it will not be so in the expansion of plane waves. This is to be expected since the switch from an orthogonalized plane-wave expansion to a plane-wave expansion is not a one-to-one transformation of two state-vector spaces but only a replacement by a cruder mathematical analogue.

Our analysis does not include any contributions to the electron–phonon interaction arising from charge shift of the conduction electrons. This effect can be taken into account formally by a simple extension of Bardeen's method (Bardeen 1937) but there are some difficult technical points concerning the role of correlation and exchange in such a calculation. This problem is being studied further.

In conclusion, we shall show the relation of our calculation to an older calculation. In the case where the cancellation between the crystal potential and pseudo-potential is nearly complete—i.e. $U+U_{\mathrm{R}}$ is nearly constant in $0 < r < r_{\mathrm{s}}$ and zero outside—

single plane waves are good approximations to the wave functions

$$\begin{aligned}\mathscr{I}_{\mathbf{q}p}(\mathbf{k},\mathbf{k}') &= -i\mathbf{e}_{\mathbf{q}p}\cdot(\mathbf{k}'-\mathbf{k})C_{\mathbf{k}'\mathbf{o}}C_{\mathbf{ko}}\frac{4\pi}{\Omega_0}\int_0^\infty r^2(U+U_{\mathrm{R}})j_0(|\mathbf{k}'-\mathbf{k}|r)\,dr\\ &= -i\mathbf{e}_{\mathbf{q}p}\cdot(\mathbf{k}'-\mathbf{k})C_{\mathbf{k}'\mathbf{o}}C_{\mathbf{ko}}[U(r_{\mathrm{s}})+U_{\mathrm{R}}(r_{\mathrm{s}})]\frac{4\pi}{\Omega_0}\int_0^{r_{\mathrm{s}}} r^2j_0(|\mathbf{k}'-\mathbf{k}|r)\,dr\\ &= -i\mathbf{e}_{\mathbf{q}p}\cdot(\mathbf{k}'-\mathbf{k})C_{\mathbf{k}'\mathbf{o}}C_{\mathbf{ko}}[U(r_{\mathrm{s}})+U_{\mathrm{R}}(r_{\mathrm{s}})]\mathscr{G}(|\mathbf{k}'-\mathbf{k}|r_{\mathrm{s}})\end{aligned}$$

where

$$C_{\mathbf{ko}} = \left(1-\sum_t |b_{t\mathbf{ko}}|^2\right)^{-1/2}.$$

Comparing this result with Mott and Jones' calculation based on the rigid ion model using the Wigner–Seitz method (Ziman 1960, p. 185) we see the similarity of the two expressions. $C_{\mathbf{k}'\mathbf{o}}C_{\mathbf{ko}}[U(r_{\mathrm{s}})+U_{\mathrm{R}}(r_{\mathrm{s}})]$ simply takes the place of $U(r_{\mathrm{s}})-\mathscr{E}_0$ where $\mathscr{E}_0$ is the energy at $\mathbf{k} = 0$.

ACKNOWLEDGMENTS

I am deeply indebted to Dr. J. M. Ziman for suggesting this problem and for constant guidance, and to Dr. V. Heine for many stimulating and helpful discussions. I also wish to thank the Master and Fellows of Churchill College for the award of a Research Studentship.

Excitation of Helium to the (1s, 2p)^{1}P and (1s, 3p)^{1}P States by Proton and Alpha Particle Impact

BY R. J. BELL

Department of Applied Mathematics, The Queen's University of Belfast

MS. received 7th July 1961

Abstract. The distortion approximation is applied to the processes

$$\mathrm{H^+\ (or\ He^{2+}) + He(1s^2)^1S \rightarrow H^+(or\ He^{2+}) + He(1s,\ 2p)^1P}$$
$$\mathrm{H^+\ (or\ He^{2+}) + He(1s^2)^1S \rightarrow H^+(or\ He^{2+}) + He(1s,\ 3p)^1P}$$

cross sections being obtained for incident proton energies in the range 10 kev to 1000 kev and for incident alpha particle energies in the range 40 kev to 4000 kev. For proton impact the maxima cross sections are found to be $0{\cdot}18\pi a_0^2$ and $0{\cdot}035\pi a_0^2$, at 88 kev and 124 kev respectively; and for alpha particle impact they are found to be $0{\cdot}61\pi a_0^2$ and $0{\cdot}101\pi a_0^2$ at 511 kev and 935 kev respectively.

§ 1. INTRODUCTION

BATES (1959) has given reasons for expecting that the effect of distortion on inelastic collisions between heavy systems is greater than might at first be supposed. Detailed calculations on atomic hydrogen (Bates 1959, 1961) confirm this expectation.

It was judged desirable to carry out similar calculations on helium, this being the simplest atom which lends itself readily to experimental study. Accordingly the following processes have been treated:

$$\mathrm{H^+ + He(1s^2)^1S \rightarrow H^+ + He(1s,\ 2p)^1P} \tag{1}$$
$$\mathrm{H^+ + He(1s^2)^1S \rightarrow H^+ + He(1s,\ 3p)^1P} \tag{2}$$
$$\mathrm{He^{2+} + He(1s^2)^1S \rightarrow He^{2+} + He(1s,\ 2p)^1P} \tag{3}$$
$$\mathrm{He^{2+} + He(1s^2)^1S \rightarrow He^{2+} + He(1s,\ 3p)^1P} \tag{4}$$

Atomic units are used throughout the paper.

§ 2. THEORY

Let the target system be situated at the origin of coordinates and let the incident system, with position vector $\mathbf{R}$, move with constant velocity $\mathbf{v}$ in the positive direction along a line distant ρ from the Z axis. It is convenient to choose the zero of time so that $Z = vt$.

The electronic wave function may be represented as

$$\Psi(\mathbf{r}, t) = \sum_m a_m(t)\phi_m(\mathbf{r}) \exp(-i\epsilon_m t) \tag{5}$$

where $\mathbf{r}$ symbolizes the coordinates of electrons, and $\phi_m(\mathbf{r})$ and ϵ_m are the unperturbed eigenfunctions and eigenenergies of the target system in the state indicated by the subscript. The coefficients a_m, as well as being functions of the time, are naturally also dependent upon ρ and v.

Application of time-dependent perturbation theory yields the following set of coupled equations:

$$iv\frac{\partial}{\partial z}a_m(Z) = \sum_s a_s(Z)V_{ms}(\mathbf{R})\exp(-i\alpha_{sm}Z) \tag{6}$$

with

$$\alpha_{sm} = (\epsilon_s-\epsilon_m)/v \tag{7}$$

and

$$V_{ms}(\mathbf{R}) = \int d\mathbf{r}\phi_m{}^*(\mathbf{r})V(\mathbf{r}, \mathbf{R})\phi_s(\mathbf{r}) \tag{8}$$

$V(\mathbf{r}, \mathbf{R})$ being the instantaneous interaction potential. Taking the initial conditions in (6) to be

$$a_0(-\infty) = 1, \qquad a_s(-\infty) = 0 \qquad (s\neq 0) \tag{9}$$

the probability of excitation from state 0 to state m is

$$\mathscr{P}_{0m}(\rho) = |a_m(\infty)|^2 \tag{10}$$

and the cross section describing the transition is given, in units of $\pi a_0{}^2$, by

$$Q_{0m} = 2\int_0^\infty \mathscr{P}_{0m}(\rho)\rho\, d\rho. \tag{11}$$

According to the impact parameter version of the first Born approximation

$$a_m(\infty) = -\frac{i}{v}\int_{-\infty}^{\infty} V_{m0}(\mathbf{R})\left\{\exp\left(-\frac{i}{v}\int_0^Z (\epsilon_0-\epsilon_m)\,dZ\right)\right\}dZ \tag{12}$$

(Frame 1931); and according to the distortion approximation

$$a_m(\infty) = -\frac{i}{v}\int_{-\infty}^{\infty} V_{m0}(\mathbf{R})\left\{\exp\left(-\frac{i}{v}\int_0^Z (\epsilon_0+V_{00}-\epsilon_m-V_{mm})\,dZ\right)\right\}dZ \tag{13}$$

(Bates 1959), in which a complex outside factor of modulus unity has been discarded.

The relationship between the two approximations may be appreciated by observing that ϵ_0 and ϵ_m, the unperturbed eigenenergies appearing in (12), appear in (13) modified by V_{00} and V_{mm}, their first-order corrections under the perturbation $V(\mathbf{r}, \mathbf{R})$. The magnitude of $V_{00}-V_{mm}$ at the origin is about 1·5; for close encounters, at the lowest energy considered, its presence effects a change of the order of π in the phase of the exponential function.† For medium and distant encounters $V_{00}-V_{mm}$ is much smaller than unity and little change of phase is occasioned.

Calculations confirm that, for a selected energy, the effects of distortion upon the probability decrease with increasing impact parameter; and that, for a selected impact parameter, they decrease with increasing energy.

§ 3. CALCULATION AND RESULTS

3.1. *The Atomic Wave Functions*

The ground state of the target system was described by a product of functions

$$\phi(1s^2;\, {}^1S|\mathbf{r}) = \psi_0(\mathbf{r}_1)\psi_0(\mathbf{r}_2). \tag{14}$$

---

† Note that $1/v = 4{\cdot}997(M/E)^{1/2}$ where M is the mass of the incident proton or alpha particle on the ^{16}O scale and E is the energy in kev.

The analytic form of the orbitals

$$\psi_0(\mathbf{r}) = N_0[\exp(-\alpha r)+a\exp(-\beta r)] \tag{15}$$

was originally suggested by Löwdin (1953), who obtained values for the parameters by extrapolation from his results for helium-like ions. The following parameters calculated by Green, Mulder, Lewis and Woll (1954) have been chosen as the more accurate: $\alpha = 1{\cdot}455\,799$, $\beta = 2{\cdot}911\,598$, $a = 0{\cdot}60$.

The form adopted for the eigenfunctions of the excited states was

$$\phi(1\mathrm{s}, n\mathrm{p}; {}^1\mathrm{P}|\mathbf{r}) = \frac{1}{\sqrt{2}}[\psi_1(\mathbf{r}_1)\psi_n(\mathbf{r}_2)+\psi_n(\mathbf{r}_1)\psi_1(\mathbf{r}_2)]. \tag{16}$$

In this case, the orbitals are due to Morse, Young and Haurwitz (1935) and Goldberg and Clogston (1939). Specifically, these orbitals are given by

$$\psi_1(\mathbf{r}) = N_1\exp(-\gamma r) \tag{17}$$

with $\gamma = 2{\cdot}0$,

$$\psi_2(\mathbf{r}) = N_2 r\exp(-\delta r)\cos\theta \tag{18}$$

with $\delta = 0{\cdot}485$

and

$$\psi_3(\mathbf{r}) = N_3 r[r\exp(-\lambda r)+b\exp(-\mu r)]\cos\theta \tag{19}$$

with $\lambda = \mu = 0{\cdot}325$ where N_0, N_1, N_2, N_3 are normalization constants; b is chosen to make $\psi_3(\mathbf{r})$ orthogonal to $\psi_2(\mathbf{r})$.

Using the dipole-length formula, these eigenfunctions give oscillator strengths of 0·259 and 0·0728 for the $(1\mathrm{s}^2)^1\mathrm{S} \rightarrow (1\mathrm{s}, 2\mathrm{p})^1\mathrm{P}$ and $(1\mathrm{s}^2)^1\mathrm{S} \rightarrow (1\mathrm{s}, 3\mathrm{p})^1\mathrm{P}$ transitions respectively. These are in satisfactory agreement with the values, 0·255 and 0·0706, obtained by Low (1959) who described the ground state by the six-parameter eigenfunction due to Hylleraas (1929) and the excited states by the eigenfunctions cited above.

3.2. *Preliminary Analysis*

Some analysis is required to transform (12) and (13) to a form suitable for computation. For the processes considered

$$V(\mathbf{r}, \mathbf{R}) = \mathscr{Z}\left\{\frac{2}{R}-\frac{1}{|\mathbf{R}-\mathbf{r}_1|}-\frac{1}{|\mathbf{R}-\mathbf{r}_2|}\right\} \tag{20}$$

where $\mathscr{Z}$ is the charge on the incident system. Expansion of (20) in spherical harmonics leads to analytical expressions for the matrix elements involved. We may set

$$V_{n\mathrm{p}_0,1\mathrm{s}}(\mathbf{R}) = -\tfrac{1}{2}\mathscr{Z}(\epsilon_{n\mathrm{p}}-\epsilon_{1\mathrm{s}})\frac{Z}{R}\xi_{n\mathrm{p}}(R) \tag{21}$$

$$V_{n\mathrm{p}_{\pm1},1\mathrm{s}}(\mathbf{R}) = -\tfrac{1}{2}\mathscr{Z}(\epsilon_{n\mathrm{p}}-\epsilon_{1\mathrm{s}})\frac{\rho}{R}\xi_{n\mathrm{p}}(R) \tag{22}$$

$$V_{n\mathrm{p}_0,n\mathrm{p}_0}(\mathbf{R})-V_{1\mathrm{s},1\mathrm{s}}(\mathbf{R}) = \mathscr{Z}(\epsilon_{n\mathrm{p}}-\epsilon_{1\mathrm{s}})\left\{\eta_{n\mathrm{p}}(R)+\frac{2Z^2-\rho^2}{R^2}\zeta_{n\mathrm{p}}(R)\right\} \tag{23}$$

$$V_{n\mathrm{p}_{\pm1},n\mathrm{p}_{\pm1}}(\mathbf{R})-V_{1\mathrm{s},1\mathrm{s}}(\mathbf{R}) = \mathscr{Z}(\epsilon_{n\mathrm{p}}-\epsilon_{1\mathrm{s}})\left\{\eta_{n\mathrm{p}}(R)+\frac{2\rho^2-Z^2}{R^2}\zeta_{n\mathrm{p}}(R)\right\} \tag{24}$$

where each state is now labelled according to its highest orbital. Equations (12) and

(13) may then be rewritten to give the Born approximation

$$\mathscr{P}_{1s,np_0} = \left|\alpha_{np}\mathscr{Z}\int_0^\infty \frac{Z}{R}\xi_{np}(R)\sin\alpha_{np}Z\,dZ\right|^2 \qquad (25)$$

$$\mathscr{P}_{1s,np_{\pm1}} = \left|\alpha_{np}\mathscr{Z}\int_0^\infty \frac{\rho}{R}\xi_{np}(R)\cos\alpha_{np}Z\,dZ\right|^2 \qquad (26)$$

and the distortion approximation

$$\mathscr{P}_{1s,np_0} = \left|\alpha_{np}\mathscr{Z}\int_0^\infty \frac{Z}{R}\xi_{np}(R)\sin\alpha_{np}\{Z+B_{np_0}(\mathbf{R})\}\,dZ\right|^2 \qquad (27)$$

$$\mathscr{P}_{1s,np_{\pm1}} = \left|\alpha_{np}\mathscr{Z}\int_0^\infty \frac{\rho}{R}\xi_{np}(R)\cos\alpha_{np}\{Z+B_{np_{\pm1}}(\mathbf{R})\}\,dZ\right|^2 \qquad (28)$$

with

$$\alpha_{np} = \frac{\epsilon_{np}-\epsilon_{1s}}{v} \qquad (29)$$

$$B_{np_0}(\mathbf{R}) = \mathscr{Z}\int_0^Z\left\{\eta_{np}(R)+\frac{2Z^2-\rho^2}{R^2}\zeta_{np}(R)\right\}dZ \qquad (30)$$

and

$$B_{np_{\pm1}}(\mathbf{R}) = \mathscr{Z}\int_0^Z\left\{\eta_{np}(R)+\frac{2\rho^2-Z^2}{R^2}\zeta_{np}(R)\right\}dZ. \qquad (31)$$

$$\epsilon_{2p}-\epsilon_{1s} = 0{\cdot}7797, \qquad \epsilon_{3p}-\epsilon_{1s} = 0{\cdot}8484. \qquad (32)$$

The explicit forms of $\xi_{np}(R)$, $\eta_{np}(R)$ and $\zeta_{np}(R)$ are displayed in the appendix.

3.3. *Numerical Procedure and Presentation of Results*

The work was done with the aid of a high speed computer. Gaussian quadratures were used to evaluate the integrals in (25) to (28) over the range from 0 to Z_0 where Z_0 is such that for $Z \geqslant Z_0$, B_{np_0}, $B_{np_{\pm1}}$ can be taken as constant, and $\xi_{np}(R)$ as proportional to R^{-2}. The range from Z_0 to ∞ remained. Consider

$$\mathscr{I} = \int_{Z_0}^\infty f(Z)\exp(i\alpha Z)\,dZ. \qquad (33)$$

Repeated integration by parts yields the asymptotic series

$$\mathscr{I} = \{-(i\alpha)^{-1}f^{(0)}(Z_0)+(i\alpha)^{-2}f^{(1)}(Z_0)-(i\alpha)^{-3}f^{(2)}(Z_0)+ \dots +(-i\alpha)^{-p-1}f^{(p)}(Z_0)+\dots\}\exp(i\alpha Z_0) \qquad (34)$$

where bracketed superscripts refer to differentiation with respect to Z. For $Z \geqslant Z_0$, successive derivatives of $(Z/R)\xi_{np}(R)$ or $(\rho/R)\xi_{np}(R)$ may be computed by recurrence relations based on the properties of Legendre polynomials. This possibility is due to the original expansion of $V(\mathbf{r}, \mathbf{R})$ in spherical harmonics. The method is applicable for all transitions. In the present case, it yields a series whose terms decrease until p exceeds αZ_0. If the series is truncated before this point is reached, an approximation to $\mathscr{I}$ is obtained which is correct to the order of magnitude of the last term retained.

The results, reckoned to be accurate to within 0·5%, are presented: in diagrams (*a*) to (*f*) as graphs of Q_{0m} against E (E is the energy of the ion, in kev, the target system being taken as fixed); in diagrams (*g*) to (*n*) as graphs of the coefficients $\boldsymbol{a}_m(\infty)$ against

ρ for selected values of E; and in diagrams (*o*) to (*r*) as graphs of $a_m(\infty)$ against E for selected values of ρ. Curves for processes (3) and (4) are superimposed on a suitably reduced scale for ease of comparison.

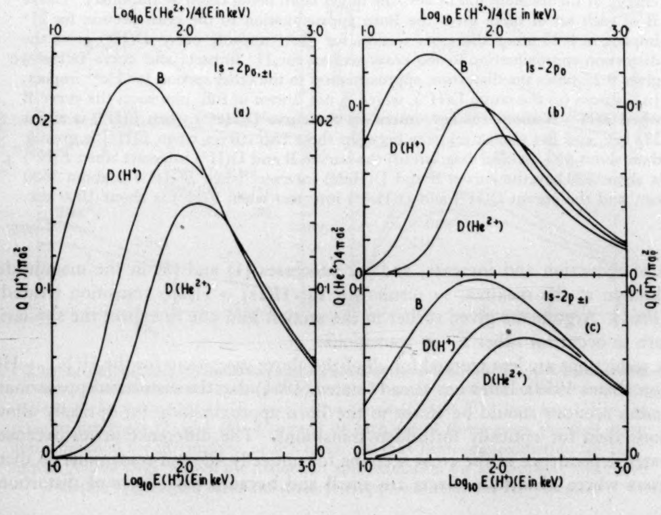
§ 4. DISCUSSION OF RESULTS

Some effects of distortion are understandable from a knowledge of $B_{n\mathrm{p}_0}$ and $B_{n\mathrm{p}_{\pm1}}$. These quantities are comparable with Z near the origin, becoming much smaller than unity for distant encounters. Both are positive with the exception that $B_{n\mathrm{p}_{\pm1}}$ becomes negative for very distant encounters, for which the conclusions drawn below must be reversed.

At low energies the presence of $B_{n\mathrm{p}_0}$ and $B_{n\mathrm{p}_{\pm1}}$ accentuates the already sharp oscillation of the trigonometric functions in the integral, reducing probabilities and cross sections.

At high energies, the presence of $B_{n\mathrm{p}_0}$ shifts the first peak of the sine function closer to the origin. For small ρ the peak is moved closer to, and for large ρ farther from, the maximum of $(Z/R)\xi_{n\mathrm{p}}(R)$, thus successively increasing or decreasing the integral; and, since the effects of distortion and the probabilities themselves both diminish with increasing ρ, the cumulative effect should be to increase the 1s–$n\mathrm{p}_0$ cross sections. The presence of $B_{n\mathrm{p}_{\pm1}}$, by hastening the initial decay of the cosine function, decreases the magnitude of the corresponding integral. It is doubtful whether the reverse behaviour shown for very distant encounters will ever compensate sufficiently to prevent the 1s–$n\mathrm{p}_{\pm1}$ cross sections from being smaller than those given by the Born approximation.

Although distortion reduces the maximum cross sections for processes (2) and (4) more than those for processes (1) and (3), it has not been possible to make any detailed predictions concerning excitation to higher p states. The results are similar in their



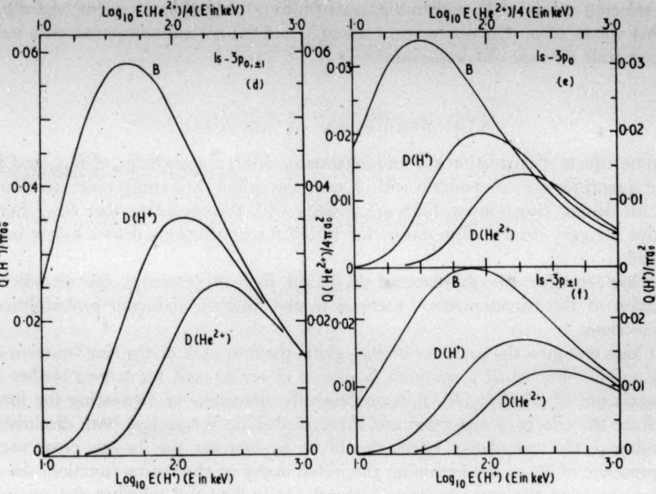


Figure 1. First Born and distortion approximations to the cross sections for:

(*a*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 2p_{0\pm1})^1P$,
(*b*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 2p_0)^1P$,
(*c*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 2p_{\pm1})^1P$,
(*d*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 3p_{0\pm1})^1P$,
(*e*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 3p_0)^1P$,
(*f*) $H^+(\text{or } He^{2+}) + He(1s^2)^1S \rightarrow H^+(\text{or } He^{2+}) + He(1s, 3p_{\pm1})^1P$,

plotted against $\log_{10}E$ for H^+ impact, or $\log_{10}E/4$ for He^{2+} impact where E is the energy of the incident ion in kev, the target atom being taken as stationary. Curve B of each set of three gives the Born approximation to the cross section for H^+ impact, or 0·25 times the cross section for He^{2+} impact; curve D(H^+) gives the distortion approximation to the cross section for H^+ impact; and curve D(He^{2+}) gives 0·25 times the distortion approximation to the cross section for He^{2+} impact. In diagram (*a*) the curve D(H^+), which is not drawn in full, intersects the curve B when $E(H^+)$ is about 165 kev, intersects the curve D(He^{2+}) when $E(H^+)$ is about 255 kev, and lies almost midway between these two curves when $E(H^+)$ is greater than about 450 kev. In diagram (*d*) the curves B and D(H^+) intersect when $E(H^+)$ is about 750 kev, the curves B and D(He^{2+}) intersect when $E(He^{2+})$ is about 3600 kev, and the curves D(H^+) and D(He^{2+}) intersect when $E(H^+)$ is about 1000 kev.

pattern of reduction and increase, and for processes (1) and (3) in the magnitude of the reduction at the maxima, to results for the H(1s) → H(2p) transition treated by Bates (1961). Arguments given earlier in the section lead one to expect the similarities in pattern to occur for other s → p transitions.

The reductions are less marked for all of the above cases than for the H(1s) → H(2s) transition (Bates 1959). Bates has already stated (1961) that the distortion approximation to the cross sections should be closer to the Born approximation for optically allowed transitions than for optically forbidden transitions. The difference arises because of the greater dependence of the cross sections for optically allowed transitions on distant encounters where distortion effects are small and because the effects of distortion at

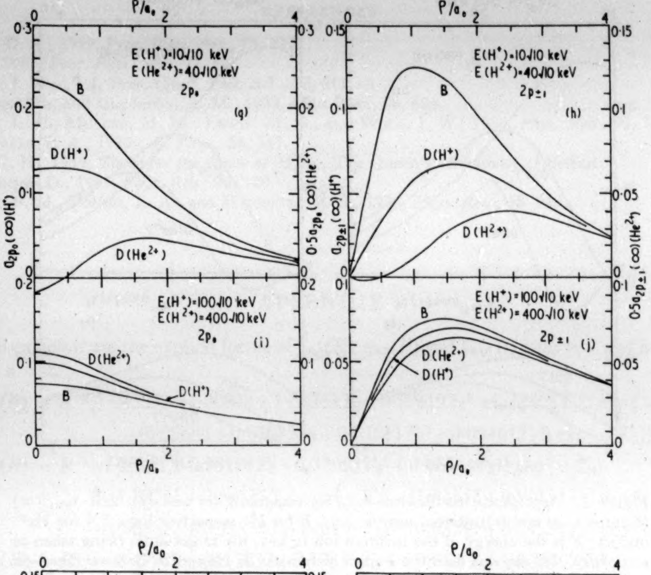

Figure 2. Asymptotic coefficients $a_{np_0}(\infty)$ (diagrams on left) and $a_{np_{\pm1}}(\infty)$ (diagrams on right) plotted against impact parameter ρ. The energy of the incident ion is as indicated. Diagrams (*g*) to (*j*) refer to processes (1) and (3); diagrams (*k*) to (*n*) refer to processes (2) and (4). Curve B of each set of three gives the first Born approximation for H⁺ impact, or 0·5 times the first Born approximation for He²⁺ impact; curve D(H⁺) gives the distortion approximation for H⁺ impact; and curve D(He²⁺) gives 0·5 times the distortion approximation for He²⁺ impact.

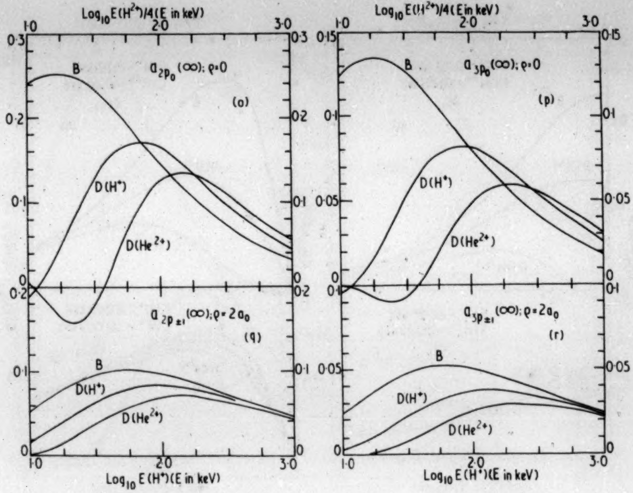

Figure 3. Asymptotic coefficients $\boldsymbol{a}_{n\mathrm{p}_0}(\infty)$ (diagrams (*o*) and (*p*)) and $\boldsymbol{a}_{n\mathrm{p}_{\pm 1}}(\infty)$ (diagrams (*q*) and (*r*)) plotted against $\log_{10} E$ for H^+ impact or $\log_{10} E/4$ for He^{2+} impact; *E* is the energy of the incident ion in kev, the target atom being taken as stationary. In the $n\mathrm{p}_0$ case the impact parameter is chosen to be zero (head-on collision) and in the $n\mathrm{p}_{\pm 1}$ case it is chosen to be $2a_0$. Diagrams (*o*) and (*q*) refer to processes (1) and (3); diagrams (*p*) and (*r*) refer to processes (2) and (4). The designations on the curves are as in the preceding figure.

high energies are in opposite senses for the two components of the transition so that cancellation occurs.

Since excitation probabilities for processes (1) to (4) are small,† the neglect of back-coupling should not have led to serious inaccuracy. Recent calculations by Skinner (1962, to be published) indicate that the effect of $n\mathrm{p}_0$–$n\mathrm{p}_{\pm 1}$ coupling is also unimportant. The results may, however, require modification at low energies to allow for the resonance capture processes

$$\mathrm{He}^{2+} + \mathrm{He}(1\mathrm{s}^2)^1\mathrm{S} \rightarrow \mathrm{He}(1\mathrm{s}^2)^1\mathrm{S} + \mathrm{He}^{2+}$$

$$\mathrm{He}^{2+} + \mathrm{He}(1\mathrm{s}, n\mathrm{p})^1\mathrm{P} \rightarrow \mathrm{He}(1\mathrm{s}, n\mathrm{p})^1\mathrm{P} + \mathrm{He}^{2+}$$

and to a lesser extent, to allow for the various non-resonance capture processes which are possible. The cross sections may also be influenced by the effect of polarization.

ACKNOWLEDGMENTS

The author has pleasure in thanking Professor D. R. Bates for suggesting this problem and for his continued assistance throughout the course of the work.

This research has been supported by the Air Force Cambridge Research Center, Geophysics Research Directorate, of the Air Research and Development Command, U.S. Air Force, through its European Office, under Contract No. AF61(052)–131.

---

† $\mathscr{P}_{1\mathrm{s},n\mathrm{p}_0}$, $\mathscr{P}_{1\mathrm{s},n\mathrm{p}_{\pm 1}}$ do not exceed 0·03 for proton impact and 0·08 for alpha particle impact.

The Radiative Capture of Protons by Neutrons at 50 MeV

By N. C. BARFORD, R. B. PALMER AND B. TALLINI†

Imperial College, London

MS. received 31*st May* 1961

Abstract. By using an internal lithium deuteride target in the Harwell cyclotron, and 'hardening' the resulting scattered neutrons with polythene, a low intensity beam of neutrons with an energy peak at 50 MeV was produced. This beam passed through a 9 cm hydrogen bubble chamber and produced in it reactions of the type

$$n+p \rightarrow d+\gamma$$

which were distinguished by the range–angle distribution of the deuterons from the background of elastic n–p scatters. A cross section of 110 ± 60 μbn was found for the process.

§ 1. INTRODUCTION

No MEASUREMENTS of the cross section for the radiative capture of neutrons by protons,

$$n+p \rightarrow d+\gamma,$$

have previously been made except at thermal energies (Stooksberry and Crouch 1959). The inverse process of photodisintegration of deuterium has been investigated for protons of a wide range of energies (for example Allen 1955), and, from these results, using detailed balance arguments, one may predict the capture cross section to be 20 ± 4 μbn for 50 MeV neutrons (Palmer 1960).

A neutron experiment of such low cross section is feasible even with quite small bubble chambers, because of the absence of beam tracks in the chamber. It was found in preliminary proton experiments with the Imperial College 9 cm hydrogen chamber that simple nuclear reactions could be observed and measured against a background of about 20 beam proton tracks crossing the chamber. For the neutron capture experiment there are, of course, no beam tracks and the only significant background is caused by those proton tracks arising from elastic n–p scatters. At 50 MeV the cross section for this is 155 mbn, from which one may show that up to about 500 neutrons per pulse could be allowed to enter the chamber before the scattered proton tracks would give a background equivalent to the 20 beam protons found permissible in the preliminary experiments.

Hence, to observe 100 neutron captures, 36 000 photographs (stereo-pairs) would be required. We may note that a proton experiment of the same cross section would require 900 000 photographs.

§ 2. THE NEUTRON BEAM

The experiment would be best performed with a parallel monoenergetic beam of neutrons. At 50 MeV these would form deuterons giving tracks in the liquid hydrogen of length 3 cm at angles up to 5° to the beam direction (Palmer 1960). These tracks would be easily observed and distinguished from those of knocked-on protons of the same angular spread whose range would exceed 15 cm.

---

† Now at the Department of Physics, Birmingham University.

Such a neutron beam could be obtained from a thin deuterium target placed in an external proton beam of adequate flux. Unfortunately, this method was impracticable at the Harwell cyclotron.

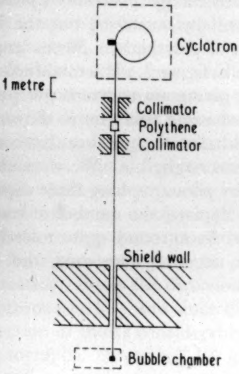

Figure 1

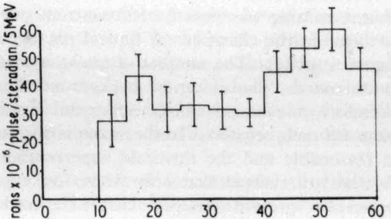

Figure 2

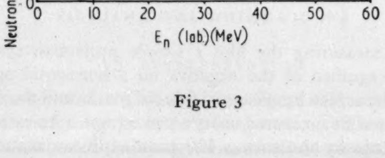

Figure 3

Instead, a lithium deuteride target was used in the circulating beam and neutrons were taken off tangentially (see figure 1). These neutrons were far from monoenergetic. Firstly, the neutrons from the lithium in the lithium deuteride have a wide energy spread, even when the incident protons have a precise energy. Secondly, these protons do in fact have an energy spread of 15–20 MeV caused by radial oscillations in the circulating beam and energy losses in the target itself, which increases with target thickness. A target 20 mm thick was chosen as giving the best compromise between overheating the lithium deuteride and unduly degrading the incident proton energy.

With a circulating beam intensity of approximately 10^{10} protons per pulse the total forward neutron intensity was approximately 4×10^8 neutrons per steradian. The energy spectrum of these neutrons is shown in figure 2. Since the flux was in excess of what the chamber could utilize it was possible to sharpen this energy spectrum by passing the beam through hydrogenous material, thus preferentially scattering out the low energy neutrons. After some trials with various lengths of polythene, a 50 cm length was chosen. The resultant 'hardened' spectrum is shown in figure 3. The total forward flux remaining was then 2×10^7 neutrons per steradian, giving six neutrons per pulse per cm^2 in the chamber. A typical photograph obtained using this flux is shown in figure 4 (plate). The number of tracks is small and well below the number that could be tolerated. The unwanted background illumination was negligible. We were able, therefore, to economize both in film and scanning effort by photographing three expansions on each negative. In the example shown in figure 5 (plate) the number of tracks is reasonable and the threefold superposition of optical background quite tolerable. A trial run showed that only when five exposures per negative were used, did the optical background seriously obscure the tracks.

§ 3. CHAMBER OPERATION AND PHOTOGRAPHY

Beam pulses of 100 μsec duration were obtained from the Harwell cyclotron at a rate of 100 per second. This repetition rate was far too great to be matched by the bubble chamber and its camera, which were operated conveniently at 20 cycles per minute. An electronic gating system (Palmer 1960) was used to lock the chamber expansion and photography to one in approximately every 300 of the cyclotron pulses. To avoid the overheating and consequent decomposition of the lithium deuteride target by the unwanted proton pulses, the cyclotron was set to accelerate protons only for a few pulses around the one photographed.

Photographs were taken as stereo pairs on a single reel of 35 mm film, using Dallmayer 'Serrac' 3 in. lenses. These were 30 cm from the chamber and provided a stereo angle of 15° and demagnification of 1 : 3. With a Siemens SF 7 light source, using 20 joules per flash at 4 kv, good quality photographs were obtained after a bubble growth time of 1 msec.

§ 4. SCANNING AND ANALYSIS

For scanning and measuring the film a simple projection system was used that gave an image 20 × magnified of the negative on a horizontal opaque screen. This image was located on the screen by means of fiducial marks and the cartesian coordinates of the ends of the tracks were measured using a pantograph. An estimate of the accuracy of the method was made by measuring 100 proton–proton scatters, whose included angle should be 90°. The overall error, after three-dimensional reconstruction, was found to be equivalent to a measurement error of 10 μ on the film or to an uncertainty of 0·3° in the direction of a 3 cm track in the chamber.

In order to determine the neutron spectrum 100 pairs of negatives were selected from the beginning and end of the film, and every track on these was measured without any attempt to identify corresponding pairs in the two stereo views. The coordinates of the ends of the tracks were typed directly on to punched tape; this was later fed into a MERCURY computer, which identified corresponding tracks and reconstructed them in space. A single track image could be measured and typed out in a minimum of 10 seconds and an average of 15 seconds. From the reconstructed tracks, we selected only those satisfying the following conditions: firstly they were required to lie in a rectangular volume 5·6 cm × 7·7 cm × 5·6 cm, which was visible to both cameras; secondly the event represented by the track must have been caused by a beam neutron which, apart from passing through the 6 mm aluminium wall of the bubble chamber vacuum tank, had passed only through the 3 mm copper wall of the chamber itself.

Because of the very small cross section, only one in 7000 of the selected tracks represented a neutron capture event; the rest were scattered protons. It was thus legitimate, in determining the neutron spectrum, to take all tracks to be protons and to calculate an energy distribution of the corresponding neutrons, using known cross sections for elastic n–p scattering (P. H. Bowen *et al.*, to be published). A correction factor, which arose from the restricted selection of proton tracks, was calculated exactly as a function of energy and was then applied to this distribution to give the true neutron energy spectrum, shown in figure 3.

Four thousand pairs of photographs were examined for examples of deuteron formation. Since the directions of deuteron tracks make only small angles with beam neutrons (see § 3), and since the beam was well collimated, we were able to restrict the selection of tracks considerably. Only those were chosen whose images, in both stereo photographs, lay within 10° of the beam direction. This did, however, involve the identification of corresponding images during the scanning. This criterion selects all tracks whose directions in space are within 10° of the beam, as well as a readily calculable proportion of those at greater angles. Consequently, we were able to construct an angular distribution of tracks up to about 30°.

If, as will be shown in § 5, most of these tracks are caused by protons arising from elastic n–p scatters, we would expect the main angular distribution to show a constant number of tracks per steradian (in the centre-of-mass system) at all angles. To show deviation from this we have accordingly divided the number of tracks in each angular interval by $d\Omega_{\text{c.m.}} = 4\pi \sin 2\theta_{\text{lab}}\, d\theta_{\text{lab}}$ to give the distributions shown in figures 6 (*a*, *b* and *c*). The track length ranges of 0·8–1·8 cm, 1·8–3·1 cm, and 3·1–4·8 cm used for these distributions correspond to energies E_N (lab.) of 10–15 MeV, 15–20 MeV and 20–25 MeV respectively, where E_N (lab.) is that energy of a neutron in the laboratory frame of reference which would elastically scatter a proton having the observed track length. The corresponding values of neutron energy $E_N{}^D$ (lab.), which would give deuterons in these range intervals are 27–40 MeV, 40–54 MeV, 54–67 MeV.

§ 5. INTERPRETATION

Restricting the discussion for the moment to figure 6(*b*), we can say that particles giving the tracks may arise in one of the following ways. (i) They are deuterons formed by collimated beam neutrons in the energy interval 40–54 MeV; figure 3 shows that this interval accounts for about 50% of all beam neutrons. (ii) They are protons knocked-on by collimated beam neutrons in the energy interval 15–20 MeV; this includes only 1% of all beam neutrons. (iii) They are protons knocked-on by neutrons not in the collimated beam, which have been scattered out of the beam by the hydrogen or other parts of the apparatus. (iv) They are deuterons formed from such scattered neutrons.

(v) They are charged particles of any kind from interactions of beam neutrons with impurities in the liquid hydrogen.

We should expect the intensity only of the deuterons in category (i) to vary rapidly with angle, since they will all be concentrated within 5° of the beam direction. The intensities of the particles in all the other categories should vary only slowly up to about 30°. Moreover, since the cross section for deuteron production is so small, the deuterons of category (iv) will be negligible in comparison with the protons of category (iii) and, since the impurities in the hydrogen are small (~ 0·02% deuterium, for example), particles of category (v) will be negligible in comparison with the protons of category (ii). Consequently, we may expect to see an angular distribution of tracks which varies only slowly up to 30°, arising almost entirely from protons, on which is superimposed a peak below about 5°, caused by deuterons.

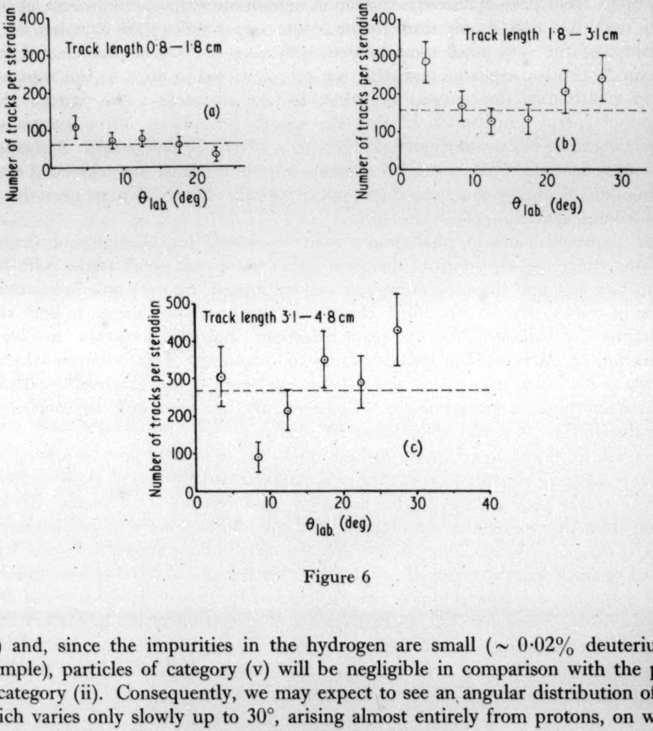

Figure 6

The presence of such peaks is evident in figures 6 (*a*, *b* and *c*). One might construct for each histogram a curve through all the points except the first, extrapolate this to the left, and subtract it from the experimental value at the smallest angle to give the magnitude of the peak there. On this basis, for example, practically all the tracks shown at 3·5° in figure 6(*c*) would represent deuterons. However, no reasonable explanation has been found for the distribution of proton tracks in the range $0 < \theta_{\text{lab}} < 30°$ to differ by more than a few per cent from that given by isotropic scattering in the centre-of-mass system. Assuming isotropy, the proton background averaged from the observations is shown as the dotted line in each figure. The resulting estimates of the numbers of neutron captures in each energy range are given in the following table, together with the number of elastic n–p scatters. From these and the cross sections for n–p scattering (P. H. Bowen *et al.*, to be published), the capture cross sections were derived.

Neutron energy (MEV)	27–40	40–54	54–67
Elastic n–p cross section (mbn)	265	170	130
Number of elastic scatters	16 800	31 800	21 700
Number of neutron captures	8 ± 5	20 ± 10	7 ± 15
Capture cross section (μbn)	126 ± 80	107 ± 50	42 ± 90

A weighted mean of these gives for the neutron capture cross section the value 110 μbn over the range of neutron energies considered, with a statistical error of ± 45 μbn. When the effects of other errors, such as those due to uncertainty in the neutron spectrum, are included, we obtain a final value for the cross section of 110 ± 60 μbn. This appears rather high, but the errors are such that no definite discrepancy with theory can be asserted.

In spite of the limited number of photographs examined, the present work establishes the value of the hydrogen bubble chamber for neutron experiments. Events with a cross section in the 10–100 μbn region can be studied with good statistical accuracy using less than 50 000 photographs.

ACKNOWLEDGMENTS

We are especially indebted to Mr. B. Rose for suggesting this as an experiment to be carried out at the Harwell cyclotron, and for generously providing us with the necessary facilities. Mr. Phillips gave valuable assistance on the theoretical aspects of the problem.

Most members of the Bubble Chamber Group at Imperial College helped to operate the bubble chamber; in this connection we wish particularly to thank Mr. D. L. Reed and Dr. I. Butterworth.

The work was carried out with the support of a Department of Scientific and Industrial Research Special Research Award and, in the case of one of us (R.B.P.), a Research Studentship from the Department of Scientific and Industrial Research.

PROC. PHYS. SOC., 1961, VOL. 78

On the Momentum Spectrum of Cosmic-ray Muons at Sea Level

By A. L. RODGERS†

Department of Physics, University of Manchester

MS. received 18*th April* 1961, *in revised form* 31*st May* 1961

Abstract. The Manchester spectrum of muons arriving vertically at sea level is discussed in terms of the processes leading to the formation of the sea-level hard component of cosmic radiation. Evidence is presented to show that above a momentum of 20 GeV/c there are particles, probably muons, at sea level which cannot be explained in terms of π–μ decay only.

§ 1. INTRODUCTION

THE Manchester cosmic-ray spectrograph, described by Hyams *et al.* (1950) and Holmes *et al.* (1961a), has been used to measure the momentum spectrum of single muons arriving vertically at sea level in the East–West plane at a latitude of 57 °N. The results are described by Owen and Wilson (1955) and Holmes *et al.* (1961b); together they form a continuous momentum spectrum from 0·5 GeV/c to an upper limit in the region of 1000 GeV/c.

In order to ascertain how far a single π–μ decay mechanism explains the observed sea-level variation of muon intensity with momentum, the measured sea-level momentum spectrum is compared with one derived from the accepted primary proton spectrum, the Fermi–Landau multiplicity model and a first-order process to describe the diffusion of the mesonic component in the atmosphere. Information is obtained on the primary collision in the primary energy range 10^3 to 10^4 GeV from the comparison in the sea-level momentum range 50 to 500 GeV/c.

It is assumed that the momentum variation in the sea-level spectrum may be adequately defined by the primary proton spectrum alone, the primary charge spectrum, in terms of energy per nucleon, remaining constant with energy. It is however known that the primary alpha-particle spectrum may fall more rapidly with energy than does the proton spectrum. The effect on the conclusions of this investigation is to increase the observed insufficiency of a single π–μ decay process to explain the measured sea-level spectrum at high momentum.

From considerations of the shape of the primary proton spectrum and Fermi–Landau theory of secondary particle production it is expected that beyond a secondary momentum of 5 GeV/c the contribution to the muon generation spectrum from non-primary nucleons and parent mesons other than those arising directly from the primary nucleon–nucleon collision is small, and accordingly, only primary nucleons and first generation mesons are considered. It is expected that the error introduced by this assumption is 3% at 5 GeV and decreases rapidly with increase in energy. The proposal is to some extent substantiated by the fact that the observed maximum in the sea-level charge ratio of muons, which is interpreted as ending the influence of secondary processes, is not much different from 5 GeV/c.

---

† Now at Atomic Weapons Research Establishment, Aldermaston, Berks.

Because the investigation is indirect the conclusions are subject to the confidence which may be placed in the parameters which occur in the processes leading to the sea-level component. It would seem, however, that the low statistics in present direct observations limit the usefulness of the information which may be gained from them and that a continuous description of the energy dependence in the characteristics of the primary collision may only be afforded by indirect observations of the present type.

§ 2. THE CALCULATED SEA-LEVEL MOMENTUM SPECTRUM

2.1. *The Pion Spectrum at Production derived from the Primary Proton Spectrum*

The pion spectrum at production is determined from the accepted primary proton spectrum. The experimental primary spectrum is taken from Barrett *et al.* (1952), the slope s of the integral proton spectrum being given by

$$s = 1{\cdot}35 + 0{\cdot}04 \ln \frac{E_{\mathrm{p}}}{3{\cdot}2 \times 10^{9}} \tag{1}$$

for $E_{\mathrm{p}} \gg 10^9$ ev where E_{p} (ev) is the proton energy.

It is assumed that high-energy pions are created according to the Fermi–Landau theory of multiple meson production, i.e. the mean number n of pions produced in the primary collision is given by

$$n = kE_{\mathrm{p}}^{1/4} \tag{2}$$

of average energy $E_\pi = KE_{\mathrm{p}}^{3/4}$.

The constant of proportionality in equation (2) is determined by making use of Barrett's observation that muons of mean energy 800 GeV are associated with primaries of mean energy 4×10^4 GeV, viz.

$$E_{\mathrm{p}} = 8{\cdot}62 \times 10^{10} \left(\frac{E_\pi}{10^{10}}\right)^{4/3}.$$

For a multiplicity process which varies as the fourth root of the primary energy the exponent r of the pion production integral spectrum is related to s by

$$\begin{aligned} r &= \frac{s-\frac{1}{4}}{1-\frac{1}{4}} \\ &= 1{\cdot}65 + 0{\cdot}07 \ln\left(\frac{E_\pi}{10^{10}}\right) \end{aligned} \tag{3}$$

where E_π is measured in ev.

The differential momentum spectrum at production $S'(\pi, \mathrm{p})$ of the pions is accordingly given by

$$S'(\pi, \mathrm{p})\, dp_\pi = (2{\cdot}65 + 0{\cdot}33 \log p_\pi) \exp[-6{\cdot}1 \log p_\pi + 0{\cdot}38(\log p_\pi)^2]\, dp_\pi \tag{4}$$

where p_π(ev/c) is the momentum of the pion.

2.2. *The Sea-level Spectrum in terms of π–μ Decay only*

An exact analysis leads to a diffusion equation of extreme complexity and the following determination is regarded as a close approximation.

The depth of the atmosphere is taken to be 1000 g cm^{-2} and it is assumed that pions are produced at a unique pressure level of 100 g cm^{-2} below the top of the atmosphere by the total absorption of the primary proton component of geometrically nuclear interaction cross section. Duperier (1951) has shown that such an assumption leads to only a small error in the numbers of mesons surviving to sea level. It is expected that the maximum effect in the whole of the momentum range investigated is less than 10%, the discrepancy being greater at low momentum.

It is assumed that the momentum of the muon is always 0·8 of that of the parent pion and that the subsequent rate of energy loss for muons in excess of 1 GeV is 2·2 MeV g^{-1} cm^2.

In the absence of a suitable computer at the time of calculation the process of meson diffusion was treated numerically, the lower 900 g cm^{-2} of the atmosphere being divided into nine equal homogeneous layers, of density corresponding to that of the mean depth of the layer. The variation in density with depth for the Standard Atmosphere is taken from Rossi (1948). This method is considered to be sufficiently accurate in view of the overall uncertainties involved in the analysis.

The rate of capture of pions in the incremental layer dZ g cm^{-2} is proportional to $1/\lambda_\pi$ where λ_π is the pion nuclear interaction length in air. The rate of decay of pions in dZ g cm^{-2} is proportional to $1/L$ where L is the mean range before decay and is equal to $5{\cdot}13 \times 10^{-6}\, p_\pi$ cm for pions of momentum p_π ev/c.

For a layer of atmosphere of mean density $\bar{\rho}$ g cm^{-3} bounded between the depths Z_1 and Z_2 g cm^{-2} the number of pions interacting in the incremental layer dZ g cm^{-2}, distance Z g cm^{-2} from Z_1, is $N(\pi, Z)\, dZ/\lambda_\pi$, and the number decaying is $N(\pi, Z)\, dZ/L\bar{\rho}$ where $N(\pi, Z)$ is the number of pions surviving at depth Z g cm^{-2}.

The fraction of pions lost by decay and interaction is therefore given by

$$-\frac{dN(\pi, Z)}{N(\pi, Z)} = \left(\frac{1}{\lambda_\pi} + \frac{1}{L\bar{\rho}}\right) dZ. \tag{5}$$

The number of pions surviving at Z_2, $N(\pi, Z_2)$, is found by integrating between the limits Z_1 and Z_2:

$$N(\pi, Z_2) = N(\pi, Z_1) \exp\left[-(Z_1 - Z_2)\left(\frac{1}{\lambda_\pi} + \frac{1}{L\bar{\rho}}\right)\right]. \tag{6}$$

The pion spectrum at sea level is found by using equation (6) to determine the fraction of pions surviving at the lower boundary of successive homogeneous layers. In terms of the production spectrum $S'(\pi, \mathrm{p})$ the sea level spectrum $S(\pi)$ is

$$S(\pi) = S'(\pi, \mathrm{p}) \exp\left[-100\left(\frac{9}{\lambda_\pi} + \frac{1}{L}\sum_{i=1}^{i=9} \frac{1}{\bar{\rho}_i}\right)\right] \tag{7}$$

where $\bar{\rho}_i$ is the mean density of the ith layer.

The survival probability $P(\pi)$ is, from equation (7),

$$P(\pi) = \frac{S(\pi)}{S'(\pi, \mathrm{p})} = \exp\left[-\left(\frac{900}{\lambda_\pi} + \frac{3{\cdot}1 \times 10^{11}}{p_\pi + p_0}\right)\right] \tag{8}$$

where $p_0 = 2{\cdot}2 \times 10^9$ ev/c.

Numerical analysis shows that, due to the competing processes of interaction and decay, $S(\pi)$ passes through a maximum at $p_\pi = 100$ GeV/c, the absolute value of intensity being dependent on the magnitude of the 'constant' pion cross section for nuclear interaction.

The production spectrum of muons is determined by considering the contribution $dN(\mu, dZ)$ from an incremental layer dZ g cm^{-2}:

$$dN(\mu, dZ) = N(\pi, Z)\frac{dZ}{L\bar{\rho}}$$

where

$$N(\pi, Z) = N(\pi, Z_1) \exp\left[-(Z_1 - Z)\left(\frac{1}{\lambda_\pi} + \frac{1}{L\bar{\rho}}\right)\right]. \tag{9}$$

The number, $N(\mu, Z_1, Z_2)$, of muons produced by the decay of pions in the layer $(Z_1 - Z_2)$ g cm^{-2} is obtained by integrating equation (9) between the limits Z_1 and Z_2 g cm^{-2}:

$$N(\mu, Z_1, Z_2) = \frac{N(\pi, Z_1)}{1 + (L\bar{\rho}/\lambda_\pi)}\left[1 - \exp\left\{-(Z_1 - Z_2)\left(\frac{1}{\lambda_\pi} + \frac{1}{L\bar{\rho}}\right)\right\}\right]. \tag{10}$$

Rewriting equation (10) in terms of the probability function $P'(\mu)_i$, the muon production spectrum $S'(\mu)_i$ in the ith atmospheric layer is

$$P'(\mu)_i = \frac{S'(\mu)_i}{S'(\pi, \mathrm{p})} = \exp\left[-100\left\{\frac{i-1}{\lambda_\pi} + \frac{1}{L}\sum_{r=1}^{r=i}\frac{1}{\bar{\rho}_i}\right\}\right]\left\{1 - \exp\left[-100\left(\frac{1}{\lambda_\pi} + \frac{1}{L\bar{\rho}_i}\right)\right]\right\}. \tag{11}$$

The sea-level muon spectrum is found by summing equation (11) for the nine homogeneous atmospheric layers and correcting for μ–e decay. The sea-level muon spectrum $S(\mu)$, derived from considerations of the pion component only, and a single decay mechanism, is given by

$$S(\mu) = \sum_{i=1}^{i=9} S'(\mu)_i p(\mu) \tag{12}$$

where $p(\mu)$ is the probability of μ–e decay and is given by

$$p(\mu) = \exp\left[-\frac{100}{M}\sum_{r=1}^{r=i}\frac{1}{\bar{\rho}_i}\right]. \tag{13}$$

M is the mean range before decay of muons whose sea-level momentum is 0·8 that of the parent pion, less the momentum lost by ionization in traversing the residual amount of atmosphere to sea level.

§ 3. DISCUSSION AND CONCLUSIONS

The probability functions (8), (11) and (13) are displayed in figures 1, 2 and 3 respectively. Figure 4 shows the calculated ratio of pion flux to muon flux at sea level with momentum on the assumption of a single π–μ decay mechanism. In the absence of information on the interaction of very high energy pions the expected variations appropriate to a pion nuclear interaction cross section of geometric and 0·3 geometric are shown, the corresponding curves being denoted A and B respectively.

It would seem unlikely, however, that the pion is a weakly interacting particle at higher energies, and the discussion is confined mainly to the expectations realized by a nuclear geometrical interacting pion.

The sea-level spectrum $S(\mu, \pi)$ composed of pions and muons only, and derived from the sum of equations (7) and (12) relevant to a constant pion cross section of

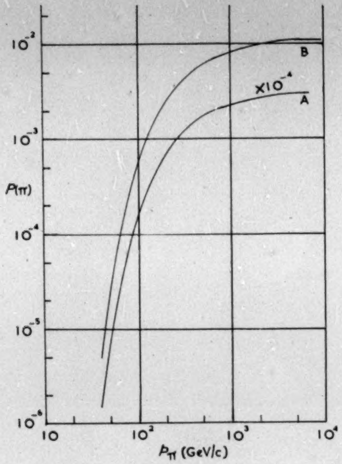

Figure 1. Pion survival probability to sea level.

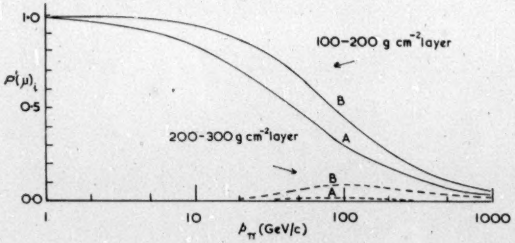

Figure 2. Muon production per layer expressed as a fraction of the muon production spectrum.

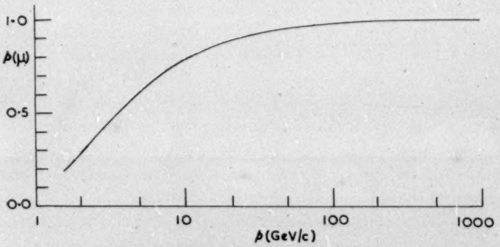

Figure 3. Muon survival probability to sea level.

nuclear geometric, is compared with the measured sea-level spectrum $S(p)$ in figure 5.

For ease of comparison with other workers it is convenient to relate the evidence to the production level. Thus figure 6 shows $S'(\pi, \mathrm{p})$, the pion spectrum derived from the primary proton component, together with $S'(\pi, \mathrm{s})$, the spectrum derived from the measured sea-level spectrum $S(\mathrm{p})$ and the first-order diffusion model. There is good agreement over the momentum range 4 GeV/c to 20 GeV/c. Between 6 GeV/c and 20 GeV/c the two spectra agree to within 1% and at 4 GeV/c the discrepancy is 5%, which is to be expected from the approximations used in the analysis. A comparison of $S'(\pi, \mathrm{p})$ with the results of Puppi (1956) shows good agreement from 3 GeV/c to his upper limit of 40 GeV/c.

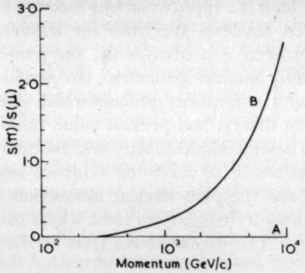

Figure 4. Ratio of pions to muons at sea level from π–μ decay.

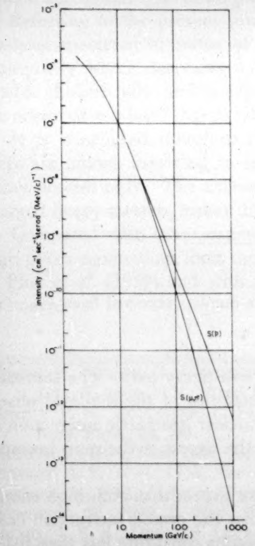

Figure 5. The calculated and observed sea-level spectra, $S(\mu, \pi)$ and $S(\mathrm{p})$.

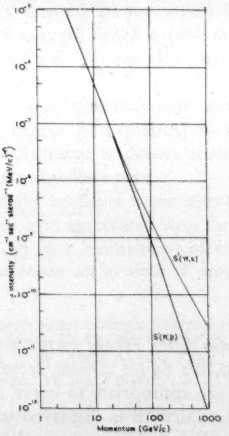

Figure 6. Pion production spectra. $S'(\pi, \mathrm{p})$ is derived from the primary proton component. $S'(\pi, \mathrm{s})$ is derived from the measured sea-level spectrum.

The conclusion of the investigation is subject to the validity and approximations of the parameters in the model adopted. Basically two experimentally determined spectra are available which are linked by the statistical model of meson production and a first-order meson diffusion process. However, the good correlation between the two spectra of figure 5 for secondary momenta below 20 GeV/c suggests that, provided the unlikely situation does not exist in which the approximations entering the analysis are completely self-balancing, the observed sea-level spectrum for momenta less than 20 GeV/c is adequately explained in terms of π–μ decay only, the pion cross section for nuclear interaction remaining sensibly nuclear geometric. In particular, the conclusions add some argument in favour of a multiplicity process which does not greatly differ from the predictions of the Fermi theory, and provide some validity for the model adopted in § 2.2, the two inferences being complementary and mutually dependent.

For secondary momenta above 20 GeV/c the evidence suggests that, provided the Fermi theory is still valid and the pion–nuclear interaction remains unchanged from geometric, there are particles surviving at sea level which cannot be explained by the single process of π–μ decay. The excess at sea level is shown in figure 7, where R is the ratio of the excess particles to those expected on π–μ decay only. The statistical errors in this figure, arising from the measured uncertainties of the sea-level observations, are appropriate to curve A corresponding to nuclear geometric interaction of the pion. Curve B is displayed to show the effect on the excess if the pion becomes less strongly interacting at very high momenta.

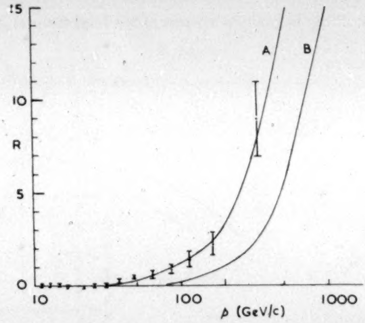

Figure 7. Ratio of the excess muons at sea level to the number expected from π–μ decay only.

If we relate the conclusions to curve A of figure 7 we expect that both high energy proton and pion flux at sea level are small. Provided that the proton interaction cross section remains nuclear geometric it is expected that protons constitute less than 0·1% of the total particles at sea level above 20 GeV/c. This is substantiated by the fact that there is no considerable increase in the charge ratio of particles at sea level (Holmes *et al.* 1961b). Pions at sea level are excluded on the grounds of the probability function, equation (8) (see figure 1), and electrons are eliminated in the spectrograph measurements. Because of the short heavy meson lifetime it is expected that negligible numbers of heavy mesons survive to sea level even if the interaction cross section falls to a small value at high energies. It is concluded, therefore, that the excess particles at sea level are muons arising extraneous to π–μ decay. The inclusion of the expected primary alpha-particle spectrum would cause an increase in the numbers of excess particles at high energy.

Alternatively, to explain the difference in terms of predominant π–μ decay it is necessary to examine the relevant assumptions which are made in the analysis.

A primary proton spectrum of smaller slope than that given by equation (1), or a proton cross section for nuclear interaction which decreases with increasing energy, would tend to reduce the difference between the observed and calculated spectra. Both effects would, however, have to be considerable to obtain correlation in terms of π–μ decay only. Cudakov *et al.* (1958) have measured the collisional mean free path of very high energy protons in nitrogen nuclei and find that it is substantially nuclear geometric. It would be difficult to reconcile a decreased slope of the primary proton spectrum with the observations at much greater energies.

The evidence in favour of the Fermi theory is that Cocconi (1954) has shown that the characteristics of a large number of relativistic showers in cosmic radiation may be satisfied by the 'tunnel' effect when the Fermi model is used to predict the multiplicity in a single nucleon–nucleon collision. Cocconi concludes that the Heisenberg (1949) model, in which the range of nuclear forces is not limited, would not explain the observed cases of low nuclear excitation. McCusker and Roesler (1957) have confirmed this general agreement with more recent experimental observations.

Referring to the present investigation it is apparent that to explain the measured sea-level spectrum in terms of pion production only beyond 20 GEV would imply a multiplicity which decreases with increasing primary energy. Such a process is untenable theoretically, and is experimentally inconsistent with shower observations and the observed sea-level charge ratio variation with momentum.

It is concluded therefore that, conditional upon self-balancing approximations, there are muons surviving to sea level whose origin cannot be explained on the π–μ decay process only. The excess at sea level may be attributed to decays arising from charged heavy mesons, either directly or through an intermediate pion.

Compared with other extended measurements of the sea-level muon spectrum of high upper momentum limit the Manchester spectrum is in agreement with the results of Pine *et al.* (1959) and with Ashton *et al.* (1960) up to a momentum in excess of 100 GEV/c.

Existence of Energy Gaps in One-Dimensional Liquids

By R. E. BORLAND

Mathematics Division, National Physical Laboratory, Teddington, Middlesex

Communicated by P. Dean; MS. received 31st August 1961

Abstract. It is shown that a definite energy gap exists in a one-dimensional liquid provided that the maximum deviation of the distance between atoms is less than a critical value. Higher gaps successively appear as the disorder is further reduced.

§ 1. INTRODUCTION

IN A RECENT paper Makinson and Roberts (1960) posed the question whether in an infinite chain of atoms lacking long range order there may be energy gaps in which there are no states whatever, or whether the states are always thinly spread with a density approaching zero as the range of order increases to infinity. In this paper we shall prove that, subject to the usual assumptions, energy gaps exist in a chain lacking long range order provided that the short range order is sufficiently small. We consider a model in which the minimum distance between atoms is of length a and the maximum distance of length $a+b$. No assumptions are made about the type of disorder so that the results derived are valid whether long range order exists or not.

§ 2. CHAIN OF NEGATIVE DELTA FUNCTIONS

To simplify the proof we consider first the special case of a chain of δ-functions of strength $-k_0$. The extension of the argument to a general atomic potential will be discussed later. Hence we are concerned with the eigenvalues E of the Schrödinger equation for an infinite chain

$$\left[-\frac{d^2}{dx^2}-k_0\sum_i \delta(x-x_i)\right]\psi = E\psi \tag{1}$$

with appropriate boundary conditions, and subject to the condition that

$$a \leqslant x_{i+1}-x_i \leqslant a+b.$$

We shall restrict ourselves to positive electron energies and write $E = k^2$.

It has been shown by James and Ginzbarg (1953) that the number of eigenstates $N(E)$ per atom with energy less than E is equal to the average phase increase per atom divided by π. The phase ϕ is defined by

$$\tan\phi(E,x) = -\frac{c\psi'(E,x)}{\psi(E,x)},$$

and the condition that ϕ changes continuously with x, c being an arbitrary positive constant. In this case c is chosen as $1/k$ in order that the phase increase from the right of the ith δ-function to the left of the $(i+1)$th δ-function is equal to $k(x_{i+1}-x_i)$.

The phase ϕ_i' immediately to the right of the ith δ-function can be related to the phase ϕ_i immediately to the left of the δ-function by integrating equation (1) from $x_i-\epsilon$ to $x_i+\epsilon$ and taking the limit as ϵ tends to zero.

We obtain

$$\tan\phi'_i = \tan\phi_i+\alpha \tag{2}$$

where $\alpha = k_0/k$.

We shall now prove that the integrated density of states is equal to unity for the range of k satisfying the inequalities

$$\pi-2q \leqslant ka \leqslant \pi-kb, \tag{3}$$

where q is the principal value of arctan $\frac{1}{2}\alpha$.

Clearly an integer m exists for which the phase ϕ_i lies either in the interval

$$m\pi-q \leqslant \phi_i < m\pi+\tfrac{1}{2}\pi \tag{4}$$

or in the interval

$$m\pi-\tfrac{1}{2}\pi \leqslant \phi_i < m\pi-q. \tag{5}$$

For reasons which will become obvious we call the interval (4) a stable phase interval and the interval (5) an unstable phase interval.

Consider first the situation in which ϕ_i lies in the stable interval (4). Using equation (2) it follows that ϕ'_i lies in the interval

$$m\pi+q \leqslant \phi'_i < m\pi+\tfrac{1}{2}\pi,$$

since ϕ_i equal to $m\pi-q$ gives ϕ_i' equal to $m\pi+q$. Provided that the inequalities (3) are obeyed ϕ_{i+1} lies in the interval

$$(m+1)\pi-q \leqslant \phi_{i+1} < (m+1)\pi+\tfrac{1}{2}\pi$$

and by repeating the argument ϕ_{i+M} lies in the interval

$$(m+M)\pi-q \leqslant \phi_{i+M} < (m+M)\pi+\tfrac{1}{2}\pi.$$

Therefore the average phase increase is π per δ-function giving an integrated density of states $N(E)$ equal to unity.

Now consider the alternative that ϕ_i lies in the unstable phase interval (5). In this case there is a tendency for the phases to the left of successive δ-functions to drift into a stable phase interval. To see this it is necessary to consider equation (2). This equation shows that the phase increase $\phi'-\phi$ across a δ-function is a monotonically increasing function of ϕ in an unstable phase interval, and a monotonically decreasing function in a stable interval. Hence any tendency for successive phases to slip back, in the sense that $\phi_{i+1}-\pi < \phi_i$, is accelerated when ϕ_{i+1} lies in an unstable phase interval and retarded in a stable phase interval.

This is of course not a rigorous argument and it is possible to construct chains for which ϕ_i lies in an unstable phase interval for all i. However, even for these unlikely chains the average phase increase is still equal to π if the inequalities (3) are obeyed. For this to be otherwise it would be necessary either that successive phases ϕ_i and ϕ_{i+1} lie in the same unstable phase interval or that at least one empty unstable phase interval separates ϕ_i and ϕ_{i+1}. The former case would require that $ka \leqslant \pi/2-q$ and the latter would require that $ka+kb > \pi$. Both these requirements conflict with the inequalities (3).

The inequalities will in general hold over a range of k provided that the ratio of b to a is sufficiently small. For this range of energy $N(E)$ is equal to unity and consequently no states can exist within this range.

By a trivial modification of the argument it follows that energy gaps will exist for all integers n for which the following inequalities hold over a range of k

$$n\pi - 2q \leqslant ka \leqslant n\pi - kb. \tag{6}$$

The second and higher energy gaps become smaller or non-existent.

§ 3. GENERALIZATION OF RESULT TO ARBITRARY ATOMIC POTENTIALS

If we take the atoms to be represented by δ-functions of strength $+k_0$ instead of $-k_0$, then similar reasoning applies. Equation (2) becomes instead

$$\tan\phi_i' = \tan\phi_i - \alpha. \tag{7}$$

The phases to the left of succeeding δ-functions drift into and are trapped in the phase intervals

$$m\pi - \tfrac{1}{2}\pi < \phi_i \leqslant m\pi + q \tag{8}$$

for the energy ranges for which the following inequalities hold

$$n\pi \leqslant ka \leqslant n\pi + 2q - kb. \tag{9}$$

Again these inequalities will hold over a range or ranges of energy provided that the ratio of b to a is sufficiently small.

Finally we consider the general problem in which we have a chain of potentials all identical, which are separated by regions of zero potential which have a maximum deviation of length b. Again the phase ϕ' immediately to the right of an atomic potential will be some function $\phi'(\phi, E)$, where ϕ is the phase immediately to the left of the atomic potential, but ϕ' will of course be a different function from that given by equation (2). However, as we prove in the Appendix, it is always possible for a fixed positive electron energy E to replace the atomic potential by a δ-function surrounded by two regions of zero potential which together have the same transformation properties as the atomic potential upon the wave functions to the right and left of it. Thus the phase increase $\phi' - \phi$ for the substitute atomic potential will be the same function of ϕ as given by the original atomic potential apart from an additive integral multiple of π. This multiple is determined by the condition that the phase is a continuous function of x, and the only consequence of this addition is to alter the integrated density of states by an integer. Thus for a fixed energy a problem involving arbitrary atomic potentials can always be transformed into one involving only δ-function potentials. In the transformed problem the distances between adjacent atoms have to be increased (or decreased) by a constant amount.

It is clear from the foregoing work that if the deviation of the original nearest neighbour distances is sufficiently small it is in general possible to find a range or ranges of energy for which the transformed problems give rise to an integrated density of states equal to an integer. These ranges of energy are therefore forbidden bands.

§ 4. CONCLUSION

The conclusion to be drawn from this work is that forbidden bands in one-dimensional crystals depend essentially upon short range order. Any solution to the wave equation in the forbidden band has a tendency to adjust itself in order to keep in step with the atoms, so that there is only one node between atoms for the first gap, two nodes between atoms for the second gap, and so on.

ACKNOWLEDGMENT

The work described above has been carried out as part of the research programme of the National Physical Laboratory and this paper is published by permission of the Director of the Laboratory.

APPENDIX

Assume the atomic potential is some function of x between two points x_1 and x_2, and that there is a region of zero potential to the left of x_1 and to the right of x_2. The solution of Schrödinger's equation in the region of zero potential to the left of x_1 can be written as

$$\psi_i = A_1 \exp[ik(x-x_1)]+B_1 \exp[-ik(x-x_1)]$$

and to the right of x_2 as

$$\psi_2 = A_2 \exp[ik(x-x_2)]+B_2 \exp[-ik(x-x_2)].$$

Since the specification of ψ and its derivative at a point is sufficient to determine the solution of a second-order differential equation, and as

$$\begin{pmatrix}\psi_1(x_1)\\ \psi'_1(x_1)\end{pmatrix} = \begin{pmatrix}1 & 1\\ ik & -ik\end{pmatrix}\begin{pmatrix}A_1\\ B_1\end{pmatrix} \tag{10}$$

it follows that the vector, whose components are the amplitudes of the waves travelling to the right and left, is sufficient to determine the solution.

We can therefore represent the atomic potential from x_1 to x_2 by a transformation matrix as follows:

$$\begin{pmatrix}A_2\\ B_2\end{pmatrix} = \begin{pmatrix}T_{11} & T_{12}\\ T_{21} & T_{21}\end{pmatrix}\begin{pmatrix}A_1\\ B_1\end{pmatrix}. \tag{11}$$

We wish to show that we can replace the atomic potential by a δ-function surrounded by two regions of zero potential which together give the same transformation matrix. First we need to know the general form of the transformation matrix for an arbitrary atomic potential.

Regarding the atomic potential as a scattering system we have at the point x_1 an incident wave of amplitude A_1 and a scattered wave of amplitude B_1. Similarly at x_2 we have an incident wave of amplitude B_2 and a scattered wave of amplitude A_2. We can therefore express the vector of scattered wave amplitudes in terms of the vector of incident wave amplitudes by means of a scattering matrix for the potential

$$\begin{pmatrix} B_1 \\ A_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} A_1 \\ B_2 \end{pmatrix}. \tag{12}$$

It is well known that for such a system described by a real Hamiltonian the scattering matrix must be unitary and symmetric as a consequence of conservation of probabilities and time reversal symmetry. These restrictions give the following relationships between the scattering matrix elements:

$$S_{12} = S_{21} \tag{13a}$$

$$S_{11} = S_{22}^*|S| \tag{13b}$$

$$-S_{12} = S_{12}^*|S| \tag{13c}$$

where the asterisk denotes the complex conjugate and

$$|S| = S_{11}S_{22} - S_{12}^2.$$

On solving equation (12) to obtain equation (11) we find that

$$T_{11} = -\frac{|S|}{S_{12}}, \qquad T_{12} = \frac{S_{22}}{S_{12}}$$

$$T_{21} = -\frac{S_{11}}{S_{12}}, \qquad T_{22} = \frac{1}{S_{12}}.$$

Using equation (13*c*) we find that

$$T_{11} = \frac{1}{S_{12}^*} = T_{22}^*. \tag{14}$$

Equations (13*b*) and (13*c*) give

$$T_{21} = \frac{S_{22}^*}{S_{12}^*} = T_{12}^*. \tag{15}$$

One further restriction on the elements of the transformation matrix is imposed by the condition that the determinant of the matrix must be equal to unity, since

$$\begin{aligned} T_{11}T_{22} - T_{12}T_{21} &= \frac{(1 - S_{22}S_{22}^*)}{S_{12}S_{12}^*} \\ &= \frac{(1 - S_{22}S_{11}/|S|)}{S_{12}S_{12}^*} = -\frac{S_{12}^2}{|S|S_{12}S_{12}^*} = 1. \end{aligned}$$

We see therefore that the transformation matrix for an arbitrary atomic potential is of the form

$$\begin{pmatrix} T_{11} & T_{12} \\ T_{12}^* & T_{11}^* \end{pmatrix},$$

where $T_{11}T_{11}^* - T_{12}T_{12}^* = 1$.

Now let us attempt to represent the transformation properties of this atomic potential by a potential which going from left to right consists of a region of zero potential of length g, a δ-function of strength μ and finally another region of zero potential of length h. The transformation matrix representing a length g of zero potential is

$$\begin{pmatrix} e^{ikg} & 0 \\ 0 & e^{-ikg} \end{pmatrix}.$$

Denote the wave function immediately to the right and left of the δ-function by ψ_+ and ψ_- respectively. We have on integrating the wave equation across the δ-function of strength μ and assuming continuity of ψ

$$\begin{pmatrix} \psi_+ \\ \psi_+' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ \mu & 1 \end{pmatrix} \begin{pmatrix} \psi_- \\ \psi_-' \end{pmatrix}.$$

Using the equation analogous to (10) in both its direct and inverted form we obtain

$$\begin{pmatrix} A_+ \\ B_+ \end{pmatrix} = \frac{i}{2k} \begin{pmatrix} -ik & -1 \\ -ik & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ \mu & 1 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ ik & -ik \end{pmatrix} \begin{pmatrix} A_- \\ B_- \end{pmatrix}. \tag{16}$$

Hence on multiplying the matrices we see that the transformation matrix for the δ-function of strength μ is

$$\begin{pmatrix} 1 - i\mu/2k & -i\mu/2k \\ +i\mu/2k & 1 + i\mu/2k \end{pmatrix}.$$

Therefore the transformation matrix for the combined potential is

$$\begin{pmatrix} e^{ikh} & 0 \\ 0 & e^{-ikh} \end{pmatrix} \begin{pmatrix} 1 - i\lambda & -i\lambda \\ +i\lambda & 1 + i\lambda \end{pmatrix} \begin{pmatrix} e^{ikg} & 0 \\ 0 & e^{-ikg} \end{pmatrix}$$

where $\lambda = \mu/2k$.

On multiplying these matrices we find that the transformation matrix is

$$\begin{pmatrix} (1 - i\lambda)\, e^{ik(g+h)} & -i\lambda\, e^{-ik(g-h)} \\ i\lambda\, e^{ik(g-h)} & (1 + i\lambda)\, e^{-ik(g+h)} \end{pmatrix}.$$

Now by choosing a value of μ in the range $-\infty$ to 0 or 0 to $+\infty$, the modulus of λ can be made equal to the modulus of T_{12}, and T_{11} and T_{12} can be given their correct phase factors by an independent choice of $g+h$ and $g-h$. Hence we have shown that it is possible to represent the transformation properties of an arbitrary atomic potential by a δ-function surrounded by two regions of zero potential.

The Absorption of Ozone in the Ultra-violet and Visible Regions of the Spectrum

By A. G. HEARN[†]

Cavendish Laboratory, Cambridge

MS. received 18*th May* 1961, *in revised form* 27*th July* 1961

Abstract. The absorption coefficient of gaseous ozone has been measured for the mercury lines at 2537, 2894, 2967, 3021, 3342, and 5770 Å, by measuring the optical absorption and the pressure as the ozone decays in a sealed quartz absorption tube. This avoids the chemical determination of the ozone. The determination gives independent and absolute values of the absorption coefficients, and their standard deviations are 2½% or less. Previous measurements of the absorption coefficients disagree by as much as 25%, but the present results generally agree within the limits of error with those of Inn and Tanaka.

§ 1. INTRODUCTION

THE ABSORPTION band of ozone in the ultra-violet is of great interest to meteorology, but the measurement of the absorption coefficients is difficult because of the unstable nature of gaseous ozone. The absorption coefficients have been measured on several occasions, but the most detailed studies are those by Ny and Choong (1933), Inn and Tanaka (1953) and Vigroux (1953). Their results are illustrated in figure 1. The absolute values disagree by up to 25% and the coefficients throughout the absorption band have been found not to be self-consistent (Vassy 1937, Walshaw 1957). The absorption coefficients at the wavelengths of six mercury lines have been measured to try to resolve the differences between these determinations. The method yields absolute values of the absorption coefficients and the individual measurements are independent.

§ 2. THE PRINCIPLE OF THE DETERMINATIONS

The method is a modification of that used by Läuchli (1928). If pure ozone is sealed into an absorption tube and maintained at a constant temperature, then as the ozone decays into oxygen the pressure increases reaching a final pressure one and a half times the original when all the ozone has decayed. The absorption coefficient k is given by

$$k = xL = -\frac{1}{2l} p_0 \frac{T}{T_0} \frac{dD}{dp} (\text{cm NTP})^{-1}$$

where p_0 and T_0 are standard pressure and temperature, p and T are the pressure and temperature of the gas, l is the length of the absorption tube, x is the molecular absorption coefficient, L is Loschmidt's number and D is the optical density measured to the base 10.

So the absorption coefficient may be obtained simply from the rate of change of the optical density with pressure of the gas mixture while the ozone decays.

[†] Now at the Atomic Energy Research Establishment, Harwell, Berks.

There are several assumptions implicit in the derivation of this relation. Firstly, the absorption coefficient is independent of pressure. This has been investigated by Vassy (1936a), Strong (1941), Barbier and Chalonge (1942) and Vigroux (1953), who all found no significant effect of pressure. Secondly, intermediate products must not accumulate during the decay of the ozone. The work of Benson and Axworthy (1957), Heidt (1935) and Heidt and Forbes (1934) show that their lifetimes are very short. Thirdly, all the ozone must be converted to oxygen and none must be lost by chemical reaction with the apparatus, which requires the apparatus to be designed so that contact of the ozone with substances such as tap grease is avoided. Fourthly, no ozone must be lost by physical adsorption onto the surface of the apparatus. Preliminary experiments indicated that this was prevented by using absorption tubes made of fused silica.

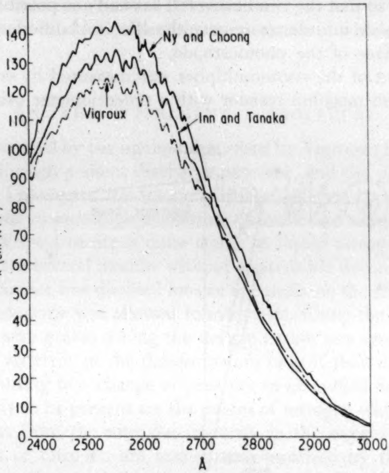

Figure 1. The absorption coefficients measured by Ny and Choong, Vigroux, and Inn and Tanaka.

§ 3. THE APPARATUS

The optical system is shown in figure 2. A mercury vapour lamp was used as the light source and its intensity was stabilized by means of a vacuum photocell controlling the current through the lamp. The lamp was under-run, which reduced the width of the resonance line at 2536 Å to 0·9 Å. The widths of the other lines were less than 0·1 Å. The fine structure of the absorption band of ozone was examined by Chalonge and Lefebvre (1933) using a six metre concave grating spectrograph in the region from 3603 to 3395 Å and they found no structure finer than one or two Ångströms.

The light from the mercury lamp was split into two beams, one of which passed through the absorption tube, and the other was used as a reference beam. The two beams were selected by a rotating shutter and passed, each in turn, into a quartz spectrometer. Their intensities at the required wavelength were compared by means of a photomultiplier. To reduce the error caused by reflections at the windows of the absorption tube, the beam was allowed to traverse the absorption tube only once. A Chance OX7 ultra-violet transmitting filter was placed in front of the mercury lamp so that stray light coming from the visible region would be removed. The spectrograph was a Hilger E1 instrument, which is a quartz Littrow spectrograph with a prism of 4·9 cm base and a focal length of approximately one and a half metres. The plate holder of the spectrograph was replaced by a carriage holding the photomultiplier. The optical system was arranged so that the two beams fell as nearly as possible onto the same portion of the photocathode in order to remove the effects of differential changes in sensitivity across the surface of the photocathode.

The anode current of the photomultiplier was measured by comparing the voltage developed across a ten megohm resistor with a potentiometer using a valve voltmeter as a null detector. Two potentiometers were used, one for each beam. The photomultiplier was selected for low dark current, which was sufficiently constant for it to be subtracted from the measurement by adjusting the zero of the valve voltmeter.

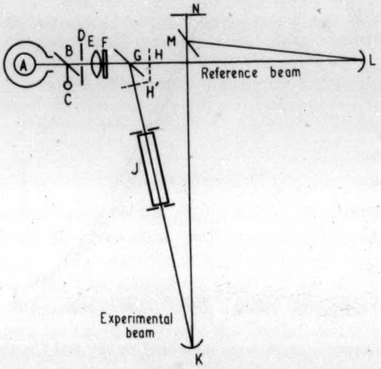

Figure 2. The optical system: *A*, mercury lamp; *B*, quartz plate; *C*, photocell; *D*, diaphragm; *E*, quartz lens; *F*, OX7 filter; *G*, quartz beam splitter; *H*, rotating shutter; *J*, absorption tube; *K*, concave mirror; *L*, concave mirror; *M*, beam splitter; *N*, spectrometer slit.

A Mazda 27M3 photomultiplier was used, which has a window transmitting down to 2200 Å. The h.t. supply to the photomultiplier was stabilized by the circuit described by Fellgett (1954). The current drawn from the photomultiplier did not exceed 0·1 microamp. In view of the investigations into the linearity of photomultipliers of the 931A and similar types made by Engstrom (1947), Kortum and Maier (1953), and Hermann (1957), there is no reason to doubt the linearity of its response.

The grid current of the valve voltmeter was 10^{-12} A. The faintest intensity measured during the work was represented by an anode current of 10^{-9} A.

Three absorption tubes were used for the measurements. They were made from fused silica and were nominally 15, 10 and 0·75 cm long. The pressure of the mixture of gases in the absorption tube was measured with a small pyrex spiral manometer backed by a conventional mercury manometer. A McLeod gauge was used to calibrate the spiral manometers. Their rotation was measured with a galvanometer mirror attached to the free end. The most sensitive spiral had a sensitivity of about 10 cm per cm Hg pressure at a distance of one metre. The spiral manometers were kindly supplied by the University Chemistry Laboratory in Cambridge.

The decay of ozone releases 34·2 kcal (g mol)$^{-1}$. To ensure that the temperature of the gas did not rise excessively, a thermocouple was sealed into the absorption tube. The thermocouple was made from two alloys, 10% iridium with 90% platinum and 40% palladium with 60% gold. The calibration remained constant during the experiments indicating that the ozone had no action on it.

The apparatus was housed in a cellar, the temperature of which was thermostatically controlled.

§ 4. THE EXPERIMENTAL PROCEDURE

The ozone was prepared by the method described by Vigroux (1949). Dried cylinder oxygen was passed through a silent discharge ozonizer, and the products liquified in a liquid nitrogen trap. The oxygen was fractionally distilled away by reducing the pressure. There is no evidence of an azeotropic maximum of ozone and oxygen (Jenkins, Di Paolo and Birdsall 1955). Liquid ozone is quite stable at liquid nitrogen temperatures, and it was kept in a bulb for several months without appreciable decomposition. The ozone required for an experiment was distilled into an appendix on the absorption tube, which was then sealed. The ozone was allowed to evaporate, filling the absorption tube. By this method contact with grease during the determination was avoided.

Impurities cause an error in the determination only if they decompose during the measurement contributing to a change of pressure or of optical density. The only unstable impurities likely to be present are the oxides of nitrogen which are formed during the ozonizing process from the nitrogen impurity in the oxygen. Except for nitrous oxide, all the oxides of nitrogen are immediately oxidized by the ozone to nitrogen pentoxide. This was estimated by means of its absorption line at 740 cm^{-1} and it was found that the ozone contained less than 0·1% nitrogen pentoxide. This could not cause any significant error.

Preliminary experiments using a pyrex absorption tube indicated that ozone was being desorbed from the walls during the later stages of the determination. This phenomenon had been investigated by Vassy (1936b, 1937). To estimate the desorption of ozone from the quartz absorption tubes, the 0·75 cm absorption tube was filled to nearly atmospheric pressure with ozone, and after an hour the gas was pumped away and the tube sealed. During the following eight hours no evidence of desorbed ozone was found using the large absorption of the mercury resonance line at 2536 Å. The experiment was first tried with the 10 cm tube, but while the ozone was being pumped away it exploded, completely shattering the absorption tube.

The effect of the desorption of ozone would be most serious for those experiments requiring a low pressure of ozone. For three of the six determinations of the absorption coefficient at 2536 Å, for which a pressure of only 1 cm Hg was required, a side arm of the absorption tube was filled with quartz wool having a surface area equivalent to five times that of the absorption tube. The difference between the two sets of measurements is not significant, nor is the standard deviation greater in one than the other.

The decay of the ozone in a quartz absorption tube was very slow. Since this is mainly a surface effect, it suggests that the interaction of the ozone with the quartz is much less than with pyrex. The decay was hastened by illuminating the absorption tube with light from two extra mercury lamps. It was necessary to allow time for the heat generated by the decay of the ozone to dissipate.

One of the potentially most serious sources of error in a photometric system is stray light. It was possible to estimate the stray light and to correct for its effect. It could only come from the mercury lines transmitted by the OX7 filter. The absorption coefficient of ozone varies so rapidly between these lines, that the wavelengths shorter than that being measured are heavily attenuated and should not contribute to the stray light; whereas the longer wavelengths are barely attenuated and their contribution to the stray light predominates; and because of the low absorption coefficient, it remains approximately constant over the range of ozone partial pressures used. The effect of the stray light may be calculated if it is independent of the optical density of the ozone and if it is small in intensity compared with that of the required wavelength. If D is the true optical density, D' is the measured optical density and p is the total pressure of the gas in the absorption tube then

$$\frac{dD'}{dp} = \frac{dD}{dp}\left(1 - \frac{S}{I_0}10^D\right)$$

where I_0 is the intensity of the measuring beam before entering the absorption tube and S is the (constant) intensity of the stray light. So the effect of the stray light is that the measured optical density plotted against the pressure is no longer a straight line. In practice the curvature cannot be detected over the range of optical densities used, but the error in the slope of the graph when fitted by least squares is equal to the error determined at the middle point of the optical density range. For most determinations the density range was from 0·2 to 0·8 or 1·0 so that the error due to the stray light is

$$\frac{dD'}{dp} - \frac{dD}{dp} \simeq \frac{3S}{I_0}\frac{dD'}{dp}.$$

By starting with a high concentration of ozone, the deviation from the straight line becomes measurable, and the ratio S/I_0 can be deduced, since as the optical density becomes very large, the measured optical density tends towards $\log(S/I_0)$. This estimation of the effect of stray light is only approximate, but the precautions taken reduced the stray light to a level where only an order of magnitude determination of its effect is required. The largest correction required was 0·3%.

§5. THE RESULTS

The slope of the optical density and pressure relation was found from the experimental results by the method of least squares. The results of separate determinations were combined by taking the unweighted mean, and these are given with their standard deviations in table 1. The absorption coefficients at some wavelengths were determined using two different absorption tubes, and these are quoted separately.

The determinations at 2967·3 and 3021·5 Å made at high pressures with the short absorption tube are much less accurate than those made with the longer absorption tube. There is no significant difference between the mean values. If it is assumed that the pressure dependence of the absorption coefficient is of the form $k_p = k_0(1+ap)$ where k_p and k_0 are the absorption coefficients at a pressure p and at zero pressure respectively, then the pressure coefficient a is less than 0·002 (cm Hg)$^{-1}$ at 2967·3 Å and less than 0·0015 (cm Hg)$^{-1}$ at 3021·5 Å. Because of the poor accuracy of the absorption coefficient determinations at high pressure, this is not a sensitive method of determining the effect of pressure. The two sets of results have not been combined for the

Table 1

Summary of the Experimental Results

Wavelength (Å)	Tube length (cm)	Mean abs. coeff. (cm NTP)$^{-1}$	R.M.S. deviation (%)	Number of determinations
2536·5	0·744	133·9	1·05	6
2893·6	10·09	17·2	1·8	2
2967·3	10·09	6·948	0·24	6
2967·3	0·744	6·93	3·2	5
3021·5	10·09	3·308	0·24	6
3021·5	0·744	3·300	2·3	4
3341·5	10·09	0·0498	1·4	13
5769·6	14·991	0·0555	1·6	4

best estimate of the absorption coefficient, but those obtained with the 10 cm tube have been taken by themselves.

Only two determinations were made at 2893·6 Å and the standard deviation given is only an estimate.

In addition to the random error of the mean, there are further errors contributed from the measurement of the length of the absorption tubes and the calibration factors of the McLeod gauge and spiral manometers. These are shown in table 2 together with the total random error of the mean from all sources. Errors due to the variation of the temperature of the ozone–oxygen mixture during the experiment are quite negligible.

In addition to these random errors, there are two sources of systematic error. The errors caused by stray light were estimated and the appropriate corrections to the absorption coefficients are shown in table 3. It was not possible to estimate the effect of the stray light for the determinations at 3341·5 and 5769·6 Å because the absorption coefficient is so small and a sufficiently high optical density could not be obtained. It is probable that the error involved is very small because the main contribution to the stray light comes from light of other wavelengths, and these two lines are particularly strong. A second source of systematic error which affects only the measurements at 3021·5 Å is the presence of companion lines which are unresolved by the spectrometer. This line has three companions at distances of +2·5, +6·5, +9·5 Å. The nearest line has an intensity of one quarter of the principal line, and the other two are less than 1%,

Table 2

Analysis of the Random Errors

Wavelength (Å)	Mean (%)	Tube length (%)	McLeod gauge (%)	Spiral gauge (%)	Total S.D. (%)
2536·5	1·05	0·54	0·81	—	1·4
2893·6	1·8	0·20	—	0·29	1·8
2967·3	0·24	0·20	—	0·29	0·43
3021·5	0·24	0·20	—	0·29	0·43
3341·5	1·4	0·20	—	0·29	1·4
5769·6	1·6	0·00	0·81	0·00	1·8

so that they are negligible. The effect of a companion can be calculated if the ratio of the absorption coefficients at the two wavelengths is known. If k_1 and k_2 are the absorption coefficients for the principal line and the companion respectively, and j is the ratio of the intensity of the companion to the principal line, then the absorption coefficient k which is measured by the spectrometer is related to the true absorption coefficient by the relation

$$(j+1)10^{-\bar{k}} = 10^{-k_1}+j10^{-k_1/m}$$

where m is the ratio k_1/k_2. This ratio obtained from the results of Ny and Choong, Inn and Tanaka, and Vigroux is 1·042, 1·034, and 1·041 respectively. 1·040 was chosen for this ratio and the equation was solved graphically. This correction is also included in table 3.

Table 3

Systematic Errors

Wavelength (Å)	Mean uncorrected abs. coeff. (cm NTP)$^{-1}$	Correction for stray light (cm NTP)$^{-1}$	Correction for companion (cm NTP)$^{-1}$
2536·5	133·9	+0·0	—
2893·6	17·2	—	—
2967·3	6·948	+0·021	—
3021·5	3·308	+0·003	+0·029
3341·5	0·0498	—	—
5769·6	0·0555	—	—

The absorption coefficient at 3021 Å has been published (Hearn, Walshaw and Wormell 1957), but the value given of 3·310 ± 0·009 (cm NTP)$^{-1}$ did not include this correction for the effect of the companion. There is no other difference between the two results. If a mercury lamp, run under similar conditions to those used for these determinations, is used for the measurement of ozone, then the uncorrected value should be used, since it is the effective absorption coefficient for the line and its companion. The corrected value is the best estimate of the monochromatic absorption coefficient at 3021 Å.

The best estimates of the monochromatic absorption coefficients are given in table 4. For convenience the equivalent molecular absorption cross section is also given.

Table 4

Best Estimates of the Absorption Coefficients

Wavelength (Å)	Absorption coefficient (cm NTP)$^{-1}$	Molecular absorption cross section (10^{-19} cm^2)	Temperature (°c)
2536·5	133·9 ±1·9	114·7 ±2·4	22
2893·6	17·2 ±0·3	14·7 ±0·3	19
2967·3	6·969 ±0·030	5·971 ±0·026	22
3021·5	3·340 ±0·014	2·860 ±0·011	20
3341·5	0·0498 ±0·0007	0·0427 ±0·0006	20
5769·6	0·0555 ±0·0010	0·0476 ±0·0009	21

§6. DISCUSSION

For comparison the absorption coefficients measured by Ny and Choong, Vigroux, and Inn and Tanaka are shown in table 5. Inn and Tanaka made the measurements photoelectrically and the others photographically. They all used a continuous source, and the values quoted are interpolations from the absorption coefficients measured at maxima and minima. Since no information is available regarding the shape of the absorption bands, the interpolation of these results is rather arbitrary.

Table 5

Other Measurements of the Absorption Coefficients (cm NTP)$^{-1}$

Wavelength (Å)	Ny & Choong	Vigroux	Inn & Tanaka	Present work
2536·5	142·6	124·3	133·1	133·9
2893·6	21·6	18·2	17·1	17·2
2967·3	8·19	6·83	6·72	6·969
3021·5	3·72	3·29	3·32	3·340
3341·5	0·067	0·058	0·061	0·0498
5769·6	—	0·0553	0·052	0·0555

Inn and Tanaka state that the maximum deviation from the average value of the absorption coefficient was about 5%. The others give no indication of the accuracy of their measurements. The results of Ny and Choong are some 10% higher than the others and possibly this is due to the side reactions in the chemical estimation which are described by Juliard and Silberschatz (1928).

With the exception of 3341·5 Å, there is no significant difference between the present measurements and those of Inn and Tanaka; whilst for those of Vigroux at 2536·5 and 2893·6 Å, the differences are significant. The value obtained for 3341·5 Å is much less than that of any other worker. This discrepancy appears to be due to the difficulty of interpolating the absorption coefficients of Vigroux and Inn and Tanaka. Also, compared with the wavelengths given by Vigroux and Ny and Choong, those given by Inn and Tanaka are 1 Å wrong. If the interpolation of Inn and Tanaka's coefficients is made with the aid of the values given by Ny and Choong, in which the detail is greater because of the higher resolution of their spectrograph, then it is found that the result is not inconsistent with the present determination. Support for this low value comes from measurements of the infra-red absorption of ozone using the ultra-violet absorption for estimating the ozone (Walshaw 1957).

It appears that for general purposes, the absorption coefficients of Inn and Tanaka are the most accurate and self-consistent. The accuracy which the authors claim for their measurements corresponds to a standard deviation of about 2% in the absorption coefficients. The Cary recording spectrophotometer is designed for measuring the absorption across the ultra-violet band with an accuracy in the wavelength of a few Ångström units. The wavelength measurements of Ny and Choong are probably the most reliable, and it seems that the results of Inn and Tanaka could be improved slightly by checking the wavelength calibration against the results of Ny and Choong. For laboratory measurements of ozone, the use of the emission lines of a mercury vapour lamp has the advantage that the wavelength is clearly defined and that an interpolation from continuous measurements of the absorption coefficients is not necessary.

ACKNOWLEDGMENTS

I am very grateful for the advice and encouragement given to me throughout the work by Dr. T. W. Wormell and Dr. C. D. Walshaw, and to the Gassiot Committee of the Royal Society for financial support. The principle of the determination was suggested by Professor R. M. Goody.

PROC. PHYS. SOC., 1961, VOL. 78

The Inversion of Specific Heat Curves

By R. G. CHAMBERS
H. H. Wills Physics Laboratory, University of Bristol

MS. received 30*th June* 1961

Abstract. It is shown that the methods proposed by Montroll and Kroll for deriving the lattice frequency spectrum from the experimental specific heat curve will in practice yield only a 'smoothed' spectrum, averaged over a range of 1·6 : 1 or more in frequency. Any practicable improvement in experimental accuracy will reduce this smoothing only slightly. The same smoothed spectrum can be derived more simply by a procedure involving only one quadrature, and a still simpler trial-and-error method is also described and illustrated.

§ 1. INTRODUCTION

A NUMBER of authors have considered the problem of determining the lattice vibration spectrum $g(\nu)$ from the specific heat $C_V(T)$, either by approximate methods (Grayson-Smith and Stanley 1950, Katz 1951, Hwang 1954, Barron, Berg and Morrison 1957, Weiss 1959, Barron and Morrison 1960, Hovi and Pautamo 1961) or by formally exact inversion techniques (Montroll 1942, Kroll 1952, Taylor 1956). Several of these methods are reviewed by Blackman (1955). The solutions of Montroll and Kroll both involve two successive quadratures; in this note we derive a solution which involves only one. The 'exact' solution so obtained is of purely formal significance, because the integrand is oscillatory and divergent, but this difficulty can be overcome if we are content to evaluate a smoothed spectrum $\bar{g}(\nu)$, averaged over a certain frequency range. The methods of Montroll and Kroll will in practice only yield a similarly smoothed spectrum, so that the present method will yield the same information with less labour. A still simpler approximate method is also discussed, which is probably adequate for all practical purposes.

§ 2. ANALYTIC METHOD

If the spectrum obtained by inversion is to be of any significance, the specific heat data must first be corrected for the effects of thermal expansion and anharmonicity, and any other extraneous effects, as stressed by Katz and by Barron *et al.* Writing $\beta = 1/kT$, $\epsilon = h\nu$, we then have

$$C_V(\beta) = 3R\int_0^\infty g(\epsilon)E(\beta\epsilon)\,d\epsilon \qquad (1)$$

where $kE(\beta\epsilon)$ is the Einstein specific heat function for a single oscillator, and $g(\epsilon)$ is normalized to give

$$\int_0^\infty g(\epsilon)\,d\epsilon = 1.$$

To derive $g(\epsilon)$, we need to work with some function of E which vanishes at high temperatures, e.g. $(\beta\epsilon)^n E(\beta\epsilon)$, or more generally $F_{m,n}(\beta\epsilon) = (-)^m(\beta\epsilon)^{m+n}\,d^mE/d(\beta\epsilon)^m$. Writing

$L_{m,n}(\beta) = (-)^m\beta^{m+n}d^m(C_V/3R)/d\beta^m$ and $G_n(\epsilon) = \epsilon^{1-n}g(\epsilon)$, we find from equation (1), dropping the subscripts, that

$$L(\beta) = \int_0^\infty G(\epsilon)F(\beta\epsilon)\frac{d\epsilon}{\epsilon}. \tag{2}$$

Changing variables to $\alpha = -\ln\beta$, $\eta = \ln\epsilon$, we can write this in the form

$$L(\alpha) = \int_{-\infty}^{\infty} G(\eta)F(\alpha-\eta)\,d\eta \tag{3}$$

so that the measured function $L(\alpha)$ is simply the convolution of the required function $G(\eta)$ with the known function $F(\alpha-\eta)$, as noted by Taylor (1956). The 'unfolding' of $L(\alpha)$ to find $G(\eta)$ is a familiar problem in spectroscopy, where $L(\alpha)$ is the observed line-shape, $G(\eta)$ the true line-shape, and $F(\alpha-\eta)$ the instrumental broadening factor. It has been discussed by many authors (e.g. White and Millington 1928, Shull 1946, Stokes 1948), and it is easily shown that if $L(x)$, $G(x)$ and $F(x)$ are the Fourier transforms of $L(\alpha)$, $G(\eta)$ and $F(\alpha-\eta)$, the solution is $G(x) = L(x)/F(x)$.† This is essentially Montroll's solution, which thus requires two quadratures: first to find $L(x)$ from $L(\alpha)$ and then to find $G(\eta)$ from $G(x)$.

If, formally, we define $H(\eta-\alpha)$ as the function whose Fourier transform is $H(x) = 1/F(x)$, then formally the inversion follows at once from a single quadrature:

$$G(\eta) = \int_{-\infty}^{\infty} L(\alpha)H(\eta-\alpha)\,d\alpha. \tag{4}$$

Now in fact for large $|x|$,

$$\begin{aligned} F_{m,n}(x) &\simeq \Gamma(m+n+2+ix) \\ &\simeq (2\pi)^{1/2}|x|^{(m+n+\frac{3}{2})}\exp(-\tfrac{1}{2}\pi|x|)\exp i[x\ln x - x + \tfrac{1}{2}\pi(m+n+\tfrac{3}{2})] \end{aligned}$$

so that $H(x)$ diverges and this result is of no practical significance. If, less ambitiously, we seek to evaluate not $G(\eta)$ itself but a smoothed spectrum $\bar{G}(\eta)$, formed by the convolution of $G(\eta_1)$ with a weighting factor $W(\eta-\eta_1)$, we need a function H_W such that

$$\bar{G}(\eta) = \int_{-\infty}^{\infty} G(\eta_1)W(\eta-\eta_1)\,d\eta_1 = \int_{-\infty}^{\infty} L(\alpha)H_W(\eta-\alpha)\,d\alpha. \tag{5}$$

The Fourier transform of equation (5) gives $G(x)W(x) = L(x)H_W(x)$, so that $H_W(x) = G(x)W(x)/L(x) = W(x)H(x)$. Thus if $W(x)$ falls more rapidly than $\exp(-\frac{1}{2}\pi|x|)$ for large $|x|$, $H_W(x)$ will tend to zero for large $|x|$, and $H_W(\eta-\alpha)$ will be well-behaved. If for instance $W(x) = \exp(-ax^2)$, $W(\eta) = (4\pi a)^{-1/2}\exp(-\eta^2/4a)$; if $W(x) = 1$ for $|x| \leqslant x_0$, zero for $|x| > x_0$, $W(\eta) = \sin(\eta x_0)/\pi\eta$. But if $W(\eta)$ has a half-width less than about 0·4 in η, $H_W(x)$ still rises to extremely large values before falling to zero, and correspondingly $H_W(\eta-\alpha)$ becomes a rapidly oscillatory function of very large amplitude. Extreme accuracy would therefore be required in the measured values of $L(\alpha)$ to obtain a close idea of $G(\eta)$ in this way, as we shall see below.

---

† Since $g(\epsilon) \simeq \epsilon^2$ for small ϵ, we need $n \leqslant 3$ if $G_n(\eta)$ and $L_{m,n}(\alpha)$ are to remain finite as η, $\alpha \to -\infty$. If $n = 3$, we can avoid singularities in $L(x)$ and $G(x)$ by cutting off $L(\alpha)$ at some large negative α.

If we put $G(\eta) = \delta(\eta)$, equation (3) gives $L(\alpha) = F(\alpha)$, and then equation (5) becomes

$$W(\eta) = \int_{-\infty}^{\infty} F(\alpha) H_W(\eta-\alpha)\, d\alpha. \tag{6}$$

(This also follows at once from $W(x) = F(x)H_W(x)$.) Thus H_W is that function which, folded with the relatively broad function F, produces the narrower function W. As an alternative to the analytic approach, we can replace H_W by a set of delta-functions of strength H_i located at the points $\eta-\alpha = \gamma_i$, and attempt by trial and error to choose H_i and γ_i so that the sum $\Sigma\, H_i F(\eta-\gamma_i) = W(\eta)$ is as narrow as possible. It is difficult in this way, however, to produce a function W with a half-width less than 0·6 in η, corresponding to a range of 1·8 : 1 in frequency. This is not a great deal less than for F itself: for instance, $F_{0,2}$, $F_{1,1}$ and $F_{1,3}$ have half-widths in η of 1·33, 1·13 and 0·93 respectively. This result merely confirms the conclusion from the analytic approach.

Thus the prospect of analytic inversion using equation (5) appears unpromising. Montroll's method, though in principle free from convergence difficulties, will in practice be no more useful, when experimental inaccuracies are taken into account, and since essentially the same limitations apply to all inversion methods it is worth discussing them in a little detail.

§ 3. EFFECT OF EXPERIMENTAL ERROR

Suppose for example that the experimental data consist of N values of C_V, equally spaced over the relevant range of α, and each having a standard error $\sigma(C_V) = sC_V$. For the function $L_{0,1} = C_V/3RkT$ used by Montroll, the resultant standard error in the Fourier transform $L(x)$ is approximately $\sigma(L(x)) \simeq 1{\cdot}1 N^{-1/2} s L(0)$, independent of x. (Here and in what follows, $L(0)$ signifies $L(x = 0)$.) But the actual magnitude of $|L(x)/L(0)|$ will fall rapidly with increasing $|x|$; in fact it will be comparable with or less than $|F(x)/F(0)|$, since $G(x) = L(x)/F(x)$ converges. The value of $L(x)$ and so of $G(x)$ will therefore become increasingly uncertain for large $|x|$, and will have to be set equal to zero beyond some point x_0 say. This is precisely equivalent to using a smoothing function $W(\eta) = \sin(\eta x_0)/\pi\eta$, of width $2\pi/x_0$ between zeros, and half-width approximately π/x_0.

Thus if $N = 100$ and $s = 10^{-2}$, for example, we have $\sigma(L(x)) \simeq 10^{-3}L(0)$, while for the function $F_{0,1}$ we have $|F(x)/F(0)| = 10^{-2}, 10^{-3}, 10^{-4}$ at $|x| \simeq 5{\cdot}5, 7{\cdot}4, 9{\cdot}2$. Thus even if $|L(x)/L(0)|$ falls no faster than this, we shall need to cut off the transform at some point $x_0 \lesssim 7$. The experimental data can therefore only yield a spectrum smoothed over a half-width of at least $\pi/x_0 = 0{\cdot}45$ in η, i.e. a range of 1·6 : 1 in frequency. If the number and accuracy of the experimental points are increased to $N = 1000$ and $s = 10^{-3}$, we shall still need $x_0 \lesssim 9$, corresponding to only a small decrease in the range of smoothing. Some advantage might be gained by working with the function $L_{1,3}(\alpha)$ instead of $L_{0,1}(\alpha)$, because $F_{1,3}(x)$ and therefore $L_{1,3}(x)$ fall off a little more slowly with $|x|$: for $F_{1,3}$ we have $|F(x)/F(0)| = 10^{-2}, 10^{-3}, 10^{-4}$ at $|x| \simeq 8{\cdot}3, 10{\cdot}5, 12{\cdot}5$. But this advantage will be largely offset by the reduced accuracy of $L_{1,3}(\alpha)$ and hence of $L_{1,3}(x)$, because $L_{1,3}(\alpha)$ involves dC_V/dT rather than C_V.

We need not discuss Kroll's method in detail: it is somewhat similar to Montroll's, and suffers from precisely the same limitations. Finally, it is easily seen that the single-quadrature method of equation (5) involves exactly the same combination of the experimental data as Montroll's method with a cut-off at $|x| = x_0$, so that again the same limitations apply. In other words, equation (5) will yield exactly the same information as Montroll's method, with the use of only one integration intead of two.

The information obtainable by inversion techniques is of course limited basically by the breadth of the functions F and L. Replacing G by $\bar{G}$ is equivalent to replacing L by a similarly smoothed function $\bar{L}$:

$$\bar{L}(\alpha) = \int_{-\infty}^{\infty} L(\alpha_1)W(\alpha-\alpha_1)\,d\alpha_1 = \int_{-\infty}^{\infty} \bar{G}(\eta)F(\alpha-\eta)\,d\eta = \int_{-\infty}^{\infty} G(\eta)\bar{F}(\alpha-\eta)\,d\eta,$$

where the last form follows when the smoothing is applied to F instead of G. Clearly it will be impossible to distinguish $\bar{G}$ from G if the resultant smoothed function $\bar{L}(\alpha)$ is experimentally indistinguishable from $L(\alpha)$. Now it is easily shown that the difference $\delta F(\alpha)$ between $\bar{F}$ and F will be imperceptible if the smoothing function $\sin(\eta x_0)/\pi\eta$ has a half-width π/x_0 less than about 0·4. (In fact $|\delta F(\alpha)/F_{\max}(\alpha)| \leqslant |F(x_0)/F(x=0)|$.) Since $L(\alpha)$ is effectively already a 'smoothed' and therefore broadened version of $F(\alpha)$, it will be even more difficult to distinguish $\bar{L}(\alpha)$ from $L(\alpha)$ (corresponding to the fact that $L(x)$ falls off even more rapidly than $F(x)$), and no method of inversion can circumvent this difficulty.

§ 4. TRIAL-AND-ERROR METHOD

Perhaps the most practical method of estimating $G(\eta)$ along these lines is to return to the basic equation (3), and simply attempt by trial and error to find a form for $G(\eta)$ which reproduces the observed $L(\alpha)$. This method, though inelegant, is quite rapid, and has the merit that the uncertainties in the resultant spectrum are readily apparent: more sophisticated techniques may obscure these uncertainties, and give a spurious air of accuracy to the results.

Of the possible functions $F_{m,n}$ we choose $F_{1,3}$ because this has the smallest half-width, and because the resultant frequency spectrum $G_3(\epsilon) = g(\epsilon)/\epsilon^2$ gives directly the departures from a Debye spectrum. The corresponding specific heat function $L_{1,3}(\beta) = -\beta^4\, d(C_V/3R)/d\beta$ can be derived from the usual plot of the equivalent Debye temperature $\theta(T)$ by using

$$L_{1,3} = (kT)^{-2}\frac{d(C_V/3R)}{d(kT)} = (k\theta)^{-3}\left[1 - \frac{d(\ln\theta)}{d(\ln T)}\right]B\left(\frac{\theta}{T}\right) \tag{7}$$

where the function

$$B\frac{\theta}{(T)} = -\left(\frac{\theta}{T}\right)^4\frac{d(C_V/3R)}{d(\theta/T)}$$

gives the value of $(k\theta)^3 L_{1,3}$ for a Debye solid. Values of $B(\theta/T) = B(\beta\epsilon_D)$, derived from Beattie's (1926) table of $C_V/3R$ as a function of θ/T, are given in the table, together with values of $F_{1,3}(\beta\epsilon)$. For a Debye spectrum, $G_3(\epsilon) = 3/\epsilon_D{}^3$ for $\epsilon \leqslant \epsilon_D$ and $G_3(\epsilon) = 0$ for $\epsilon > \epsilon_D$, and in equation (7), $k\theta = \epsilon_D$ is independent of temperature, so that from (2), we have $\beta\epsilon_D\, dB/d(\beta\epsilon_D) = 3F_{1,3}(\beta\epsilon_D)$.

A plot of $L_{1,3}$ against $-\ln\beta = \alpha$ now gives at once, from equation (3), a qualitative indication of the form of $G_3(\eta)$. To proceed further, we rewrite equation (3) in the form

$$L(\alpha) = \sum G_i(\eta_i)\bar{F}(\alpha-\eta_i)\delta\eta_i \tag{8}$$

in which $G(\eta)$ is approximated by a set of rectangular blocks of height G_i and width

$\beta\epsilon$; $\beta\epsilon_D$	$F_{1,3}(\beta\epsilon)$	$B(\beta\epsilon_D)$	$\beta\epsilon$; $\beta\epsilon_D$	$F_{1,3}(\beta\epsilon)$	$B(\beta\epsilon_D)$
1·0	0·151	0·09	7·0	76·950	150·4

$\delta\eta_i$ centred on the points η_i, and $\bar{F}$ is the average of F over a range $\delta\eta_i$ about η_i. A set of parameters $G_i(\eta_i)$ satisfying equation (8) can be found quite simply and rapidly by graphical trial-and-error methods; at the same time the latitude in the choice of these parameters can readily be estimated. At low frequencies ($\eta \to -\infty$), $G_3(\eta)$ tends to the constant value $3/\epsilon_0^3$, where $\epsilon_0 = h\nu_0 = k\theta_0$, and θ_0 is the low-temperature limit of $\theta(T)$. It is convenient to renormalize $G(\eta)$ and $L(\alpha)$ using this factor, and to take as variables $\eta-\eta_0 = \ln(\nu/\nu_0)$ and $\alpha-\eta_0 = \ln(T/\theta_0)$.

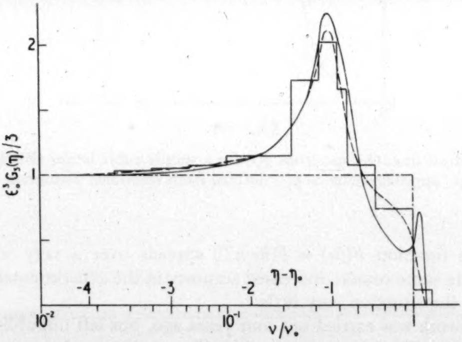

Figure 1. Full line: the spectrum $G_3(\eta)$ for a simple cubic lattice (derived from Blackman 1937). Histogram: approximation to $G_3(\eta)$ derived from Blackman's $\theta(T)$ curve, using equation (8). Dashed curve: smoothed version of histogram. Chain curve: Debye spectrum giving the same low-temperature θ.

To test this method, we have attempted to re-derive a known lattice spectrum from the resultant specific heat curve, using for the purpose the results of Blackman (1937) for the simple cubic lattice. Figure 1 shows the spectrum $G_3(\eta)$ so derived from Blackman's $\theta(T)$ curve, together with Blackman's original spectrum. The low-frequency end is not too badly reproduced, but the narrow peak at the high-frequency end is lost. Unfortunately, when we draw a smooth curve through the histogram and convert from

$G_3(\eta)$ to $g(\epsilon)$, this lack of detail is seen to be disastrous (figure 2). The result would not be improved appreciably by enforcing normalization of $g(\epsilon)$ to give

$$\int_0^\infty g(\epsilon)\, d\epsilon = 1;$$

this has not been done here. All inversion techniques will fail in this way, basically because the relevant variable in the inversion procedure is $\ln \nu$ rather than ν itself,

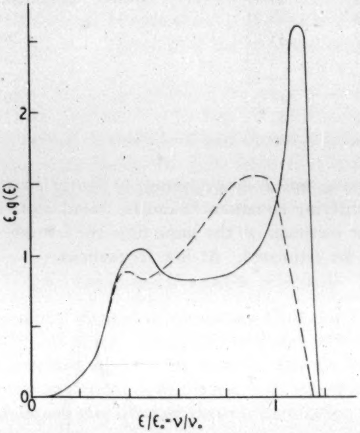

Figure 2. Full line: the spectrum $g(\epsilon)$ for a simple cubic lattice (Blackman 1937). Dashed line: approximation to $g(\epsilon)$ derived from smoothed histogram of figure 1.

and because the function $F(\beta\epsilon) = F(h\nu/kT)$ spreads over a very wide ratio of frequencies. For the same reason, increased accuracy in the experimental measurement of C_V will improve the situation very little.

Most of this work was carried out four years ago, but left unpublished when it was found that Lifshitz (1954) had already derived and discussed the inversion equations (4) and (5). It is published now partly to draw attention to Lifshitz's paper, which is apparently unknown to workers in this field, and partly to point out the limited practical value of inversion techniques generally, and to suggest that the information obtainable in this way may be most simply derived by the trial-and-error method outlined here.

Post-arc Temperature Decay

By J. W. S. ALLAN†, H. EDELS and D. WHITTAKER

Department of Electrical Engineering, University of Liverpool

MS. received 19*th June* 1961

Abstract. A method is described for determining the inter-electrode gas temperature at any chosen time following the current interruption of an arc discharge, using a rotating mirror camera to measure the velocity of a shock wave passing through the gas. From a series of such measurements the rate of temperature decay may be found, and results are given for times between 100 μsec and 1 sec after interrupting arcs in air between carbon electrodes. The average rates of decay of the mean core temperature during 1 msec following current interruption were 1·5 deg μsec^{-1} for an 8 mm gap (10 or 40 A) and 2·8 deg μsec^{-1} for a 2 mm gap (40 A). The temperature decay subsequent to a 40 A arc has also been calculated from a knowledge of the gas properties and with the assumptions of cylindrical symmetry and energy loss by thermal conduction only.

§ 1. INTRODUCTION

THE TEMPERATURE decay of the inter-electrode gas following the interruption of an arc discharge is of basic interest in the general study of electrode gap properties under varying applied electrical conditions. From a knowledge of the temperature distribution as a function of time assistance is given to the determination of the variation of other properties such as the total electrical conductivity, energy content, and the voltage required for arc re-ignition by either thermal or spark breakdown.

A direct investigation of the decay of arc gas temperature has been carried out by Wienecke (1955, 1956) on a 200 A carbon arc. From the known temperatures of the arc core and the boundaries of aureoles produced by CaO and CN molecules, he was able to record the temperature decay following current interruption by photographing the arc every 4·8 μsec. Indirect information of temperature decay has been obtained by Crawford and Edels (1960) from their measurements of re-ignition voltage against time; Paschen's law is used to estimate mean axial temperatures at decay times greater than 10 msec when the re-ignition voltage depends on gas density.

The temperature decay measurements described in this paper were obtained from the velocity of a shock wave which passed through the electrode gap. This method has been previously used by Edels and Whittaker (1957) to determine the temperature of the luminous core of a steady arc discharge. The shock wave may be considered as a moving probe whose speed is related to the gas temperature at each point in its path. A rotating mirror camera records the shock propagation which is shown by an increased brightness of the arc; in the non-luminous regions surrounding the arc the shock is displayed by means of a Schlieren system. In order to calculate the temperature, the shock strength as well as the shock speed must be known. The variation of the shock strength with the local gas temperature may be calculated for a plane wave from a theoretical relationship, and the attenuation introduced by the convexity of the wave front may be allowed for empirically.

---

† Now at Atomic Weapons Research Establishment, Aldermaston, Berks.

When applying this shock wave technique to time-dependent temperature distributions it is desirable that the temperature changes are small during the time taken for the high speed 'probe' to traverse the region of interest, so that the derived temperature distribution may be considered as an instantaneous picture. Because the passage of the shock alters the temperature distribution and its subsequent decay it is only possible to obtain one distribution at one chosen time for a given recovering arc. However, by probing a series of recovering arcs at various times after current interruption a set of radial temperature distributions with time as a parameter may be obtained, on the assumption that each arc recovers in the same way.

The steady state radial temperature distribution may be calculated independently of measurements for a given arc current and electrical field strength if the electrical and thermal conductivities of the arc gas are known functions of temperature. The temperature decay following current interruption may then be calculated if the enthalpy and gas density are also known as functions of temperature. This paper describes both the measurement and independent calculation of post-arc temperature decay.

§ 2. SHOCK WAVE THEORY

The analysis by which arc temperatures are obtained from shock velocities has already been treated in detail (Edels and Whittaker 1957), but a summary of this treatment follows.

An arc discharge can be considered to present a series of infinitesimal contact discontinuities to a shock wave travelling normal to the arc axis. At each of these discontinuities the incident shock wave results in the production of a transmitted shock and a reflected shock or rarefaction. The Rankine–Hugoniot shock wave equations and the equation governing the mass flow through a rarefaction wave may be applied in differential form to the interaction. The result of this analysis is a differential equation in terms of the incident shock velocity u, incident Mach number M and local ratio of specific heats γ. This relation fails to satisfy the integrability condition but insertion of typical experimental values shows that the change of γ across the shock front may be neglected. Integration of the remaining terms results in an equation of the form

$$uF(M,\gamma) = 1/c$$

where

$$F(M,\gamma) = \left(1-\frac{1}{M^2}\right)\left[\left(M^2+\frac{2}{\gamma-1}\right)^{1/2}+\left(M^2-\frac{\gamma-1}{2\gamma}\right)^{1/2}\right]^{[2(\gamma-1)/\gamma]^{1/2}}$$

$$\times\frac{[2\gamma M^2-(\gamma-1)]^{1/2}-[(\gamma-1)M^2+2]^{1/2}}{[2\gamma M^2-(\gamma-1)]^{1/2}+[(\gamma-1)M^2+2]^{1/2}} \qquad (1)$$

and c is a constant for a given shock. This relation is shown graphically in figure 1.

The value of c is found for each shock by measurement of its velocity at a point of known temperature outside the arc. The gas temperature at any other point may then be determined by measurement at that point of the velocity of the same shock.

In the original paper it was suggested that the value of γ to be used throughout the analysis was the steady-state value obtaining in front of the shock. However, measurements by Blackman (1956) have shown that the relaxation time of the vibrational degrees of freedom in nitrogen at 5500 °K is 5 μsec, and extrapolation of his results suggests that this time is reduced to 3 μsec at a typical steady-state arc temperature of 6500 °K.

This is the value for the relaxation time relating to a high pressure arc in air as the oxygen component is completely dissociated. In the work described in this paper the shock front passed through the arc in 2 μsec and hence it would seem reasonable to assume that only processes which occur within 2 μsec of the passage of the shock influence the arc temperature measurement. The vibrational degrees of freedom may therefore be considered as inert during the immediate shock transition. Such a consideration applies only to a relatively weak shock, in which the temperature rise across the front is small. In practice, the value of γ chosen is not critical because of the parallelism of the family of γ curves in figure 1 for say m less than 2. Hence the results of Edels and Whittaker are virtually unaffected by the assumption that the vibrational degrees of freedom are immediately active during the shock transition.

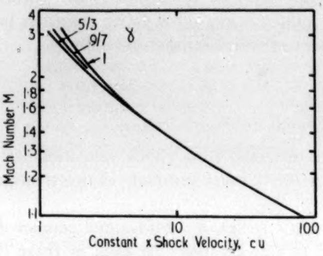

Figure 1. Variation of Mach number with shock velocity.

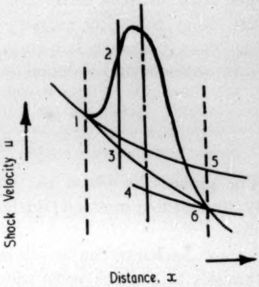

Figure 2. Attenuation of shock passing through arc channel.

The foregoing analysis applies only to the propagation of a shock front which remains plane throughout its passage. It is this planarity which allows the determination of the Mach number and shock velocity at any one point to define directly the value of the constant c at all other points. However, in the practical measurement of an arc temperature by the passage of a shock front through the discharge and its immediate surroundings the wave front becomes convex and the shock strength attenuates. The convexity is set up by normal spherical expansion of the shock front while outside the arc, and also by interaction with the radial temperature distribution of the discharge while within the arc boundaries (Poritsky and Suits 1935).

The attenuation caused by the open-atmosphere expansion of a shock wave can often be represented for many gases at various temperatures and pressures by the empirical relation

$$\log\frac{M_1-1}{M_2-1}=\frac{x_2-x_1}{d} \tag{2}$$

where d is a constant of the order of 5 cm (Edels and Whittaker 1957). However, although this equation describes attenuation when the initial Mach number is less than about 2·6, it underestimates the effect at higher shock strengths. Hence an upper limit of $M_1 = 2{\cdot}6$ was placed on the shock strength used in temperature measurements.

As expected the arc produces additional shock attenuation because of its radial temperature distribution. The effects of attenuation are depicted in figure 2. Thus in a constant-temperature gas, shocks would attenuate according to equation 2 along, for example, line 1,5 or 4,6. Within the arc, however, a velocity distance curve 1,2,6 is obtained. If now the stream lines which exist in the arc were followed in a constant-temperature gas then some curve such as 1,3,6 would be obtained. If these lines were plotted with the ordinate linear in $\log(M-1)$ then lines 1,5 and 4,6 would be straight and parallel. The exact position of line 1,3,6 will depend on the spatial details of the extra attenuation caused by the arc, but fortunately little error will be produced by an inaccurate guess and a convenient and not unreasonable assumption is that it too is straight. Hence at point 3 when a fraction f of the distance x_6-x_1 has been traversed, M_3 is obtained from $M_3-1 = (M_1-1)^{1-f}(M_6-1)^f$. As u_3, M_3 and u_2 are now known the curves of figure 1 may be used to find M_2 and hence the velocity of sound and temperature at point 2. The radial temperature distribution may thus be found by allowing f to vary, and the core value obtained when $f = \frac{1}{2}$.

§ 3. EXPERIMENTAL METHOD AND RESULTS

The increase in density occurring across a shock front which is traversing a self-luminous gas is accompanied by an increase in luminosity. The propagation of this increased luminosity through a horizontally burning d.c. arc is recorded by a rotating mirror camera, as indicated in figure 3. The correction for shock attenuation and the application of the plane wave theory require a knowledge of the shock velocity at two points outside the arc. This information is obtained by the inclusion of a Toepler–Schlieren system, which also serves in the measurement of the shock velocity within the arc when the self-luminosity of the discharge has decayed. The shock wave originates from a spark gap at the back of a shock tube, the mouth of which lies 2 cm from and perpendicular to the arc axis. The arrival of the shock in the arc is synchronized with the correct rotating mirror position by reflection of light from an auxiliary mirror on the main shaft into a photomultiplier PM_1, the output of which trips the shock-generating spark. The electronic flash tube constituting the Schlieren source is synchronized with the generation of the shock.

Figure 3. Schematic layout of optical system.

The arc under investigation is initiated by spark breakdown of the inter-electrode space. Current from the d.c. mains supply follows through and an arc discharge is established. After 150 msec of current flow the discharge is interrupted within 5 μsec by the diversion of the current through a mercury thyratron connected across the arc. The delay time at which the gas temperature is made is then determined by an electronic delay unit which is activated by the input pulse to the diverting thyratron. The output of the unit operates the shutter, thereby triggering the shock wave and allowing a single exposure of its passage through the decaying arc plasma. For post-extinction times less than the period of rotation of the mirror (3·3 msec), the delay between arc extinction and shock production is provided by a second photomultiplier PM_2. This is operated by light reflected from a second auxiliary mirror and the output trips the diverting thyratron. The decay time at which temperature measurements are made is therefore determined by the relative positions of the two auxiliary mirrors on the rotating shaft.

All events in the experimental cycle which do not require precise timing, such as initiation of the arc and its extinction on the longer delays, are controlled by a rotary cam system.

Temperature measurements are made with the mirror rotating at a predetermined speed. This speed is monitored by a third photomultiplier PM_3, the output of which is displayed oscillographically against a standard oscillator. Measurement of an angle on the streak photograph and a knowledge of the constants of the optical system give the shock velocity at any point in the field of view.

Figure 4 (plate) shows a set of rotating mirror photographs of the passage of a shock front through the decaying hot gas at various times after interrupting the current of a horizontal 10 A d.c. arc between 4 mm diameter spectroscopic carbon electrodes 8 mm apart in air at one atmosphere pressure. The results presented in figure 5 are mean temperatures across the arc core. They were obtained at the longitudinal mid-points of d.c. arcs burning horizontally between spectroscopic carbon electrodes. No temperature measurements could be made in the range from 5350 °K to 3400 °K as the self-luminosity of the arc was too weak and the Schlieren sensitivity was insufficient at the low gas densities. As the camera was operating at its optimum performance (Edels and Whittaker 1955) this gap in the measurements could be best filled by increasing the sensitivity of the Schlieren system. The present system can detect only a deflection of about 10^{-2} radian at 3400 °K, which is in accordance with theoretical expectations. It is possible to build a Schlieren system to detect easily angular deflections of 10^{-4} radian, but with the difficult conditions of a steady state arc in the light path this is increased to 10^{-3} radian (Sperling 1950). The sensitivity of the present system could be improved by either increasing the focal length of the second Schlieren lens or reducing the unobscured width of the static Schlieren source image at the knife edge.

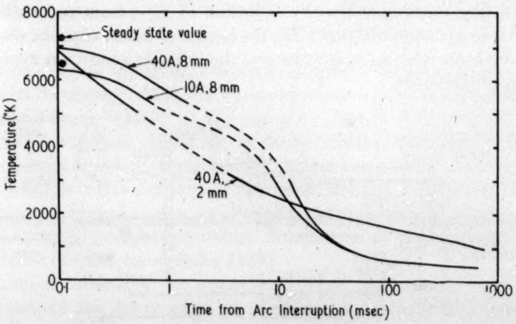

Figure 5. Decay of mean core value of arc gas temperature. Horizontal arc in air at 1 atmosphere pressure between 4 mm diameter spectroscopic carbon electrodes.

This latter method may not be useful because of increasing diffraction effects, although replacing the knife edge by a graded filter could help (Holder and North 1953).

The estimated errors in the temperature values are ±3% for those lying above 3000 °K, ±5% for values between 3000 °K and 1000 °K and ±10% for values below 1000 °K. The error in the measurement of decay time does not exceed ±2% throughout the whole range.

The variation of temperature with radius at any required time may be determined from the rotating mirror photographs by measuring the variation of shock velocity as it passes through the arc. The best records were measured in detail at points corresponding to every 4·5 mm along the arc diameter (0·45 mm on the photographic record), and after allowing for shock attenuation as described in § 2 the radial temperature distribution may be obtained. However, the accuracy of these measurements is at present poor compared with the average core temperatures because of the difficulty of measuring angles over short distances on the photographs, and so only the steady state distribution and the axial temperatures of the decaying arc are shown in figure 8.

In order to check that the discharges under investigation had reached complete equilibrium before interruption some steady-state temperature measurements were made both on arcs which had been burning for 150 msec and on arcs which had burned for several seconds. The results obtained for these two arc conditions agreed well within the experimental errors.

§ 4. THEORETICAL TEMPERATURE DECAY

The energy balance equation for a gas which has an electrical input due to an applied field strength E and losses caused by thermal conduction and gas flow may be written

$$\sigma E^2 = -\nabla . k\nabla T + \rho\left(\frac{\partial h}{\partial t} + v . \nabla h\right) - \left(\frac{\partial p}{\partial t} + v . \nabla p\right) \tag{3}$$

where T, ρ, h and p are the gas temperature, density, enthalpy and pressure, $\sigma(T)$ and $k(T)$ are the electrical and thermal conductivities of the gas, and v is the gas velocity.

In a steady-state well-stabilized arc which is convection-free and cylindrically symmetric the arc current I and the tube radius R at a temperature T_{R} completely determine the radial temperature distribution for a given gas. The axial temperature T_0 is a monotonic increasing function of IE, and ER is a slowly varying function of I/R. An analytic solution for the temperature distribution of this model may be obtained from the simplified energy equation which is derived from equation (3) by putting $\partial/\partial t = 0$ and $v = 0$, thus

$$\sigma E^2 = -\frac{1}{r}\frac{d}{dr}\left(rk\frac{dT}{dr}\right). \tag{4}$$

If we choose new variables $x = Er$ and $S = \int kdT$ from T_{a} to T (where T_{a} is an arbitrary temperature), and take a piecewise linear function to approximate to the actual nonlinear relationship between σ and S a solution may be obtained in terms of Bessel functions (Maecker 1959, Goldenberg 1959). Pelzer (1958) calculated for a carbon arc in air that the contribution of radiation to the total energy loss is small, and therefore its omission from equation (4) will not cause a large error.

After current interruption there is no power input, and the gas cools to the ambient temperature. A direct consequence of this cooling is a reduction of pressure towards the axis, which causes gas to flow radially inwards. The pressure gradient necessary to produce the gas flow is quite small, and may be neglected as far as the associated energy is concerned. The equation of the conservation of mass gives the contraction velocity as

$$-v_r = \frac{1}{r\rho}\int_0^r r\frac{\partial \rho}{\partial t}dr \tag{5}$$

where the gas density is related to the temperature on the assumption of constant pressure. The combination of the inward flowing gas and the radial temperature gradient increases the rate of cooling at any given radius. The energy equation becomes for these decay conditions

$$-\rho\frac{\partial h}{\partial t} = -\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial S}{\partial r}\right) + \rho v_r \frac{\partial h}{\partial r}. \tag{6}$$

Substituting for v_r from equation (5) the equation in terms of one dependent variable h is

$$-\rho\frac{\partial h}{\partial t} = -\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{r}{\alpha}\frac{\partial h}{\partial r}\right) + \frac{1}{r}\frac{\partial h}{\partial r}\int_0^r \frac{r\rho}{\beta}\frac{\partial h}{\partial t}dr \tag{7}$$

where $\alpha = dh/dS = C_p/k$ and $\beta = -\rho dh/d\rho$. In this non-linear differential equation we have the three non-linear coefficients α, β and ρ. The equation states that the rate of decay of enthalpy at a given radius equals that due to thermal conduction plus that caused by the gas contracting. If we consider these two effects taking place alternately instead of simultaneously the radial temperature profile shown by curve *a* in figure 6 would change to curve *b* after some small time because of the conduction loss, and the contraction effect would then alter the profile to curve *c*. By use of equation (4) to obtain a steady state profile, the change during a small time interval may be calculated numerically using iterative processes based on equation (7) (Whittaker 1960).

For air at a pressure of 1 atmosphere the values of α, β, ρ and T as functions of h are given in figure 7 (T and ρ from Predvoditelev 1958 and Treanor and Logan 1956,

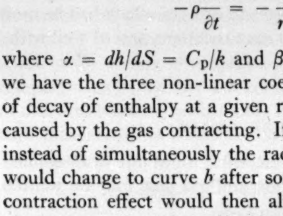

Figure 6. Temperature decay produced by conduction and contraction effects.

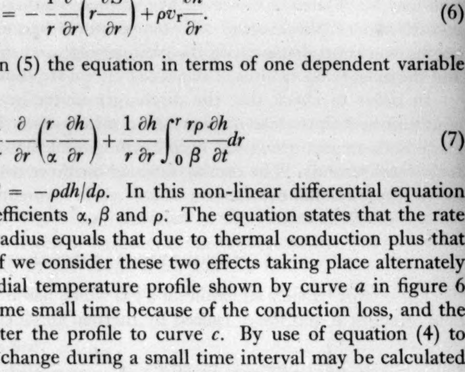

Figure 7. Variation of α, β, ρ and T with h for air at 1 atmosphere pressure.

and data for α from Wienecke 1956). In order to compare a calculated temperature decay with a measured result of § 3 the experimental conditions of the 40 A arc with a gap length of 8 mm were chosen as best suiting the theoretical assumptions of a cylindrical arc cooled by conduction. A theoretical steady-state radial temperature distribution was calculated to fit the measured temperatures at the axis and at 4·5 mm radius, and is shown in figure 8 at time $t = 0$. Normally the variation of electrical conductivity with temperature would be required to draw this curve, but as this data is not well established for air it was necessary to assume a reasonable *shape* for $n\sigma(T)$, where n is an unknown constant. The total power dissipation is obtainable from the calculated $T(r)$ curve, for at any radius where the electrical conductivity is zero we have $EI = -2\pi rk \, dT/dr$. As the experimental arc current is known, the field strength, total conductivity of the arc column, and the value of n may be calculated in turn. Temperature profiles subsequent to current interruption are given in figure 8 with time as a parameter.

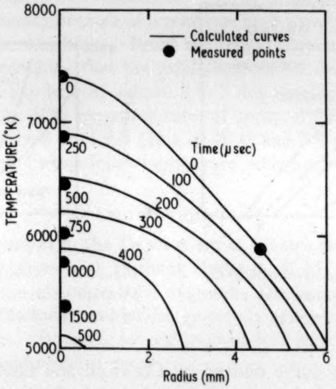

Figure 8. Decay of radial temperature distribution for a 40 A arc in air.

It is appropriate to comment on the importance of the contraction of the gas on the cooling arc, as the solution of equation (7) would be considerably easier if the last term, representing contraction, were omitted. The equation would then be similar to that of the cooling of a solid rod where contraction is negligible and for which series solutions are available. A comparison of the numerical solutions which include and omit this contraction effect for the arc already considered is shown in figure 9. It is seen that the temperature decay at large radii is considerably underestimated when contraction is neglected, and the error at the axis, although initially zero, has become appreciable at 200 μsec.

§ 5. DISCUSSION

Figure 5 shows that for the 8 mm gap length the temperature of the 40 A arc is initially higher than the 10 A arc, and remains higher throughout the decay period. This result is as expected, for both the initial power input and the thermal energy stored in the arc column are higher for the 40 A arc.

Comparison of the 2 mm and 8 mm gap length characteristics of the 40 A arc shows clearly that the initial rate of temperature decay is much more rapid in the 2 mm gap. The average rates of decay for the first millisecond are 2·8 and 1·5 deg μsec^{-1} respectively. This considerable influence of the proximity of the 4 mm diameter electrodes to the whole plasma has also been revealed by work on re-ignition phenomena (Edels and Crawford 1957). Carbon electrodes operate at temperatures in the region of 4000 °K. It follows that, in the initial stages of plasma temperature decay, the electrodes help to cool the gas by thermal conduction. The shorter the gap, the greater is the influence of the electrodes on the plasma as a whole. Because of the much greater thermal capacity of the electrodes compared with the intervening gas, they cool considerably more slowly. Hence a point will be reached in the decay at which the electrodes begin to slow down the cooling of the inter-electrode space by returning thermal energy to the gas. An intersection of two characteristics of arcs of different gap length is therefore to be expected and is, in fact, revealed in figure 5 at the reasonable gas temperature of 2200 °K.

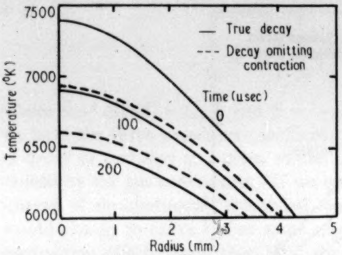

Figure 9. Comparison of temperature decay including and omitting contraction effect.

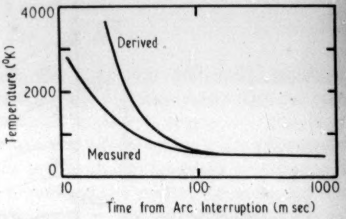

Figure 10. Comparison of measured temperature decay with that derived by Crawford and Edels (1960). (20 A, 8 mm gap, air.)

A temperature decay curve derived by Crawford and Edels (1960) from their re-ignition voltage characteristics using Paschen's law is shown in figure 10. There are large differences between this derived curve and that obtained by the shock wave technique for decay times up to 100 msec. This will be mainly due to the shock wave measuring the gas temperature midway between the electrodes, whereas the temperature derived from the re-ignition voltage assumes the gas density is longitudinally uniform and so gives a mean axial temperature. As the gas approaches the ambient temperature these two methods of measurement agree, giving about 600 °K at 100 msec and 450 °K at 1 sec.

It is not possible to compare the present results with the work of Wienecke (1956) as his initial arc current was so much greater. His photographic method which recorded the radial positions of distinctive aureoles was used to determine the temperature decay of the high temperature gas during the first millisecond after the interruption of a high current arc.

On comparing the theoretical calculations with the experimental results for the 40 A arc, 8 mm gap, figure 8 shows that for the initial fall of the central temperature from 7400 °K to 6000 °K the theoretical rate of decay is about 4 deg μsec^{-1} whilst the measured rate is 2 deg μsec^{-1}. This discrepancy would be slightly increased by some effects which have been neglected, for example, the cooling due to radiation and the electrodes. However, the experimental arc was horizontal, and so convection would produce a considerable flow of hot gas upwards, rather like a hot vertical slab of gas with the heat input near the lower edge, instead of the cylindrical model which was analysed. The theoretical figure of 4 deg μsec^{-1} for a cylinder would possibly be reduced to 3 deg μsec^{-1} for such a slab—the initial rate of decay would be halved at the centre, with smaller reductions towards the boundaries. The remaining discrepancy is probably due to measurement errors which would affect both the observed rate of temperature decay and the initial radial temperature profile used for the calculated decay. As reliable data on the electrical conductivity of air is not available it is not possible to check the initial profile against the experimental arc current, and unfortunately the calculated rate of decay depends strongly on this profile.

§ 6. CONCLUSIONS

A shock wave may act as a convenient probe to investigate the temperature of the cooling gas following arc interruption. Mean core temperatures in the range 8000 °K to ambient temperature have been measured. Radial temperature measurements were made with only poor accuracy because of limitations in the resolving power of the optical system and photographic emulsions. From the temperature measurements and theoretical calculations we conclude that the axial temperature decay of a horizontal 40 A carbon arc in air, 8 mm gap length, is from 2 to 3 deg μsec^{-1} during the first 500 μsec after current interruption. The measured rates of decay of the mean core temperature were 1·5 deg μsec^{-1} for the 8 mm gap (10 A or 40 A) and 2·8 deg μsec^{-1} for the 2 mm gap (40 A), averaged over 1 msec following current interruption.

ACKNOWLEDGMENTS

The work was carried out in the Department of Electrical Engineering, University of Liverpool, and the authors wish to thank Professor J. M. Meek for his interest in the work and the facilities placed at their disposal. The financial aid provided by the Central Electricity Research Council is also gratefully acknowledged. Thanks are also due to Mr. J. C. Holmes, who made several independent checks in this Department of the measured rates of temperature decay.

PROC. PHYS. SOC., 1961, VOL. 78

The Effect of a Thermal Gradient upon Charge Separation between Similar Polyethylene Surfaces

By A. H. BOWLES

The British Cotton Industry Research Association, Manchester 20

MS. received 1*st February* 1961, *in revised form* 12*th September* 1961

Abstract. The apparatus and method are described by which the separation of electrostatic charge between similar polyethylene spheres, initially at different temperatures, during an impulsive contact has been observed.

The amount of such a charge separation varies during a series of observations both progressively and randomly. A component of this charge separation is shown to depend upon the direction of the thermal gradient across the interface. The progressive variation in charge separation with number of impacts is shown to be consistent with a transfer of 'active centres' from one surface to the other. The quantity of charge which separates between two surfaces is also shown to vary with different contact areas on one surface.

§ 1. INTRODUCTION

An illustrative theory of charge separation between surfaces not quite in contact, but close enough for charge carriers to pass from one to the other, has been proposed by Henry (1953a), taking account of differences between the two surfaces in affinity for, and abundance of, charge carriers, and in temperature.

This model was further developed (Henry 1957), to show that if the surfaces were at different temperatures a component, due to kinetic processes, of the charge density formed over the contact area on separation, would be given by σ where

$$\frac{4\pi e\sigma}{K} = \left[\mu + \frac{V_{\mathrm{m}} - \frac{1}{2}(V_1 + V_2)}{kT} \right] \frac{k\Delta T}{D}$$

in which V_1, V_2, V_{m} are potential energies, relative to an arbitrary zero, of charge carriers at equilibrium on surface 1, surface 2, and at the point of maximum energy between the surfaces respectively, T is the mean temperature of the surfaces, ΔT the temperature difference between the surfaces, D the distance between the surfaces and e the charge on a carrier. μ is a constant of value between $\frac{1}{2}$ and 2, K the effective dielectric constant between the surfaces and k is Boltzmann's constant. Each of these parameters is determined at that instant during the separation of the surfaces when carriers just cease from crossing the gap at a significant rate. (See, e.g., Harper 1951).

The term $\Delta T/D$ in this equation represents a temperature gradient across empty space between two flat surfaces that have been assumed in the model in order to make calculation simple. In reality the two surfaces will not be flat, and the distance between them when carriers are able to cross will be a few ångströms only, comparable with the dimensions of the atoms of which they are made. Under these conditions it is impossible to assign definite positions and temperatures as for the model surfaces, but the notion of a temperature gradient across the interface remains useful. We may suppose that with a more sophisticated model temperature gradient would enter the equation for σ in a similar way to $\Delta T/D$.

This theory was invoked by Henry (1953b) to explain the observation of a separation of charge between like surfaces on being rubbed together. Such a separation has been observed by Shaw (1927), Gruner (1953) and Henry (1953b) between two similar rods rubbed together asymmetrically, that is to say the small contact area of rod A rubbed along the length of rod B and vice versa. The rod contributing the smaller area to the rubbing process was observed to acquire a particular polarity whether it was A or B. On the basis of the above theory the small contact area which during rubbing becomes on balance warmer than the other rod is supposed to lose a greater number of charge carriers than it gains. Henry (1953b) further demonstrated that charge also separated between like surfaces rubbed together in an apparently symmetrical manner. In this case the asperities on each surface presumably acquired a higher temperature than the rest of the opposing surface and lost carriers to it.

These observations suggested that a charge separation due to a temperature gradient would be measurable when separated from other effects.

§ 2. DESCRIPTION OF EXPERIMENT

A steep temperature gradient is obtained by bringing two spherical specimens together, initially at different temperatures, for a brief interval. They are mounted as the bobs of two pendula and one is allowed to fall through a pre-determined arc to strike the other once, after which they are kept apart.

Before each collision the spheres are discharged in ionized air. Charge on either sphere is measured by deflecting it into one of two Faraday cylinders connected to a vibrating reed electrometer described by Thomas and Finch (1950) and modified to degenerate external input capacitance. These give a measure of charge repeatable to 3×10^{-14} coulomb; this is about an order of magnitude smaller than the repeatability of the production of charge by a collision.

Polyethylene was chosen as the experimental material on account of its high surface resistivity, chemical simplicity, inertness to water, toughness and easy machinability. It had also been used to demonstrate charging by both asymmetric and symmetric rubbing by Henry (1953b). The material sets a limit on the maximum temperature which may be used on account of variation in the proportions of amorphous and crystalline regions above 80 °c as shown by Bunn and Alcock (1945).

An electrically screened oven below the point of suspension of the pendula allows either bob to be heated to a reproducible temperature when required. In this way the right-hand bob R at room temperature can be drawn aside and released to strike the left-hand bob L hanging inert in the oven, which can be heated or not, or vice versa.

2.1. *Apparatus*

The essential parts of the apparatus are shown in figure 1. All the apparatus, save only the oven element, insulation, pendulum trunnions and rods, is of brass in order to avoid local electric fields due to contact potential differences, which can cause currents to flow when the air in the apparatus is ionized to discharge the specimens. The pendulum head assemblies are mounted in ball bearings in adjustable supports which allow the axes about which the pendula swing to be made parallel. Each pendulum may be adjusted in length and rotated about its axis to any of eight positions determined by an indent mechanism on the pendulum head assembly. The pendula are adjusted so that on collision their contact areas are perpendicular to the direction of their relative motion, i.e. the bobs collide squarely.

Figure 1. Schematic diagram of apparatus.

The oven has a hard glass tube with a longitudinal slit to allow the passage of the pendula. The tube supports an electrical heating element of a single layer of 'Aquadag' and electrodes of 'Burnish Silver' fired on. This element is insulated from a thin brass lining by a sheet of mica as shown in figure 2. This lining is bonded to the earthed brass of the apparatus in order to extend into the oven the equipotential space in which the specimens are discharged. One junction of a thermocouple is soldered to the oven lining and the other held near a brass screen on the apparatus. The e.m.f. generated is measured with a potentiometer to give a measure of the temperature difference between the oven lining and room. At each end of the oven removable brass flaps are fitted to reduce convective cooling of specimens being heated within the oven.

Figure 2. Construction of carbon film oven.

The Faraday cylinders are arcuate brass tubes of circular cross section held on polyethylene supports. They have longitudinal slits to allow the pendulum bobs to enter and are enclosed in earthed brass screens. A well insulated lead is taken from each cylinder to a junction box and thence to the electrometer. The input resistance of the electrometer is kept at a nominal $10^{12}\Omega$ and charge is measured on one of a selection of capacitors of 10 pF or more. The charge on a pendulum bob is measured by observing the change in potential in millivolts across one of these capacitors when the bob is swung into or out from a Faraday cylinder and is recorded in units of 10^{-14} coulomb. The constant of proportionality between the charge on the bob and the charge induced on the measuring capacitor has not been accurately determined, but is not very different from unity.

The duration of contact between the colliding bobs was measured in a separate experiment on the same spheres as were used for the charge separation measurements. A fine copper wire was fused into the surface of each bob near the support tube and a just opaque film of aluminium was evaporated on *in vacuo*. These films gave a conducting path between a wire and about a third of the equator of each bob. During contact a signal was conveyed from a battery to an oscilloscope where it was compared with time marker pips from a crystal controlled oscillator.

The magnitude of the thermal gradient obtained through the interfacial region on separation may be estimated using the analysis of Carslaw and Jaeger (1947) for semi-infinite bodies at temperatures of $T \pm \Theta$ respectively and brought together at time $t = 0$ over the plane $x = 0$. The thermal gradient is given as $\partial\theta/\partial x$ where

$$\frac{\partial\theta}{\partial x} = \frac{\Theta}{(\pi\kappa t)^{1/2}} \exp\left(-\frac{x^2}{4\kappa t}\right),$$

κ is the thermal diffusivity of material $1{\cdot}4 \times 10^{-3}$ cm^2 sec^{-1} for polyethylene, t the time of separation of bobs 253 ± 8 μsec and 2Θ the difference in temperatures of bobs before impact $= 24 \pm 2$ deg.

Substitution gives $\partial\theta/\partial x = 1{\cdot}0 \times 10^4$ deg cm^{-1} and shows that over 90% of this interfacial value is maintained up to a distance of 3×10^{-4} cm from the interface.

2.2. *Preparation of Samples*

With experiments in air, dielectric breakdown of the gap between separating surfaces limits the observed charge density to about 5–10 e.s.u. cm^{-2}. This corresponds to about one electronic charge per 10^6 Å^2 of surface area, so clearly a minute amount of active impurity can be of importance. Cleanliness of this order would probably be impracticable for experiments done in the air of a laboratory. In the present work, therefore, the aim has been rather to form surfaces in a reproducible state of ordinary cleanliness. This state has been preserved for as long as possible by enclosing the apparatus in a glass case with a sliding door to allow access. In addition the air around the specimens is kept ionized whenever a charge measurement is not being made in order to dissipate charges and avoid the attraction of matter from the air.

Polyethylene rod as received by us was found to be somewhat molecularly oriented, probably during an extrusion process. This orientation causes distortion of a cut rod as it is softened, thereby showing evidence of internal stresses.

The internal stresses of the polythene to be used for making specimens are first relieved by melting the rod in a container and allowing the melt to cool very slowly. Spheres are then machined out of this material, scrubbed with soap and water, rinsed in tap water and three changes of distilled water and then extracted with ethyl alcohol in a Soxhlet apparatus during about three minutes. These cleaned spheres are then steeped in distilled water for at least an hour and allowed to dry in an ionized atmosphere during several hours. The surface of the sphere is then made smooth by immersing it for a second or two in a small tubular electric oven closed at one end. The walls of the oven are at a temperature of 900 °c or thereabouts and the surface of the sphere melts quickly while the centre remains solid. Surface irregularities and machining marks disappear to leave the sphere glossy and smooth. The above cleansing procedure is then repeated.

2.3. *Method of Operation*

A freshly prepared, or newly cleaned, pair of spheres is mounted on the tubular pendulum arms by means of short lengths of screwed duralumin rod. They are adjusted in position and discharged by ionizing the air around them by means of an 80 μc radium source for several hours.

The radium source is withdrawn and either pendulum is drawn aside to a deflection stop whence it is released to collide with the other within the oven, which may be heated or not, at a definite velocity. Twenty minutes are allowed for a change in temperature to be established in a sphere and five minutes for a temperature to be restored after an impact and measurement.

A charge on each sphere is measured both before and after a collision. The increment of charge on each sphere due to the collision is recorded, and a mean of the two (with the sign of one reversed) is taken to give the mean charge separated due to the collision. This is arbitrarily given the same polarity as the increment of charge obtained by specimen R and is represented by the charge separations q_α, q_β, q_γ, q_δ according to the type of collision (see below). Readings of room temperature and oven thermocouple e.m.f. are also recorded. During the period between observing the charge and the next collision the air around both spheres is ionized by the Ra source for a minimum of three minutes. In this way charge is measured after each of four types of collision between the same pair of spots on the spheres. The types of collision are defined and symbolized by α, β, γ, δ, where:

α	R strikes L;	both at room temperature
β	R strikes hot L;	R at room temperature
γ	L strikes R;	both at room temperature
δ	L strikes hot R;	L at room temperature

where R, L are used to denote the right-hand and left-hand spheres as seen from the front of the apparatus.

3.1. *Treatment of Results*

It is found that, after having been newly cleaned, a pair of spots suffers a change which progressively alters the charge separation between them for any type of collision. In order to be able to eliminate this effect the types of collision are intermingled successively so far as is practicable. Two successions of collision types are possible and each was used. They are

$$\alpha, \gamma, \alpha, \gamma, \beta, \beta, \delta, \delta, \alpha, \gamma, \alpha, \gamma, \beta \ldots$$

$$\gamma, \alpha, \gamma, \alpha, \delta, \delta, \beta, \beta, \gamma, \alpha, \gamma, \alpha, \delta \ldots.$$

It is too time-consuming to intermingle β, δ singly owing to the time taken in establishing a temperature change.

Observations were taken in this manner in groups. Each group contained observations limited to one particular spot on each sphere and is subdivided into a series of runs, each run being made on a different day. The groups are separated by the spheres being dismounted from the support tubes, washed, remounted and re-aligned. Thus it is probable that each group represents charge developed between a different pair of spots.

The effects of a thermal gradient may conveniently be separated from disturbing effects of comparable magnitude by plotting the observed charge separation against position in the succession of observations. The observations of group 3 run (*a*) are used to illustrate this in figure 3. In this case the succession of observations was β, β, δ, δ, α, γ, α, γ and so on. Adjacent observations of a given type are then joined by straight lines to form a track. The progressive effect which is then manifest for each type of collision may now be eliminated by forming the quantities $p_{\alpha\beta}$, $p_{\gamma\delta}$ where

$$p_{\alpha\beta} = q_\beta - q_\alpha = \text{separation between } \beta \text{ and } \alpha \text{ tracks}$$
$$p_{\gamma\delta} = q_\delta - q_\gamma = \text{separation between } \delta \text{ and } \gamma \text{ tracks}$$

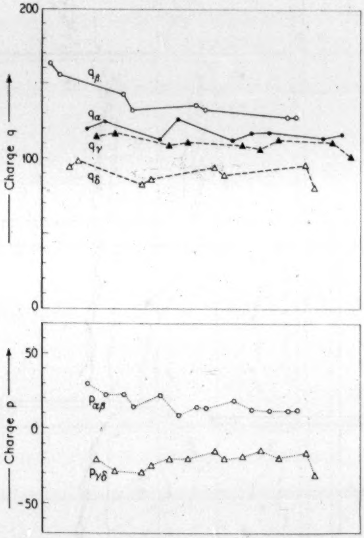

Figure 3. Explanatory diagram of method of displaying the results.

These quantities are then plotted serially in a similar manner to the *q*'s. The reversible effect due to a temperature gradient is then shown by the lines joining adjacent $p_{\alpha\beta}$ points being more positive than those joining adjacent $p_{\gamma\delta}$ points throughout their run, or vice versa.

3.2. *Results and Conclusions*

These are presented diagrammatically in figure 4 according to the scheme defined above. From examination of this figure it may be seen that

(i) several factors combine to give the charges measured as q_α, q_β, q_γ, q_δ (see Appendix II),

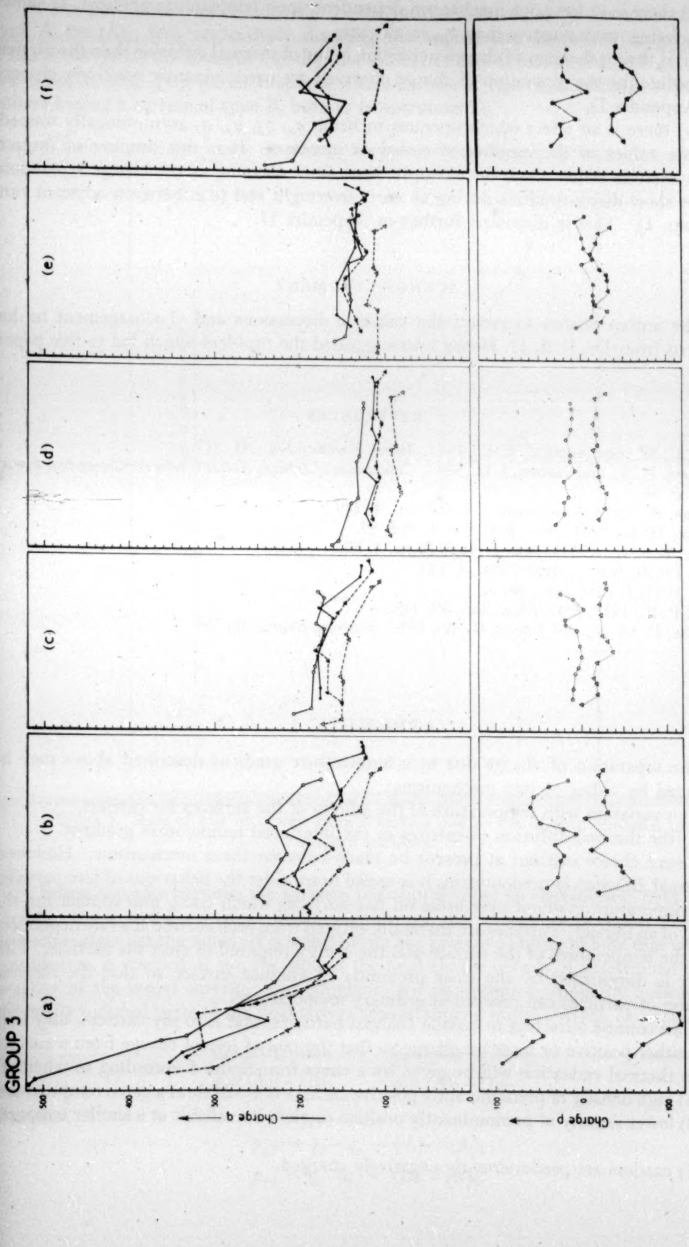

Figure 4. Diagram of the results obtained.

(ii) there is at least one mechanism dependent upon temperature gradient, as shown by $p_{\alpha\beta}$ being more positive than $p_{\gamma\delta}$ in all cases,

(iii) if the mechanism of charge separation is one of thermal diffusion then the carriers responsible for the separation of charge observed are predominantly positively charged (see Appendix I),

(iv) there is an effect which operates to bring q_α, q_β, q_γ, q_δ asymptotically towards separate values as the number of collisions increases. It is this number of impacts which matters rather than, for example, time since cleaning as the charge separations do not show discontinuities during an early overnight rest (e.g. between adjacent runs in group I). This is discussed further in Appendix II.

ACKNOWLEDGMENT

The author wishes to record the valuable discussions and encouragement he has received from Dr. P. S. H. Henry who suggested the problem which led to this paper.

APPENDIX I

The separation of charge due to a temperature gradient described above may be produced by either of two mechanisms:

(1) a variation with temperature of the affinity of the surfaces for carriers,

(2) the thermal diffusion of carriers in the interfacial temperature gradient.

A sure choice can not at present be made between these mechanisms. However, if thermal diffusion is predominant, it is useful to consider the behaviour of free particles in a temperature gradient over areas on two surfaces which come into contact for the period of an impact. Particles are thermally emitted from each surface at a rate dependent upon the temperature of the surface and the energy required to eject the particle. This energy is diminished by the close proximity of another surface so that the thermal emission of particles can proceed at ordinary temperatures.

If we confine ourselves to mobile charged particles, that is to say carriers, they may carry either positive or negative charge so that the rate of loss of charge from a surface due to thermal excitation will be given by a curve from figure 5 according to whether:

(A) high density of predominantly positive carriers is available at a given temperature,

(B) lower density of predominantly positive carriers is available at a similar temperature,

(C) carriers are predominantly negatively charged.

At two particular temperatures T_1, T_2 the rates of loss of charge from a surface of type A are $(A)_1$, $(A)_2$ respectively denoting the appropriate curve and temperature. Thus if two solids are brought together the initial net rate of loss of charge is given by, for example, $(A)_1-(B)_1$ for an L sphere with a surface of type A in collision with an R sphere having a surface of type B, both at temperature T_1.

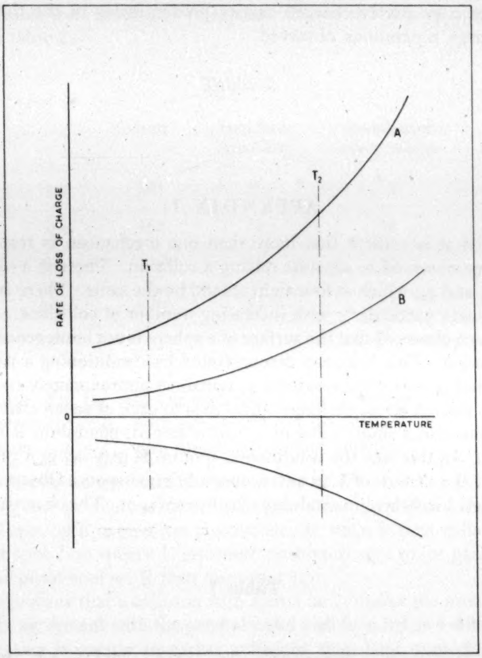

Figure 5. Rate of loss of charge from a surface due to the thermal emission of charged particles.

Charges separate between the surfaces and superimpose an electrostatic field which modifies the A and B curves so that at equilibrium the relevant rates of loss of charge by each surface are the same. It is sufficient for the present purpose to note that whether equilibrium is reached or not the sign of the final charge density is determined by the polarity of the initial current. For simplicity we assume proportionality between the thermally induced parts of the final charge separation and initial current, in which case:

$$q_\alpha \propto (A)_1-(B)_1 \qquad q_\beta \propto (A)_2-(B)_1$$
$$q_\gamma \propto (A)_1-(B)_1 \qquad q_\delta \propto (A)_1-(B)_2$$

whence

$$p_{\alpha\beta} = q_\beta - q_\alpha = (A)_2-(A)_1$$
$$p_{\gamma\delta} = q_\delta - q_\gamma = (B)_1-(B)_2.$$

By inspection of figure 5 it is clear that $p_{\alpha\beta}$ and $p_{\gamma\delta}$ are of opposite sign when surfaces A, B collide and of the same sign when surfaces A, C (or B, C) collide. Thus if $p_{\alpha\beta}$ and $p_{\gamma\delta}$ are found to be of opposite sign we conclude that the major part of the thermally induced charge separation is due to carriers of similar polarity from each surface, and vice versa.

In the case of the present experiments $p_{\alpha\beta}$ is seen to lie above $p_{\gamma\delta}$ in all cases, so it is indicated that a positively charged carrier predominates in the thermally induced part of the charge separations observed.

APPENDIX II

From figure 4 it is evident that more than one mechanism is responsible for the amount of charge observed to separate during a collision. There is a significant difference between q_α and q_γ, which at first sight should be the same. There is also a progressive variation in any particular q with increasing number of collisions.

It has also been observed that the surface of a sphere is not homogeneous with respect to charge separation. This has been demonstrated by conditioning a particular pair of spots by a series of α-type collisions until q_α remained approximately constant. Pendulum L was then rotated about its longitudinal axis to each of seven other indexed positions. At each position a single value of q_α was obtained, pendulum R remaining in its original position. In this way the conditioned spot on R may act as a proof spot to test the properties of the surface of L in seven unconditioned spots. Observation of q_α with L again in position 1 indicated the stability of the proof spot. The observations are shown in table 1.

Table 1

Position of L	1	2	3	4	5	6	1	7	8
q_α	+4·3	−8·3	−77	−21	−112	−254	+8	−30	−15

Thus it is to be expected that the actual spots used in the principal experiment were probably very different electrically in spite of the consistency of the effect of a temperature gradient.

It is tentatively suggested that the variation in surface properties shown by table 1 may be due to a differing abundance of carriers at different parts of a polyethylene surface. In the neutral state these would be localized near fixed charges of opposite polarity, or active centres. During the collision carriers are rearranged between the two surfaces in contact to give the charge separation observed. In the present experiments the maximum observed charge density is of the order of one electronic unit per 2×10^7 Å^2 of surface area. Thus the density of easily separated centres and carriers in the polyethylene surface is very small. Before much progress can be made in this subject fair identification of the carriers and centres is necessary.

The transferability of activation centres between surfaces on collision has been studied. It was arranged that, after two spots were conditioned as before, the proof spot on R collided with each of two adjacent spots on L in the following sequence 1, 1, 1, 2, 1, 1, 1, 2, 1, 1, 1, 2, 1 . . . and so on.

This provides alternative values for q_α developed with spot 1 under two conditions:

(i) the intermediate collision is with spot 1,

(ii) the intermediate collision is with spot 2.

Spot 2 was chosen as convenient and because q_α with spot 2 was very different from q_α with spot 1. Runs were made on two separate days with the same spots and gave the results shown in table 2.

Table 2

	Mean	Standard deviation	Number of observations
$q_{\alpha 1}$	203	34	57
$q_{\alpha 2}$	462	79	18
δq_S	+9	25	20
δq_D	−20	35	16

where

$q_{\alpha_1}, q_{\alpha_2}$ = value of q_α for collision with spot 1, 2 on L respectively,

δq_S = increment in q_{α_1} with similar contact between,

δq_D = increment in q_{α_1} with dissimilar contact between.

From these results we find that the probability of the observed difference between δq_S and δq_D being due to chance is less than 1% and deduce that a collision with spot 2 causes the proof spot on R to gain less positive charge when it next collides with spot 1. Also we see that spot 2 on sphere L lost more positive charge to (or gained less positive charge from) the proof spot on R than does spot 1.

These findings show that a collision with spot 2 on L makes the proof spot more like spot 2. This is in agreement with the general trend visible in figure 4 where the quantity of charge separating is greater in earlier collisions than later ones during a group of observations.

Now, since the carriers are neutralized after each observation this means that either (i) a transfer of active centres between colliding surfaces is possible or (ii) negative ions collected from the air during neutralization persist and act as active centres.

In the present case (i) is preferred because if (ii) were operative then δq_S and δq_D would both be negative since q_{α_1} and q_{α_2} are both positive.

Stable Crack Propagation in Plastics

By J. J. BENBOW

Imperial Chemical Industries Limited, Plastics Division,
Welwyn Garden City

MS. received 23rd June 1961

Abstract. A description is given of apparatus designed to measure the crack propagation energy of plastics under conditions where they are brittle. This includes a brief history of the work leading up to the present studies and details of a novel type of instrument suitable for measurements over a range of temperatures. Use of these techniques is illustrated by typical results on Perspex, polystyrene and polythene.

In addition, some of the interesting features found on the surfaces of cracks are described. The patterns found on cracks in polystyrene are illustrated and their possible origins are briefly discussed. Finally the colours found on freshly formed cracks in Perspex are described.

§ 1. INTRODUCTION

THE OBJECT of the paper is to present work done during the past two years on crack propagation in plastics. Most of the measurements were made during short term investigations, and represent a development of work on the physics of fracture started at the Akers Research Laboratories. The paper is not written at the completion of an investigation but is more in the nature of an interim progress report.

To set the work in perspective the history of the subject is briefly summarized and a short discussion is given of the relation between brittle behaviour and specimen size. Apparatus being used at present is described and results on some polymers are given.

Finally, some of the interesting structural features and colour effects found on fracture surfaces are described.

§ 2. THE GRIFFITH THEORY OF FRACTURE

The papers of Griffith (1920, 1924) have exerted a profound influence on the study of fracture processes. Two separate, fundamentally new ideas were contained in his work. One was the idea of 'flaws' or minute defects which act as stress raisers and explain the difference between the observed, macroscopic and relatively low strength of solid materials, and the high strength values predicted from the known strength of chemical bonds.

The other idea originated by Griffith was of an energy balance as the controlling law of crack propagation. He assumed that the balance was between the surface energy (or surface tension) of the newly created fracture surface on the one hand and the elastic energy stored in the stress field on the other. He tested this hypothesis by measuring the bursting strength of glass tubes in which cracks of varying length had first been made.

During the last thirty years or so most of the work done on fracture has been planned with Griffith's ideas in mind, but it is only recently that new and more accurate experiments have been done to test the basic validity of his theory. A review of work up to these new developments has been given by Orowan (1948). Up to the time covered by Orowan progress had been made in two directions. It was realized that the quantity having the dimensions of a surface tension, which appears in the Griffith energy balance criterion, may in practice exceed the true specific surface energy by a large factor. This was explained as the effect of a layer of plastically deformed material.

In addition, attempts were made by Mott (1948) to include, in the energy balance, dynamic terms to take into account the stress waves created by the fast moving crack.

§ 3. STABLE FRACTURES

Although some experiments involving stable fractures in mica were made by Obreimoff (1930) the explicit introduction of this concept is due to Roesler (1956). In his work on cone cracks he showed under what conditions brittle fracture can be stable (i.e. it can be propagated at an arbitrarily slow speed). His measurements on cone fractures in glass verified the functional form of the energy balance theory, but the numerical value of the fracture energy was found to be larger than a true surface tension can be. This shows that even in brittle materials such as glass the fracture process involves energy dissipation. More recently experiments on cone cracks in fused silica by Benbow (1960) have produced similar conclusions although the precise value of the fracture energy of fused silica has not yet been calculated.

The application of stable fractures to more practically important materials such as plastics was described by Benbow and Roesler (1957). By introducing an auxiliary compressive stress parallel to the crack, its direction and speed can be controlled. Using this technique it is possible to produce stable fractures in sheets or strips of plastics. (At the same time the method has the advantage of using easily available specimens.) The original apparatus has been improved and refined and many more measurements have now been taken. In addition a much simpler instrument based on the same original ideas has been developed which is more suitable for routine measurement of fracture energies rather than for precise tests of the energy balance criterion. Recently Svensson (1961) has described a very similar apparatus, which has been developed independently and he has given results for Perspex and polystyrene over a range of different temperatures.

§ 4. THE EFFECT OF SPECIMEN SIZE ON BRITTLENESS

If the energy balance theory is even approximately valid it has important consequences in the practical use of materials because it predicts that the size of the sample being tested may determine whether a material is brittle or not. The theory predicts that, provided the specimen is large enough, the external stresses at a large distance from the crack tip can be arbitrarily low.

The energy balance theory gives a relation of the same form between the externally applied stress and the specimen size, for all the systems which have been considered. This is:

$$\sigma = \left(\frac{kET}{b}\right)^{1/2} \tag{1}$$

where σ is the applied stress (at which the crack just propagates), E the elastic modulus relevant to the system and T the fracture energy per square centimetre.

The parameter k is a numerical function of the geometry of the system involved and has been given for particular cases in the references quoted. The quantity b is a characteristic dimension of the stress field.

In a cleavage experiment of the type which will be described later, b is the width of the sheet and E is Young's modulus of the material. Since, in general, Young's modulus depends on the rate of strain the value appropriate to the bending of both halves of the split specimen must be used since this determines the stress at the crack tip. If b is small the stress required to propagate a crack may be so large that tough failure occurs before the critical value for fracture is reached. Conversely, if b is very large the tendency for a material to show brittle behaviour will be increased. However, because the critical stress depends on the square root of the characteristic dimension the transition from tough to brittle behaviour is not likely to be very sharp.

Brittleness measurements are made on plastics for two main purposes, namely to provide a basis of comparing one material with another and to determine the conditions under which a fracture is initiated. These objects are achieved independently from the energy balance theory provided the samples tested are all of a similar size. The importance of the energy balance theory arises in respect to the engineering applications of plastics and the scaling up of tests on small samples to provide data relevant to large structures. Transitions caused by temperature or rate of strain variations are well known in plastics but important transitions can also be achieved by geometrical changes alone. When measuring the properties of materials it is desirable to express the results in terms of quantities which are characteristic of the material and not dependent upon the apparatus or the dimensions of the specimen, although this does not imply that the quantity chosen is necessarily constant under all conditions. In the case of brittleness the specific fracture energy is such a quantity. The instruments which have been developed to test the energy balance theory and to measure the specific fracture energy have resulted in the elimination of several undesirable features which occur in more conventional methods of measuring brittleness. For example, in the case of impact tests it is difficult to avoid much of the measured energy being imparted to the broken specimen in the form of kinetic energy.

§ 5. DEVELOPMENT OF EXPERIMENTAL METHODS

Details of the method used to test the energy balance theory for plastics together with a description of the original apparatus, have already been given by Benbow and Roesler. On the basis of experience gained with this apparatus a second more robust apparatus was made. The principles involved were the same in both cases but in the new apparatus the compression force was applied through heavy ball races. A photograph of this is shown in figure 1. Many different materials have been studied with this instrument; most of these were plastics, but stable fractures have also been measured in plates of glass and cast iron.

To establish the applicability of the energy criterion to plastics it was essential to use a wide range of sample sizes and in particular the width of the specimen b had to be changed as much as possible. Consequently, the size of the apparatus was also rather large and not very suitable for routine measurements since the amount of material is often limited.

Another important factor is that measurements at different temperatures and in different environments cannot be readily obtained with such a large apparatus. On the other hand, the size of the sample can only be reduced to a certain extent because otherwise tough failure will tend to occur rather than brittle fracture. A useful criterion is to ensure that $4 > S/b > 1$ where S is the crack length. Bearing these considerations in mind, a new apparatus has been designed which uses specimens 1 in. wide and roughly 6 in. long. The chief difference between this and those previously made is that two symmetrical cracks are produced simultaneously. Diagrammatically the system used is that shown in figure 2. The initially rectangular specimen has a slot cut into it along the centre line parallel to the long edges and extending about 1 in. into each half. Both ends of this slot are cut to a 'swallow-tail' with a fine saw (see figure 2 for details).

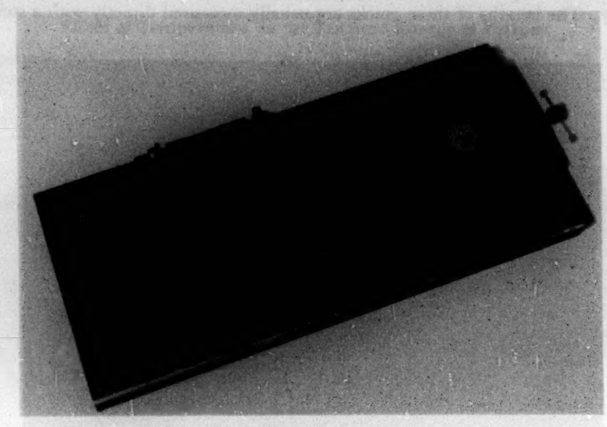

Figure 1

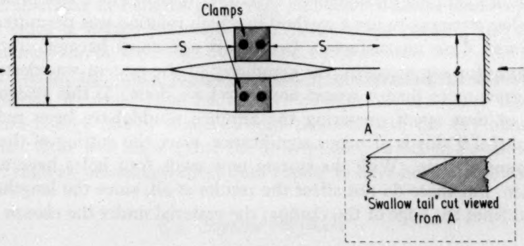

Figure 2

The compression force required to centralize the cracks can now be applied at the *fixed ends*, and thus no complicated bearings are required. This feature allows the apparatus to be greatly simplified. Two clamps are fixed to the specimen by 4 B.A. bolts, and are themselves mounted in a slot which allows them to move outwards but prevents rotation. A wedge is screwed between the clamps so that they are forced outwards by amounts which can be measured in terms of the travel of the wedge. One form of the apparatus is shown in figure 3. This particular apparatus was designed for immersion in a thermostatically controlled vessel with provision for the position of the wedge to be altered and measured externally. This new apparatus is thus in essence the same as the original, but two samples are mounted back to back and cracked simultaneously. The lengths of these cracks are usually measured directly with a steel ruler, although when making measurements at high temperatures more elaborate techniques are used.

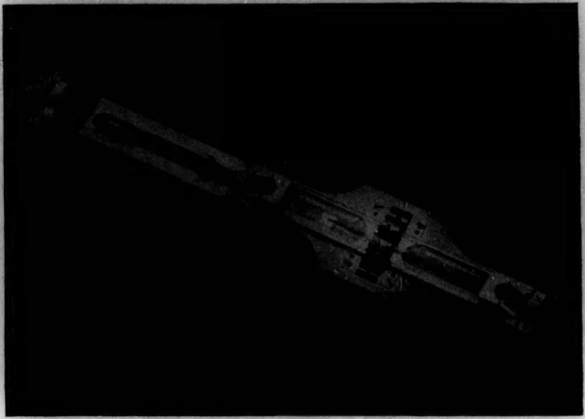

Figure 3

The type of clamping arrangement described is that which has proved most satisfactory. Earlier attempts to use a method in which rotation was permitted at the centre of the specimen were unsatisfactory because if one crack became crazed or did not grow uniformly for some reason, the symmetry of the system was destroyed, and the other crack grew more than it would normally have done. If this system had worked, the amount of time spent preparing the samples would have been reduced slightly, but it is doubtful if this is of major significance, since the cutting of the slot takes the greatest amount of time. With the system now used, four holes have to be drilled in each specimen, but these do not affect the results at all, since the lengths of the cracks are measured from the edge of the clamps; the material under the clamps is held rigidly by them.

§ 6. RESULTS

6.1. *Acrylics*

Samples of Perspex (polymethylmethacrylate) have been examined at temperatures ranging from 0 to 80 °c in the new symmetrical apparatus. The results are given in table 1 and it will be seen that there is very little change in the fracture energy as the temperature is varied. At the higher temperatures there is a slight tendency for T to increase but the smallness of this change can be seen in perspective by comparing the results obtained for several different polymers, tables 1, 2 and 3.

Table 1

Effect of Temperature on the Fracture Energy of Perspex

Temperature (°c)	3	10	20	32	43	45	50	62	76	80
Fracture energy $\times 10^5$ (dyn cm^{-1})	5·7	5·0	4·2	4·3	3·8	4·3	4·7	6·3	6·3	8·0

Table 2

Polystyrenes of Various Molecular Weights

Sample	Mol. Wt.	Type of fracture	Nature of surface	Fracture energy
A	26000	Fast	Rough (Fig. 5(*a*))	$3{\cdot}0 \times 10^5$
		Slow	Laminated	$1{\cdot}9 \times 10^6$
B	130000	Fast	Rough (Fig. 5(*b*))	$1{\cdot}5 \times 10^5$
		Slow	Laminated (Fig. 5(*a*))	$6{\cdot}1 \times 10^5$
C	80000	Fast	Rough (Fig. 5(*c*))	$1{\cdot}5 \times 10^5$
		Slow		$1{\cdot}7 \times 10^5$
D	60000	Slow	Smooth, mirror-like	$\simeq 3{\cdot}0 \times 10^4$

Table 3

Typical Polythene Results

Type of polythene	Melt index	Density	Fracture energy
High pressure, intermediate density	11·6	0·9317	$3{\cdot}6 \times 10^5$
High pressure, low density	20		$2{\cdot}71 \times 10^6$
Low pressure process	2·9		$1{\cdot}7 \times 10^6$

An interesting effect has been found by wetting the tips of cracks in Perspex with water. In general, cracks in Perspex grow very smoothly with no tendency to jerk. If such a smooth crack is wetted the crack immediately stops growing and the clamped ends of the specimen can be separated by a considerable amount before the crack jumps forward again. When the crack jumps forward it is travelling in dry material and reaches the position it would have had in the absence of water, see figure 4. The apparent fracture energy can be raised to four times that of the dry material by the addition of water. It is well known that the absorption of water in Perspex takes place very slowly but such an immediate effect does appear to have been unknown previously.

6.2. *Styrene Polymers*

The original work on the propagation of stable cracks in polymers involved a detailed study of commercially available polystyrene sheets. One of the outstanding features of this material is that two types of crack can be produced in it, one slow, the other fast. It was found that the fracture energy of slow cracks was higher than that of Perspex, whereas that for fast cracks was slightly less. Measurements have now been taken on other styrene polymers but particularly interesting results were obtained on four specially prepared specimens (supplied by D. Ridley) having number average molecular weights (determined by osmometry) of 260 000, 130 000, 80 000 and 60 000 respectively. These samples were free from residual stresses and contained virtually no monomer. The results obtained are summarized in table 2. As the molecular weight falls there is a marked decrease in the fracture energy, a change in the type of fracture surface obtained and the tendency to form fast and slow cracks becomes less until with the lowest molecular weight the cracks behave very like those in Perspex, when only smooth mirror-like cracks can be obtained without any tendency to form fast and slow cracks.

6.3. *Polythenes*

Many low density, 'high pressure' polythenes are too tough for cracks to be propagated in them at room temperature. A small number of measurements have been made on high density, high melt index polythenes made by the high pressure process, and also some high density low pressure materials have been examined. However the number of results is too small to provide more than a few typical results which are useful only for comparison with other polymers (see table 3).

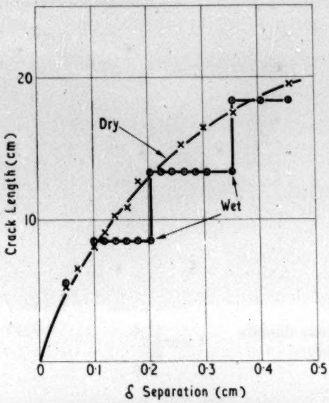

Figure 4

§ 7. FAST AND SLOW CRACKS

Two types of crack can be produced readily in high molecular weight polystyrene and biaxially stretched Perspex. Invariably the cracks of higher velocity have the lowest fracture energy. The physical reason for the two types of crack is not fully understood but their nature does offer an explanation of the fact that the slow cracks have higher fracture energies. The surfaces produced by slow cracks in high molecular weight polystyrene for example, have a number of subsidiary cracks below the main surface and have a flaked appearance (see figure 5(*d*)). Since the true surface area is many times that deduced from the length of the main crack the *apparent* value of T (slow) will be high even if the *true* value is equal to T (fast). It is possible that the true value of T is the same in both cases. A similar tendency to laminate is found in biaxially stretched Perspex sheet. At low percentage stretch the fracture energy increases with the amount of stretch but above about 50% the fracture energy of fast cracks falls steeply until it is eventually below that of the unstabilized material. However at these high extensions slow cracks can also be produced with laminated surfaces and high apparent fracture energies. Under practical conditions involving sudden impact etc. it is the fast crack which is relevant.

§ 8. SURFACE EFFECTS

The surfaces of freshly cracked specimens of plastics show many interesting features. These can be divided, for convenience, into two main classes, namely surface patterns and colours.

Surface patterns are produced readily when fast cracks are propagated in high molecular weight polystyrenes. Figures 5 (*a*, *b*, *c*) show the surfaces of the four polystyrenes already referred to.

At first sight the patterns look like deep ridges but they are in fact well defined alternate regions of smooth and rough patches and are probably Wallner (1939) lines (i.e. periodic marks on the crack faces thought to be caused by interaction between the crack front and ultrasonic stress waves). As the molecular weight decreases the spacing of the lines also decreases, see figures 5 (*a*, *b*, *c*). The sample of lowest molecular weight (60 000) showed no surface patterns at all when viewed with low magnification; the faces of the cracks were highly polished and similar to those in Perspex.

If it is assumed that a high frequency ($\simeq$ 5–10 Mc/s) stress wave is generated by the travelling crack, it is possible to explain the surface patterns formed (Andrews 1959). On the other hand, the fact that the spacing of the lines varies with molecular weight, even though the modulus of elasticity is virtually constant, cannot be easily reconciled with this stress wave theory.

Colour effects are found on the surfaces of stable cracks in polymethyl methacrylate. These second-order colours are seen when the surface is viewed by reflected light and are probably caused by interference since electron microscope photographs of the surfaces show that there is no structure present which could produce diffraction. Somewhat similar effects have been reported by Busse, Orowan and Neimark†, Wolock, Kiess and Newman (1959) and Berry (1960), but when stable cracks are used the colours are uniform in colour over large areas (several square centimetres) and the colours on opposite sides of the crack are identical when the cracks are propagated slowly. Berry reports that he obtains complementary colours on corresponding parts of the crack faces but I have only found this with extruded 'Diakon' sheet in which the crack faces are often rough.

It is quite easy to remove the 'colour' by wiping the crack faces with a dry fabric or by placing the sample in a vacuum. If the sample is cracked, with water filling the crack, no colours appear. If dry Perspex is cracked and then washed, with water, the colours disappear.

Interference colours are also seen when high molecular weight polystyrene sheets are cracked slowly, so that the laminated type of surface is formed. In this case there is interference between the light reflected at the top surface crack and that reflected at sub-surface cracks.

§ 9. CONCLUSIONS

Several points arise out of this work. Some of the more important of these can be conveniently summarized as follows:

1. The brittleness of plastics can be compared without reference to the energy

---

† *Morphology of Fractures in Polymethyl Methacrylate*, Lecture presented at the American Physical Society, March 1957.

balance theory but results which are characteristic of a material can only be found by introducing the energy criterion.

2. Materials which obey the energy balance criterion can be brittle or not depending on their size, and the concept can be important in the practical application of plastics.

3. The specific fracture energy of plastics can be easily measured in the apparatus which has now been developed.

4. Stable fractures, if necessary produced at arbitrarily slow rates of cracking, provide excellent means of studying surface features on polymer faces. A detailed study of these effects would probably lead to a better understanding of the causes of brittleness in plastics and possibly enable tougher materials to be produced.

ACKNOWLEDGMENTS

I am indebted to Dr. F. C. Roesler of I.C.I. Limited, Billingham Division, for many valuable discussions and to Miss H. M. Bell and Mr. J. G. H. Gray for their assistance with the experimental work.

The Nature of the Abrasion Process in Plastically Deformable Non-metals

By J. N. KING and H. WILMAN

Applied Physics and Chemistry of Surfaces Laboratory,

Chemical Engineering Department, Imperial College, London S.W.7

MS. received 15*th June* 1961

Abstract. The friction, wear and surface deformation in abrasion of typical very plastic non-metallic materials, AgCl and AgBr, are investigated, on emery papers at 200–500 g load. They are strikingly similar in form and magnitude to those of metals of comparable hardness. The wear rate M is related linearly to the friction coefficient μ when the emery particle diameter D is greater than 20 microns, but on finer abrasive the (M,μ) locus curves to lower μ, as for soft metals.

Optical microscopic study of single abrasion grooves shows the wear to be mainly by a cutting action like that of a lathe tool, but that much plastic flow occurs; and it indicates a high adhesion component of the friction.

Electron diffraction shows a backwardly tilted $\langle 110 \rangle$ orientation in the abraded surface region. Its form, and its preferred azimuthal range, shows its close relation to the rolling texture and to the compression texture when extensive lateral flow is permitted. The correlation between the tilt δ of the orientation axis from the specimen normal and μ is discussed.

§ 1. INTRODUCTION

THE PHYSICAL process of abrasion is important in shaping materials. It is also a prominent cause of friction and wear in machine bearings, where it often arises from adventitious hard abrasive particles (Barwell 1956, Duckworth and Forrester 1957, Burwell 1958) but sometimes from the presence of a hard phase in the bearing metal itself, e.g. pearlite in the ferrite matrix in steels (Piggott and Wilman 1957), and often also from the presence of hard oxide or other surface layers which become fragmented under the applied load.

Although many experiments have been made on the friction and wear of metals, little clear evidence has so far been obtained on the behaviour of non-metals, which are now increasingly used in certain kinds of bearings as coatings or impregnating constituents. The experiments described below in § 2 and § 3 show that at least the more highly plastic inorganic non-metallic materials behave in a way closely similar to that of metals during abrasion.

For aluminium and harder metals abraded unidirectionally on bonded abrasives such as emery papers, at load W of the order of 0·2 to 2 kg, the mass loss M (i.e. wear) per centimetre of sliding distance, at the final equilibrium stage of pick-up of abrasive particles, is related linearly to the coefficient of friction μ: $M = kW(\mu - \mu_0)$, where k and μ_0 are constants (Goddard, Harker and Wilman 1959, Avient, Goddard and Wilman 1960). M and μ are practically constant when the abrasive particle diameter D is greater than 70 microns, at least up to 220 microns. Our theoretical results (Goddard, Harker and Wilman 1959, Goddard and Wilman, to be published) account well for these observations, and the quantitative data show that the ploughing component μ_p is a large part of the total friction, μ. The linear (M, μ) relation indicates that the fraction f_{ee}, of the total load, carried on emery/emery contacts at this equilibrium stage of pick-up is practically constant, independent of D.

Further results (Avient and Wilman, to be published) on abrasion of the very soft metals tin, lead and zinc, have also shown a linear (M, μ) relation on emery papers having $D > 20$ microns, but on finer grades the (M, μ) locus curves markedly to lower μ values, indicating that an increasing part of the load is on metal (+oxide)/metal (+oxide) contacts, and a lower f_{ee} applies.

The experiments described below now show for the first time the relation between μ, M and D in abrasion of typical very plastic soft non-metals, namely AgCl and AgBr. We find this is closely similar to that for very soft metals. This exemplifies in a quantitative manner the close analogy between silver halides and metals in their high plasticity, which was indeed emphasized by Nye (1949) who referred to AgCl as equivalent to a transparent metal.

The nature of the surface deformation caused in the AgCl and AgBr by such unidirectional abrasion is also seen from our electron diffraction observations to involve a high degree of re-orientation. We find, as in metals (Scott and Wilman 1958, Avient, Goddard and Wilman 1960, Wilman 1960) and in graphite (Porgess and Wilman 1960), a pronounced one-degree orientation is developed, the orientation axis being tilted away from the surface normal, back towards the direction from which the abrasive particles came. Comparison of these results for AgCl and AgBr with our recent determinations of their compression and rolling textures (King and Wilman 1961) shows clearly the close relationship of the 'abrasion texture' with both of these.

§ 2. EXPERIMENTAL

The silver chloride and silver bromide were obtained from Messrs. Hopkin & Williams Ltd., and the purity was stated to be 99·8%. Specimens of 1·6 cm diameter and 0·3–0·6 cm height were prepared by melting and resolidifying the halide in glass moulds. Some specimens were also prepared by compression of the original materials (granular, 0·1 to 2 mm diam.) at 32 tons/in^2 in a steel die 0·5 in. diameter (giving specimens 0·2 to 0·5 cm thick).

The flat surfaces of all the specimens were examined by electron diffraction in a Finch camera, at 50–70 kv and 47 cm camera length. Patterns were recorded before abrasion, then after unidirectional abrasion under about 500 g load for sufficient distance to produce no further change in form of the surface; and at various stages of removal of the abraded surface material by etching in a 0·1% aqueous solution of KCN. This solution etched away the halide at about 2400 Å min^{-1} when freshly prepared.

The friction and wear experiments were made on the resolidified specimens, sliding on emery papers of various grades as abrasive, since these represent at least approximately defined degrees of surface roughness. Emery papers having a mean particle diameter D of 5, 10, 15, 35, 40, 70, 100 and 150 microns (grades 0000 to 3) were obtained from Messrs J. Oakey and Sons Ltd., and of approximately 15 to 35 microns (grades 000, 00 and 0) from Messrs Hubert. Each 25 cm stroke was over a fresh emery surface. The effect of sliding the silver halides under load on filter paper (Whatman No. 1) was also investigated, at 200 g load and at about 5 cm sec^{-1}. The wear rate M (mass loss/cm) was determined directly by estimation to 0·01 mg, using an Oertling semi-microbalance, the specimens being lightly brushed with a soft brush to remove any loose wear particles before weighing. The frictional force exerted on the specimen to cause non-accelerated sliding at about 5 cm sec^{-1} was determined as simply as possible by the weight required at the end of a thread passing over a low-friction pulley. The coefficient of friction μ was measured at the same time as the wear rate, so that the abrasion conditions for the two measurements were identical.

Before determinations of M and μ were made on any grade of emery paper, the halide surface was filed gently to remove any embedded emery particles from previous abrasion on other grades. Friction and wear measurements were made until they attained constant values (after a few hundred centimetres). At this final equilibrium stage of pick-up of emery particles, the mass loss/cm was then the actual rate M of removal of halide by the abrading particles.

The Vickers diamond-indentation hardness number H_{D} of the resolidified specimens, after dry 4/0 emery abrasion, was determined using a GKN hardness tester, with 30 and 100 g load. For the AgCl, H_{D} was 9 kg mm^{-2}, and for the AgBr, 10 kg mm^{-2}.

§ 3. RESULTS

3.1. *The (μ, D), (M, D) and (M, μ) Relationships for AgCl and AgBr Abraded Unidirectionally on Dry Emery Papers*

Figures 1 and 2 show the friction and wear results for abrasion of resolidified AgCl on dry emery papers under 200 g load, at the final equilibrium stage of pick-up of emery particles by the specimen surface. The friction values and the wear *volume* rates of AgBr were practically identical with those of AgCl on the same grade of emery. This agrees well with our observations that the hardnesses of the surfaces after abrasion on 4/0 emery paper, were about the same for AgCl and AgBr, namely 9 and 10 kg mm^{-2} respectively.

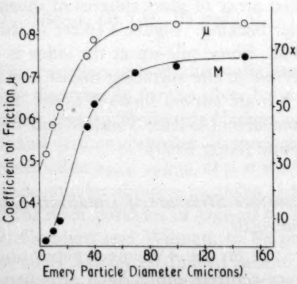

Figure 1. Observed (μ, D) and (M, D) relation for resolidified AgCl abraded on dry emery papers at 200 g load, at the final equilibrium stage of pick-up of abrasive.

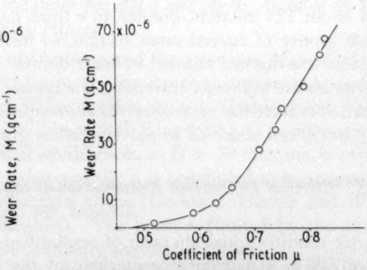

Figure 2. Observed (M, μ) relation for abrasion of resolidified AgCl as stated in figure 1.

μ was practically constant, 0·82, for both halides (see figure 1), on emery grades having $D > 70$ microns. On finer grades μ decreased rapidly with decreasing D to about 0·52 on 4/0 emery paper, due to an increasing proportion of the load being borne on contacts (mainly in the front region of the bearing surface) between the halide specimen and the halide worn-off, which partly clogs the emery paper (cf. Goddard, Harker and Wilman 1959, Avient, Goddard and Wilman 1960). For comparison, the μ of halide on halide was found to be 0·32 for lightly filed surfaces rubbed together until smooth, under a load of a few hundred grammes.

The wear rate varied with D in a roughly similar manner, but still increased slightly at large D. Experiments were also performed using specimens which, after filing, were surfaced by abrasion on the emery grade concerned, wet with propyl alcohol. The dry abrasion of these surfaces on the same grade of emery paper then led to the same final M and μ values as did the dry abrasion directly on the filed surface.

Figure 2 shows that at the final equilibrium a straight-line M/μ locus is observed for emery grades for which $D > 20$ microns. However, for finer grades, the locus curves markedly towards lower μ values.

3.2. *Short-stroke Abrasion Experiments with Silver Halides under* 200 *g Load*

A very short sliding distance of the order of 2 mm was used to facilitate the examination of individual abrasion grooves in the Vickers projection microscope. The specimens were smoothed by abrasion on 4/0 emery paper wet with propyl alcohol, and then a short abrasion stroke was made at 200 g load, perpendicular to the direction of the initial smoothing, on the particular grade of emery (dry) under consideration.

In the abrasion on relatively coarse emery (e.g. grade 0 or coarser), material was displaced by plastic flow to form lateral ridges at the sides of the grooves created by the ploughing emery particles, as figure 3 (plate I) shows. Also, some of the material was removed in the form of coiled or wavy strips by the emery particles, by a cutting or chiselling process similar to that caused by a lathe tool in a turning operation. Such adherent strips would be removed normally as wear particles during further abrasion.

On the finer emery, little cutting action is observed, but considerable pile-up of material occurs at the sides of the grooves, due to the displacement of material mainly by plastic flow.

Short-stroke sliding experiments were also performed on 'Scotchlite' reflective sheeting, which consists of an almost close-packed array of glass spheres of mean diameter about 125 microns, bonded to a thick paper backing. Figure 4 (plate I) shows a smooth groove of curved cross section, so formed. Some pile-up at the sides is seen, but there is a marked absence of wear debris. Some of the surfacing marks normal to the grooves are still seen traversing the groove, but are curved forward there. Similar forward curvature has been observed for copper and silver (Avient, Goddard and Wilman 1960), but is not observed in polycrystalline graphite (King 1960).

3.3. *Electron Diffraction Examination of the Surface Structure of Unidirectionally Abraded AgCl and AgBr*

After unidirectional abrasion of resolidified AgCl on dry 4/0 emery paper under a load of 500 g, a pattern characteristic of the face-centred cubic AgCl structure was observed, with many extra rings, identified from the ASTM file of x-ray powder pattern data (1955) as due to diaspore, α-AlOOH, which we find is always a component of the emery. Although no orientation of the halide was observed at the freshly abraded surface, a backward-tilted one-degree $\langle 110 \rangle$ orientation was found after etching in 0·1% KCN solution to a few hundred ångströms depth. The mean axis of this orientation was inclined by an angle $\delta \sim 20°$ from the outward normal of the abraded surface, towards the direction from which the abrasive particles came. Figure 5, obtained after etching to 1200 Å, showed the diaspore almost exclusively, indicating partial embedding of the emery in the silver halide surface region. The emery particles themselves (corundum, Al_2O_3, containing about 15% Fe_2O_3 and other small amounts of impurities) are so large as to be mainly opaque to the electrons, and thus contribute almost nothing to the diffraction pattern.

Abrasion of the halides on emery papers wet with propyl alcohol reduced the pick-up of abrasive particles to a negligible amount. For example, a tilted $\langle 110 \rangle$ 'fibre orientation' with $\delta \sim 8°$ was observed, figure 6 (plate II) (cf. figure 9), from resolidified AgBr abraded on 4/0 emery paper wet with propyl alcohol, and there was no indication of presence of any emery (or diaspore).

Finer abrasion than was caused by 4/0 emery paper was obtained by sliding both compressed and also resolidified specimens of the halides on filter paper (Whatman No. 1). The patterns from these surfaces showed a backwardly inclined $\langle 110 \rangle$ orientation, with $\delta \sim 8°$. The degree of orientation became more pronounced at depths of a few thousand ångströms, exposed by etching and yielding figures 7 and 8 (plate II), but δ remained practically unchanged at about 8° down to 4000 Å. Patterns recorded with the beam in an azimuth 30° from the perpendicular setting showed little change in the relative intensities of the arcs, thus a practically continuous azimuthal range of orientation round the $\langle 110 \rangle$ axis was present. The relative intensities of the arcs in figures 7 and 8, particularly the absence of the 400 arcs at the level at which $h+k = 4$ (see figure 9), whereas the 222 arcs are strong, indicates, however, an azimuthal preference such that in the mean either a [001] direction is along the abrasion direction (with more than $\pm 55°$ spread from the mean), or else a direction such as $[1\bar{1}2]$ is along the abrasion direction (with more than $\pm 35°$ spread).

When the electron beam was parallel to the abrasion direction a uniform ring pattern was always obtained, evidently because the beam then grazes also part of the side faces of the grooves, whereas in the perpendicular setting it only penetrates the tips of the edges of the grooves.

§ 4. DISCUSSION

4.1. *The* (μ, D), (M, D) *and* (M, μ) *Relations for AgCl and AgBr Abraded on Dry Emery Papers*

The variation of both the coefficient of friction μ and the wear rate M, with abrasive particle diameter D, for the silver halides (figure 1) is similar to that observed previously for many metals (Goddard, Harker and Wilman 1959, Avient, Goddard and Wilman 1960) and various graphites (Porgess and Wilman 1960, King 1960). The approximately constant value $\mu_{\mathrm{max.\ equilib.}}$ of μ at the final equilibrium, at $D > 70$ microns, is expected for these angular abrasive particles, since theoretically μ is concluded to be independent of D for such particles of conical or pyramidal shape (Goddard, Harker and Wilman 1959, Goddard and Wilman, to be published). The grooves formed by the abrasion of the silver halides are indeed seen to be markedly angular in section.

The value 0·82 found for $\mu_{\mathrm{max.\ equilib.}}$ of AgCl and AgBr (for which the hardness $H_{\mathrm{D}} \sim 10$), is close to that for the comparably soft metals such as tin ($H_{\mathrm{D}} \sim 15$ for the 4/0-emery abraded polycrystalline surface; $\mu_{\mathrm{max.\ equilib.}} \sim 0{\cdot}86$). This μ value is larger than μ_{eh} of ploughing emery/halide contacts, because it corresponds to part of the load being carried on emery/emery contacts having $\mu_{\mathrm{ee}} \sim 1$ (Goddard and Wilman, to be published). μ_{eh} was estimated to be about 0·76 by sliding a 'tripod' of sparsely distributed groups of emery particles ($\sim$ 215 microns diameter) firmly fixed to a metal base with sealing wax, on a relatively smooth surface of silver halide prepared by fusion and resolidification on a flat glass plate. This μ_{eh} value is also similar to the μ_{em} of such emery particles ploughing along a metal of similar hardness, e.g. tin (cf. Avient, Goddard and Wilman 1960).

Since the ploughing component μ_{p} can be expected to be about the same for materials of the same hardness, it appears that for the emery/halide contacts the adhesion

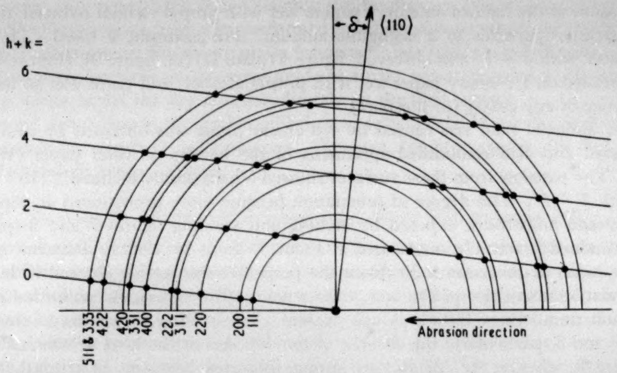

Figure 9. Ring positions and theoretical diffraction positions for face-centred cubic crystals in a one-degree orientation with a ⟨110⟩ axis inclined at an angle δ away from the surface normal.

component μ_a of the total friction μ_{eh} has a value close to that for the emery/tir (+oxide) contacts. That the adhesion component is a considerable part of the total μ i indicated by figure 4, showing the pronounced forward drag of the halide by the slidir particle, in this case a glass sphere. The forward drag is rather more than we observe with Cu and Ag (Avient, Goddard and Wilman 1960). In graphite it was negligibl corresponding to the low adhesion friction ($\mu_{gg} = 0{\cdot}14$) (King 1960).

The μ of halide on halide μ_{hh} is found to be 0·32, and is very similar to the values of approximately 0·3 found for metal (+oxide)/metal (+oxide) in the case of Cu and Ag (Avient, Goddard and Wilman 1960) and Sn (Avient and Wilman, to be published), and for Cu_2O on Cu_2O (Porgess 1960). The s/p_m values for these materials (s = shear force/unit area of the shearing contact, and p_m = flow pressure of this shearing region) are thus similar, although these materials have widely different p_m and H_D values; for example, for Cu_2O, $H_D \sim 240$–260, and for AgCl and AgBr, $H_D \sim 10$. We note, however, that for Cu_2S on Cu_2S, $\mu \simeq 0{\cdot}5$ (Bowden and Tabor 1950, Porgess 1960).

The slight increase of M with D at $D > 70$ microns, is similar to that observed for tin, lead and zinc (Avient and Wilman, to be published), although for Al and harder metals M was practically constant at $D > 70$ microns (Avient, Goddard and Wilman 1960).

The (M, μ) locus shown in figure 2 is a straight line for $D > 20$ microns, i.e. $M = k(\mu - \mu_0)$, where k and μ_0 are constants and $\mu_0 \simeq 0{\cdot}62$. However, for finer emery grades ($D < 20$ microns) the locus curves towards lower μ values. Here again the silver halide properties are strikingly similar to those of a metal of similar hardness, because this form of locus is the same as was found for the very soft metals Pb, Sn and Zn (Avient and Wilman, to be published). The curved lower part indicates that in this region the fraction f_{ee} of the load supported on emery/emery contacts is progressively less than the practically constant f_{ee} value which applies over the upper straight region (Goddard and Wilman, to be published). It seems that, for $D < 20$ microns, many of the picked-up emery particles become more or less submerged in the soft halide bearing surface, as was indeed indicated by the electron diffraction photographs from the surfaces after etching (§ 3.3 and figure 5). This, together with the rapid clogging of the emery paper in these finer grades, leads to more of the load being supported on halide/halide contacts, for which $\mu_{hh} = 0{\cdot}32$ (see above). One reason why these smaller partly embedded abrasive particles tend more to become submerged than larger particles, is probably that the frictional heating of these particles as they contact the opposing emery sheet over a considerable distance of sliding, must raise their temperature to a higher value than that reached by the larger particles. This will tend to soften the material in which they are embedded, so that deeper embedding of the smaller particles occurs.

The pick-up of emery has the effect of reducing the wear rate and increasing μ compared with the value for an emery-free surface. We have, as yet, however, no estimate of f_{ee} for the silver halides, because of the difficulties caused by the rapidity of pick-up of emery by the surface.

4.2. *The Surface Re-orientation and its Relation to the Compression Texture and the Rolling Texture*

For comparison with the above results we have determined the compression textures of these silver halides (King and Wilman 1961), by x-ray and electron diffraction. The initial granular materials compressed as described in § 2, showed a ⟨100⟩ texture with axis along the compression axis (together with a moderate proportion of ⟨110⟩ orientation with axis inclined by up to 30° away from the compression axis). When, however, resolidified specimens in the form of rectangular blocks about $0{\cdot}5 \times 0{\cdot}5 \times 0{\cdot}2$ cm, were compressed between polished, flat stainless steel plates (lubricated with oil) in a vice, only a pronounced ⟨110⟩ one-degree orientation with axis along the compression axis was observed. The reduction in thickness was more than 80%, i.e. to less than 20% of the initial thickness. The same ⟨110⟩ texture was also observed in specimens which after compression in a die were further compressed between the steel plates.

Resolidified AgCl rolled from about 0·5 cm diameter and 0·3 cm thickness to about 0·01 to 0·03 cm thickness (in about 20 stages, in the same rolling direction), then showed basically a strong ⟨110⟩ one-degree orientation, azimuthally limited, and with additional {111} twinning. The rolling direction was concluded to be $\langle 1\bar{1}2 \rangle$, in the mean, as in the $\{110\}\langle 1\bar{1}2 \rangle$ rolling texture of face-centred cubic metals.

It is thus clear that the nature of the compression texture depends on the extent to which the material can flow laterally during compression. Compression with freedom for extensive lateral flow is seen to correspond in effect to rolling the material in all radial directions simultaneously. Similarly in abrasion there is extensive laterally directed flow as the material is displaced by the indenting particles, and the ⟨110⟩ texture developed is in accordance with the ⟨110⟩ compression and rolling textures.

In the abrasion, the mean azimuthal orientation developed is (like that we find for face-centred cubic metals) with either ⟨001⟩ or a direction near this, such as $\langle 1\bar{1}2 \rangle$, parallel to the abrasion direction, and is thus probably the same as that in rolling, $\langle 1\bar{1}2 \rangle$. This close correspondence to the rolling texture seems to be due to the indenting emery particles being mostly very obtuse tipped so that in the abrasion the flow under the emery particles is indeed not much different in type and direction to the plastic flow under the roller in rolling. At the final contact with the abrasive particles the flow is then parallel to the groove direction.

The main difference in nature between the conditions in abrasion and rolling is that in abrasion the tangential frictional force (including both the adhesion and ploughing components) is large. The resultant of this force and the normal load is inclined away from the specimen normal by an amount related to the friction coefficient μ, and the orientation axis of the abrasion texture developed is correspondingly tilted away from the normal by an angle δ.

4.3. *The Surface Re-orientation in Relation to the Friction*

Previous studies of the relation between δ and μ for the hexagonal metals beryllium and magnesium (Scott and Wilman 1958) and graphite (Porgess and Wilman 1960) showed that the angle of tilt δ of the [001] orientation axis in the abraded surface regions, is about equal to $\tan^{-1}\mu$. For face-centred and body-centred cubic metals a backward-tilted $\langle 110 \rangle$ orientation, and a mixed tilted $\langle 100 \rangle + \langle 211 \rangle$ orientation respectively, were observed (Harker 1958, Goddard 1959, Avient, Goddard and Wilman 1960). However, near the surface of these metals the tilt was often considerably less than $\tan^{-1}\mu_{\text{mo}\cdot\text{mo}}$, where $\mu_{\text{mo}\cdot\text{mo}}$ is the friction coefficient of the metal (+oxide)/metal (+oxide) contacts. Etching to several thousand ångströms depth revealed a more tilted $\langle 110 \rangle$ one-degree orientation in the face-centred cubic metals, δ then approximating to $\tan^{-1}\mu_{\text{em}}$, where μ_{em} is the μ of the ploughing emery/metal (+oxide) contacts, the region of which, near the bottom of the grooves, is then accessible to the electron beam, at this stage of etching.

In the abrasion of the silver halides, μ_{hh} is about 0·32 for the halide/halide contacts, which must occur mainly at the tips of the projections of the rough abraded surface, and must thus be the main region accessible to the electron beam at grazing incidence on the freshly abraded surface. In the regions below the immediate surface, however, δ would be expected to approximate progressively to $\tan^{-1}\mu_{\text{eh}}$. The patterns (similar to figure 5) from the halides abraded on dry 4/0 emery paper and etched to only a few hundred ångströms depth, indeed show that here δ for the $\langle 110 \rangle$ orientation is about 20°, which agrees well with $\tan^{-1}\mu_{\text{hh}}$ (i.e. $\tan^{-1} 0{\cdot}32$, which is 18°); but it is less than $\tan^{-1}\mu_{\text{eh}}$ and also less than $\tan^{-1}$ (μ on 4/0 emery). However, no systematic change in δ with depth was observed on etching the surface, and at about 7000 Å depth the halide was in the form of randomly oriented crystals. This evidently indicates that a further factor is present (see below). Furthermore, in the finer abrasion of the silver halides by sliding on filter paper, δ was about 8° near the specimen surface, and also was unchanged down to several thousand ångströms depth. This δ is much less than $\tan^{-1}\mu$ (the observed $\mu \sim 0{\cdot}3$, thus approximately equal to μ_{hh}), which was about 17°.

This fact, that also for the subsurface regions the observed δ is less than $\tan^{-1}\mu$, must evidently be attributed to the effect of the forward motion of the indenting abrasive particles, additional to the oblique resultant compressive force, and be associated with the forward drag of the material by the adhesive frictional force between the ploughing particles and the halide in the way shown in figure 4. The adhesion causes a tension in the material behind the ploughing particles, and this may cause further deformation with lattice rotation resulting, reducing δ. In the abrasion of graphite, on the other hand, the close agreement of δ with $\tan^{-1}\mu$ (Porgess and Wilman 1960) is evidently associated with the low adhesion between the graphite and the emery particles, as is indicated by the absence of any forward curving of the surfacing striae across rounded grooves caused by sliding graphite on 'Scotchlite' glass spheres as for figure 4 (King 1960).

§ 5. CONCLUSION

The above results show conclusively the extensive and quantitative correspondence of the friction and wear properties of these non-metallic materials in abrasion, to those of metals of comparable hardness. Further results have now also been obtained (Dobson and Wilman, to be published) showing that this extends also to the case of abrasion of NaCl (both polycrystalline and single-crystal), in spite of its more brittle and cleavable nature. The above results on the nature of the surface re-orientation make clear the dependence of this orientation type on the occurrence of extensive lateral flow of the material displaced by the indenting abrasive particles. Abrasion textures are concluded to be generally largely analogous to the rolling texture, and also closely related to the compression texture which is observed when lateral flow is permitted.

These results thus provide a useful basis for a satisfactory understanding of the friction, wear and surface deformation of such non-metals.

Radio Wave Scattering from the Lunar Surface

By V. A. HUGHES†

Royal Radar Establishment, Malvern, Worcs.

MS. received 19*th May* 1961

Abstract. This paper describes some recent measurements on the angular scattering properties of the lunar surface at the wavelength of 10 cm. The scattering law of the surface is shown to be $P(\theta) = \sigma_0 \exp(-10{\cdot}2\theta)$ over the range of θ from 4 to 13° and a comparison with other results shows that it is independent of wavelength up to $\lambda = 1{\cdot}5$ metres. For angles up to 30° the scattering law deviates from an exponential but is still independent of wavelength up to at least $\lambda = 75$ cm. Evidence is given to show that the surface may be considered as rough at radio wavelengths.

§ 1. INTRODUCTION

SINCE the first successful radar contact with the moon by the United States Signal Corps and, independently, by Bay in Hungary in 1946, radar observations have been considerably extended. Most of the original work was carried out with radars developing comparatively low powers and to make it possible to detect the returned signal very long pulses or c.w. were used such that the whole of the lunar surface was illuminated. The c.w. measurements by Kerr, Shain and Higgins (1949) at the wavelength of 15 metres revealed the presence of two fading rates, a large slow period fluctuation together with a much more rapid one. It was suggested that the slow period was produced by Faraday rotation of the linearly polarized waves and Murray and Hargreaves (1954) showed how the moon echo technique could be used to measure the total electron content of the ionosphere. However, the more rapid fluctuations were attributed to the interference between signals scattered from the various regions on the surface which have relative motion due to lunar libration. By a method of pulse-to-pulse correlation Brown *et al.* (1956) determined the frequency spectrum of the fading and by relating this to the expected Doppler shifts Evans (1957) derived the scattering law of the lunar surface. These results showed that at a wavelength of about 1 metre the lunar surface scattered in a very directional manner.

Later measurements with microsecond pulses by Trexler (1958) at a wavelength of about 1·5 metres, by Yaplee *et al.* (1958) and by Hey and Hughes (1959) at a wavelength of 10 cm and more recently by Leadabrand *et al.* (1960) and by Pettengill (1960) at the wavelength of 75 cm, have all confirmed this highly directional scattering and have led to a more detailed study of the variation in echo strength as the pulse moves across the surface of the moon; in fact the higher powered radars at the wavelength of 75 cm have detected the weak scattering that exists out to the limb of the moon.

It has been suggested by Senior and Siegel (1960) that the lunar echo is due to specular reflection from a small number of isolated regions and the term quasi-smooth has been used to describe the surface. However, the signal takes the form of a large number of discrete echoes, each of a duration equal to the pulse length, which fade in a random fashion but with frequencies which are closely related to the expected Doppler shifts. Previous measurements at the wavelength of 10 cm (Hey and Hughes 1959) have shown that no region of the moon with dimensions corresponding to the pulse length of 5 μsec gives a consistent echo, and this suggested to the author that the results ought to be interpreted as scattering from a rough surface. The later results by Pettengill (1960) have in fact shown that a very large number of scattering areas exist and that there is no correlation of the 'radar picture' of the moon over intervals of about one minute.

---

† Now at Radio Research Station, Ditton Park, Slough, Bucks.

The object of this paper is to describe some measurements on the angular scattering properties of the lunar surface at the wavelength of 10 cm and to show that the results are compatible with reflection from a rough surface which has deviations large in comparison with the wavelength such that a large number of regions will contribute.

§ 2. THE RADAR EQUATION FOR PLANETARY STUDIES

The signal scattered back from a radar target and received at the focus of a radio telescope is given by the well-known radar equation

$$p = \frac{P_{\mathrm{T}}A^2\sigma}{4\pi\lambda^2R^4} \tag{1}$$

where P_{T} is the power transmitted from the aerial, A is the effective aperture of the telescope, R is the range and σ is defined as the effective scattering cross section of the target. In general there will also be losses in the transmission lines and in propagation through the atmosphere but for the present purposes the atmospheric losses which will be small have been ignored. However, the more appreciable transmission line loss α_{T} will reduce the transmitted power such that if the power developed by the transmitter is P, then that radiated at the aerial is given by $P = \alpha_{\mathrm{T}}P_{\mathrm{T}}$.

The power received at the focus of the telescope will also pass along the transmission line to the receiver and the performance will be measured at the receiver output in terms of the ratio of the signal power to the total noise power. If there were no loss in the transmission line then the noise power at the receiver output would be equivalent to

$$P_N = [(N-1)T_0+T_A]k\delta f \tag{2}$$

where N is defined as the noise factor of the receiver, k is Boltzmann's constant, δf is the bandwidth of the receiver and T_0 and T_A refer to room temperature (290 °K) and the effective aerial temperature respectively. T_A of course includes both the effective temperature of radiation received from celestial radio sources and that of radiation from the ground and nearby objects. The effect of losses in the transmission line is to degrade the noise factor of the receiver by an amount α_{T}, and the receiver can then be considered to produce a noise power

$$P_N' = [(\alpha_{\mathrm{T}}N-1)T_0+T_A]k\delta f. \tag{3}$$

The signal-to-noise ratio in the simple case is then given by

$$S = \frac{1}{4\pi k}\,\frac{P}{\alpha_{\mathrm{T}}[(\alpha_{\mathrm{T}}N-1)T_0+T_A]}\,\delta f\,\frac{A^2}{\lambda^2R^4}\sigma. \tag{4}$$

In practice, providing there are no large Doppler shifts, the bandwidth is normally chosen such that $\delta f = 1/t_p$ where t_p is the pulse length, and equation (4) becomes

$$S = K_1 P t_p \frac{A^2}{\lambda^2 R^4} \sigma \tag{5}$$

where

$$(K_1)^{-1} = 4\pi k\, \alpha_T[(\alpha_T N - 1)T_0 + T_A]$$

and the signal-to-noise ratio is proportional to the total energy in the transmitted pulse.

2.1. *The Effective Scattering Cross Section*

The above derivation of the signal-to-noise ratio assumes that the target or the region of the target that scatters the radiation is small in radial dimension. However, if the target scatters in depth, the power returned will be a function of the pulse length; then for rough surfaces it is more convenient to define an effective scattering cross section per unit area $\sigma_0(\theta)$, which will be a function of aspect angle, or in the case of, say, scattering from the atmosphere a cross section per unit volume. The scattering cross section will then be increased by increase in the pulse length, but at the expense of loss in range resolution. For the case of the moon the scattering cross section is given by integrating over the area of surface A illuminated by the pulse

$$\sigma = \int_A \sigma_0(\theta)\, dA \tag{6}$$

where θ is the angle of incidence at element dA, and has an upper limit when the pulse illuminates the whole of the surface.

Hence with comparatively low transmitter power but using very long pulse lengths, it was possible in early experiments at metre wavelengths to detect the integrated power scattered back from the whole of the lunar surface. The more recent development of short pulse and higher peak power transmitters at shorter wavelengths has made possible a more detailed study of the scattering mechanism of the lunar surface by making use of the improved range resolution.

2.2. *Integration*

The previous derivation of signal-to-noise ratio considered the case of a single pulse, but in general the radar will be sending out a train of pulses, so that it is possible to integrate the signal over an appreciable number of pulses. Also if the returned echo is measured over a range interval by means of a range gate it is possible to increase the signal but at the expense of range resolution. Now the noise can be considered as a number of discrete readings each of duration $1/\delta f$, so that if the duration of the range gate is t_g and the pulse repetition frequency is F, during the time constant of integration τ there will be

$$n = t_g \delta f F \tau$$

independent readings. Hence the uncertainty in the value of the noise power will be reduced by the factor $n^{1/2}$ and the signal-to-noise ratio becomes

$$S = K_3 P t_p \frac{A^2}{\lambda^2 R^4} \sigma (t_g \delta f F \tau)^{1/2} \tag{7}$$

where the constant K_3 contains, besides K_1, factors which are dependent on the shape of the receiver bandwidth and on the type of integration.

These are the principles that have been used in the design of the equipment for use with the radar for studying lunar echoes.

§ 3. THE RADAR EQUIPMENT

The equipment used for the experimental investigation on lunar scattering was basically as has been described previously (Hey and Hughes 1959), consisting of a radar with the following parameters:

Wavelength $\lambda = 10$ cm, peak pulse power $P = 2 \times 10^6$ w, pulse length $t_p = 5 \times 10^{-6}$ sec, pulse repetition frequency $F = 250$ per sec, receiver noise factor $N = 7{\cdot}5$, receiver band with $\delta f = 2 \times 10^5$ c/s, aerial diameter $D = 13{\cdot}7$ metres.

Originally the method of recording was to photograph an intensity modulated time base which was swept slowly across the cathode-ray tube, thus obtaining a range time display with integrated signal amplitude showing as a variation in brightness on the film. However, the method suffered from a number of disadvantages including a restricted dynamic range in signal amplitude, extraneous light produced a shift in the mean level, and despite frequent calibration, the film required careful and controlled development. To improve the method of recording a range gate unit was developed which allowed more accurate measurement of the signal and longer time constants of integration. The unit produced a pulse 20 μsec long (corresponding to 3 km of the time base) which sampled the receiver output after each transmitter pulse. The delay between transmitter pulse and range gate could be preset to integral values of 100 μsec (15 km) and also automatically swept over a further delay of 700 μsec (100 km) in a period of about 3 min. The output from the range gate was passed through an integrating unit, and after amplification was displayed on a recorder on which was also marked the range-gate delay.

With a time constant of integration of 2 sec it was possible to measure signals at levels down to about 3% of the noise power.

During the observation the pointing of the aerial was controlled by means of an analogue computer which converted the celestial coordinates to azimuth and elevation. The computer was set for the correct geocentric latitude and frequent adjustments were made in elevation to correct for lunar parallax in altitude.

§ 4. THE RESULTS

Thirty-one runs were analysed for the period 27th November to 11th December 1959, consisting of about four records obtained on each of a number of days. For each run the delay was set to bring the range gate near to the front of the lunar echo, the automatic swept delay was switched on and a record taken of amplitude against time-base range as the gate moved across the echo; a typical record is shown in figure 1. Owing to the fluctuating nature of the radar return, the time constant of 2 sec was not found to be sufficient and additional smoothing was applied by taking a running mean.

If the area on the surface of a large sphere of radius a illuminated by a short radar pulse of duration equivalent to a range on the time base of r_p is A_p then $A_p = 2\pi a r_p$ and is independent of the distance travelled by the pulse after first contact; hence the amplitude of the echo at any distance from the leading edge will be directly proportional

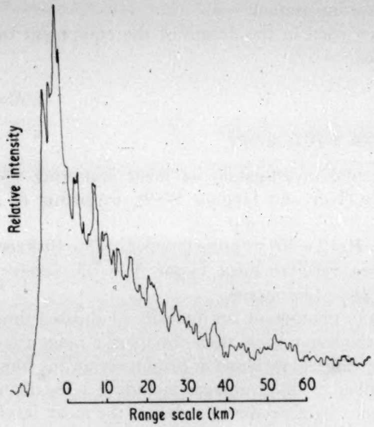

Figure 1. Typical recording of the lunar echo at the output of the integrating unit.

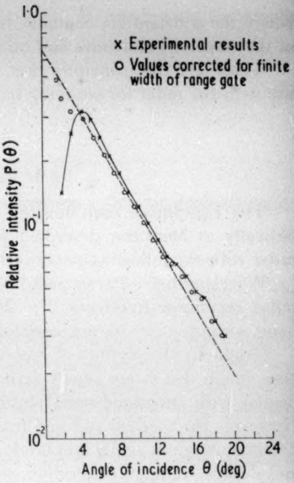

Figure 2. Angular scattering law of the lunar surface at the wavelength of 10 cm. The dashed line corresponds to $P(\theta) \propto \exp(-10{\cdot}2\theta)$.

to the angular scattering properties of the surface at that point, which we shall call $f(\theta)$. If then the conversion

$$\cos\theta = \frac{a-r}{a} \tag{8}$$

is made where r is the distance behind the leading edge the results obtained will show the angular scattering in terms of the angle of incidence θ.

Each of the 31 records were converted in this way and the mean of all the records is shown in figure 2, together with the straight line corresponding to $\exp(-10{\cdot}2\theta)$. The agreement is so close that we shall assume that between angles of incidence of at least 4° and 13° the law of scattering of the lunar surface is given by

$$f(\theta) = \exp(-10{\cdot}2\theta) \tag{9}$$

where θ is in radian measure. For angles of incidence less than 3°, an attempt was made to correct for finite width of the range gate, but owing to the very slow period fading of the front edge of the echo and to the inaccuracies involved in the corrections no great reliance could be placed on this part of the curve. However it appeared that the scattering law for values of θ near to zero might fall slightly below the exponential law.

4.1. *Comparison of Results with Short Pulse Observations at the Wavelength of* 1·5 *Metres*

Most of the radar measurements at longer wavelengths have been made with c.w. or very long pulses, apart from those by Trexler (1958) at the wavelength of 1·5 metres. These results for a pulse length of 12 μsec are given in terms of percentage of the total energy received as a function of time. To compare the scattering law at the two wavelengths, the 10 cm results were integrated assuming the scattering law $\exp(-10{\cdot}2\theta)$. The amount of energy returned after time t is then given by

$$P(t) = 2\pi a r_{\mathrm{p}} \int_0^{\theta} \exp(-10{\cdot}2\theta)\, d\theta \tag{10}$$

where r_{p} is the pulse length as defined previously, a is the lunar radius, and

$$\cos\theta = 1 - \frac{ct}{a}$$

$P(t)$ is plotted in figure 3 together with the values derived by Trexler, in terms of range in kilometres after the leading edge. The agreement is not exact, probably due to errors in reducing the values by Trexler, but up to angles of incidence of 14° is sufficient to suggest that the scattering law for small angles of incidence is sensibly independent of wavelength over the range 10 cm to 1·5 metres.

4.2. *Comparison with Measurements at* 400 *Mc/s*

More recent measurements by Pettengill (1960 and private communication) at the wavelength of 75 cm and a pulse length of 70 μsec have shown directly that the scattering from the lunar surface follows an exponential law at the small angles of incidence, but over a range of θ from 7° to approximately 50° may be represented by

$$\sigma_0 \exp(-10{\cdot}5 \sin\theta) + \sigma_{\mathrm{D}} \cos^{3/2}\theta \quad \text{where} \quad \sigma_{\mathrm{D}} = \sigma_0/160; \tag{11}$$

it has been suggested that the term involving σ_{D} may represent a diffuse scattering component. To determine if the σ_{D} component is also independent of frequency, the sensitivity of the 10 cm equipment was further improved by increasing the duration of the range gate to 100 μsec (15 km), by other improvements in the sensitivity of the receiver, and by increasing the range of the automatic sweep of the range gate. It was only possible to obtain 13 runs during 21st and 22nd December 1960, but the results are shown in figure 4 for values of θ up to 30° together with the empirical law determined by Pettengill. Again the agreement is remarkably good, and though the 10 cm results have not been obtained at all angles of libration, they are sufficient to suggest that any diffuse component of scattering is also independent of wavelength for angles of incidence up to about 30°.

No attempt will be made here to explain why the suggested diffuse component is proportional to $\cos^{3/2}\theta$. This will be discussed in a later paper where it is shown that the theoretical law with the addition of a diffuse scattering term, proportional to $\cos\theta$ can lead to the empirical law of equation (11).

4.3 *Comparison of Lunar Scattering with Scattering from Rough Surfaces*

A direct comparison can be made between the scattering law as derived from the present experiments with that obtained from various types of surface on the earth. From optical observations the lunar surface appears to have a nearly uniform reflectivity over its surface and measurements on the thermal radiation at radio wavelengths greater than 3 cm show that the surface must have a highly absorbing layer. Hence it is also reasonable to assume that the reflectivity over the surface is constant though small at a particular radio wavelength. The closest comparison with terrestrial surfaces from the point of view of angular scattering properties would then be either with desert regions or with the sea, and for the present purpose a comparison will be made with scattering from the sea.

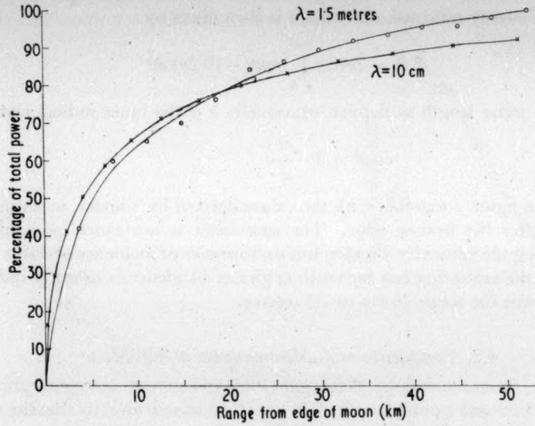

Figure 3. Comparison of results obtained at the wavelength of 10 cm with those by Trexler at the wavelength of 1·5 metres. $\lambda = 10$ cm, pulse length 5 μsec; $\lambda = 1{\cdot}5$ m, pulse length 12 μsec.

Figure 4. Comparison of angular scattering law at the wavelength of 10 cm with that obtained by Pettengill at the wavelength of 75 cm.

The earliest measurements on sea returns obtained at a wavelength of 3·2 cm have been collected by Goldstein (1951). They show an angular scattering law which varies with the state of the sea, but in general the intensity decreases rapidly at angles away from normal incidence, such that at an angle of 20° the effective scattering area has fallen by a factor of 10–20 dB from the value at normal incidence. The largest decrease corresponds to the case of a 'slight' sea, but even under these conditions the amplitude of waves and ripples is expected to be much greater than the wavelength. The corresponding decrease in scattering area of the moon at an angle of incidence of 20° is about 15 dB. Measurements of the effective scattering area for the average sea at shorter wavelengths have also been made by Grant and Yaplee (1957). They show that over a wavelength range from 8·6 mm to 3·2 cm the scattering law remains sensibly the same and is of a similar form to that obtained for the moon, including the flattening off of the curve at comparatively large angles of incidence. Hence the results are in agreement with scattering from a lunar surface which is rough in the same way as the surface of the sea is rough, implying random variation of the surface with amplitude greater than the radar wavelength.

4.4. *Bistatic Radar Measurements on the Moon*

Further indications of a random lunar surface which contributes many reflecting points was obtained in a joint experiment with the University of Texas (Straiton and Tolbert: Hughes 1960). The signals transmitted from Malvern, England, were received at Austin, Texas, after reflection from the moon and at an angle of about $1\frac{1}{2}°$ to the incident direction, corresponding to the angle subtended at the moon by the Malvern–Austin base-line. In this case the mean level of the signals showed a gradual increase over a distance of about 7 km, in comparison with the initial sharp rise observed at Malvern. This is as would be expected on the rough scattering theory since from considering the geometry of scattering with the short pulse lengths the echo amplitude is proportional to the area of the moon seen to be illuminated from Texas and this increases more gradually. In fact the increase is expected to take place over a distance of about 9 km but the initial rise would be lost in the noise level.

To summarize it is suggested that over representative annular areas of 8000 km², corresponding to the area of the lunar surface from which signals are received at a pulse length of 5 μsec, the moon would appear to consist of a large number of random scatterers, as for an undulating random surface, and this will be assumed in future discussions. Further evidence that this is consistent will be shown from the theoretical treatment of scattering from rough surfaces in a later paper.

§ 5. VARIATION OF SCATTERING CROSS SECTION WITH WAVELENGTH

To compare the echoing area of the moon at different wavelengths and different pulse lengths the angular scattering law of the surface has to be taken into account. If short pulse lengths are used, then the effective echoing area of the moon is given by

$$2\pi a r_{\mathrm{p}}[\sigma_0 \exp(-10\theta) + \sigma_{\mathrm{D}} \cos^{3/2}\theta]$$

where $r_{\mathrm{p}} = \frac{1}{2}t_{\mathrm{p}}c$ is half the length in space of the transmitter pulse, a is the lunar radius, σ_0 and σ_{D} represent the scattering cross section per unit area of the moon for the two empirical scattering components and θ is the angle of incidence of the pulse at the lunar surface. If the moon is illuminated with c.w. then the total echoing area will be given by

$$\begin{aligned}\sigma_{\mathrm{T}} &= 2\pi a^2 \int_0^{\pi/2} [\sigma_0 \sin\theta \exp(-10\theta) + \sigma_{\mathrm{D}} \sin\theta \cos^{3/2}\theta]\, d\theta \\ &= \pi a^2[2\times 10^{-2}\sigma_0 + 8\times 10^{-1}\sigma_{\mathrm{D}}] \\ &= 2{\cdot}5\times 10^{-2}\pi a^2 \sigma_0 \qquad (12)\end{aligned}$$

where it is assumed that $\sigma_{\mathrm{D}} = \sigma_0/160$. Taking the value $\sigma_0 = 0{\cdot}85$ for the wavelength of 10 cm which has been corrected from the one previously obtained (Hughes 1960) this yields a figure of

$$\sigma_{\mathrm{T}} = 2{\cdot}1\times 10^{-2}\pi a^2. \qquad (13)$$

A comparison of the results at different wavelengths, for $\sigma_{\mathrm{T}}/\pi a^2$ and σ_0 is given in the table.

Wavelength (metres)	Pulse length	Reference	$\sigma_{\mathrm{T}}/\pi a^2$	σ_0
0·1	5 μsec		$2{\cdot}1\times 10^{-2}$	$8{\cdot}5\times 10^{-1}$
0·62	c.w.	(Blevis & Chapman 1960)	$5{\cdot}0\times 10^{-2}$	2·0
0·7	c.w.	(Fricker *et al.* 1960)	$7{\cdot}0\times 10^{-2}$	2·8
0·75	70 μsec	(Pettengill, private communication)	$7{\cdot}0\times 10^{-2}$	2·8
1·0	c.w.	(Trexler 1958)	$7{\cdot}0\times 10^{-2}$	2·8
1·5	c.w.	(Trexler 1958)	$8{\cdot}0\times 10^{-2}$	3·2
2·5	30 msec (c.w.)	(Evans 1957)	$1{\cdot}8\times 10^{-1}$	4·5

Most of the measurements give a value for the integrated scattering cross section for the moon which lie in the region $5\text{–}10\times 10^{-2}$ with the exception of the results obtained at the wavelength of 10 cm. However, since these latter measurements are derived by extrapolating the results obtained for small angles of incidence, and only a small amount of scattering at the large angles could make an appreciable contribution, they may in fact be an underestimate. It may be concluded that though the total scattering cross section may vary slightly with wavelength, the amount of variation is probably small, especially so when it is considered that the accuracy of the readings is probably only ± 50%.

§ 6. CONCLUSIONS

The main object of this paper has been to describe in more detail the measurements that have been made on radar echoes from the moon at the wavelength of 10 cm. The results show that the scattering law of the lunar surface at least for angles of incidence from about 3 to 13° is sensibly independent of wavelength over the range 10 cm to 1·5 metres, and there is evidence that for angles up to 30° the scattering law at the two wavelengths is sensibly the same. The empirical law would appear to be exponential with argument proportional to θ (or $\sin\theta$) with the addition of a small component proportional to $\cos^{3/2}\theta$ as determined originally by Pettengill. It is not suggested that any physical interpretation may necessarily be applied to these two components, and a theoretical treatment is left to a further paper.

The highly directional form of the scattering law led Senior and Siegel to the conclusion that there must be about 20 or 30 smooth regions on the moon and the term quasi-smooth has been used to describe the surface. However, various factors have been shown to indicate that the results are compatible with scattering from a rough surface, by which is meant one which has deviations large in comparison with the wavelength, and in fact a similarity exists between the scattering law for the lunar surface and the surface of the sea.

An important difference between the quasi-smooth and rough theories arises when an attempt is made to derive the reflectivity of the surface. The quasi-smooth theory predicts that the reflectivity may be obtained by measuring the amplitude of the signal received from the front edge of the moon since this is reflected from a smooth spherical region which is greater than the first Fresnel zone and of radius approximately equal to the lunar radius; on the other hand, as will be seen in a future paper, the rough-surface theory predicts that the reflectivity may only be obtained by integrating the radiation scattered from the whole of the lunar surface. The value of the reflectivity determined from the two theories may differ by as much as 100 times.

ACKNOWLEDGMENTS

The experimental work was carried out at the Ministry of Aviation, Royal Radar Establishment, Malvern, and acknowledgment is made to colleagues who assisted in the construction and operation of the equipment.

Synthesis of Interference Filters

By J. S. SEELEY

Queen Mary College, University of London

MS. received 29th May 1961

Abstract. A method of synthesizing electrical circuit filters to transmit prescribed functions of frequency in a specified pass-band is applied to dielectric interference filters containing up to four half-wave layers. The method relies on an approximation that the half-wave layers are the only parts of the filter which are sensitive to frequency. The reflecting quarter-wave multilayers are described by a single parameter whose values are deduced in the synthesis. The transmission functions are either maximally flat in the pass-band or contain equal ripples. The rate of transition from the pass-band to the stop-band is increased rapidly by increasing the number of half-wave layers.

The synthesis is applied to filters specified to transmit an 8% bandwidth within which the transmissivity is not less than 0·91. The exact transmission characteristics of these examples show excellent agreement in the pass-band with the simple functions.

The method can be applied to the design of filters of moderate bandwidth for any spectral region.

§ 1. INTRODUCTION

ELECTRICAL FILTER networks of lumped inductive and capacitive elements may be synthesized by the classic method of Darlington (1939) to pass a band of frequencies following a simple type of transmission function. The method is based on the synthesis of an equivalent low-pass filter consisting of a 'ladder' arrangement of unequal elements. The elements of the band-pass filter are readily deduced from those of the low-pass prototype with a suitable transformation of the frequency variable in the transmission function.

Structures having similar general properties to the ladder networks can be built in distributed circuits by loading an appropriate waveguide with suitably spaced reactive obstacles. The application of the synthesis for band-pass filters to distributed circuits is hindered by the dependence on frequency of the transmission properties of the circuits themselves and by the magnitude and the dependence on frequency of the reflections from the obstacles. Various methods for the approximate synthesis of waveguide filters with a high degree of isolation between the pass-band and stop-band have been described. Their accuracy deteriorates for filters of bandwidth greater than 10%, as discussed by Cohn (1957), Seidel (1957) and Levy (1957) amongst others. The lengths of waveguide which separate the reflecting obstacles are designed to have an effective phase shift of π at the mid-band frequency. These are the principal elements sensitive to frequency and, together with the obstacles, form a cascade of half-wavelength resonant cavities. A Q-factor is associated with each cavity and can be related to the reflectivities of the obstacles. (This expresses the ratio of the resonant frequency to the frequency interval for which more than half the incident power is transmitted, i.e. half-width.) The Q-factors for the cavities are deduced from the lumped elements of a low-pass prototype synthesized by the Darlington method to a simple transmission function. The synthesis only predicts behaviour in the fundamental pass-band of the filter and requires that all the cavities should be resonant at the central frequency.

The dielectric multilayer type of interference filter (Polster 1952) is based on the Fabry–Pérot etalon which behaves in a similar manner to the waveguide resonant cavity when the variation of the wave impedance with frequency is considered. It is of interest to apply the Darlington method of synthesis to structures consisting of a cascade of Fabry–Pérot resonant cavities based on dielectric multilayers. In addition to providing a method of designing an interference filter to transmit a prescribed function over a moderate bandwidth the synthesis will indicate how the multilayers which are already used in various spectral regions can be deployed to the best advantage in band-pass filters.

§ 2. THEORY OF THE SYNTHESIS

2.1. *External Description of Multi-cavity Filters*

The filters are symmetrical arrangements of dielectric multilayers containing more than one half-wave layer (Smith 1958, Turner 1952) as represented in figure 1. We will consider the transmission of a plane wave through this arrangement for normal incidence. All absorption and dispersion in refractive index of the dielectric materials forming the layers will be neglected. The wave impedances of the layers will be normalized with respect to that of the external medium. If this is air the impedances for normal incidence are therefore simply the reciprocals of the refractive indices of the layers.

The amplitudes of the electric and magnetic vectors in the waves crossing the interfaces AA and BB can be written, following for example, Born and Wolf (1959), Heavens (1960) and Weinstein (1954)

$$\begin{bmatrix} \mathbf{E}_{AA} \\ \mathbf{H}_{AA} \end{bmatrix} \equiv \begin{bmatrix} M \end{bmatrix} \begin{bmatrix} \mathbf{E}_{BB} \\ \mathbf{H}_{BB} \end{bmatrix} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix} \begin{bmatrix} \mathbf{E}_{BB} \\ \mathbf{H}_{BB} \end{bmatrix} \tag{1}$$

where the matrix $[M]$ is the transfer matrix of the structure between AA and BB. The boundary conditions are

at *BB* $$\begin{cases} \mathbf{E}_{BB} = \mathbf{E}_e \\ \mathbf{H}_{BB} = \mathbf{E}_e/Z_0 \end{cases}$$

at AA $$\begin{cases} \mathbf{E}_{AA} = \mathbf{E}_i + \mathbf{E}_r = \left(m_{11} + \dfrac{m_{12}}{Z_0} \right) \mathbf{E}_e \\ \mathbf{H}_{AA} = (\mathbf{E}_i - \mathbf{E}_r)/Z_0 = \left(m_{21} + \dfrac{m_{22}}{Z_0} \right) \mathbf{E}_e. \end{cases}$$

The amplitude reflection coefficient at AA when the wave impedance Z_0 is put equal to unity is

$$\frac{\mathbf{E}_r}{\mathbf{E}_i} = \frac{m_{11} + m_{12} - m_{21} - m_{22}}{m_{11} + m_{12} + m_{21} + m_{22}}. \tag{2}$$

The amplitude transmission coefficient at BB is

$$\frac{\mathbf{E}_e}{\mathbf{E}_i} = \frac{2}{m_{11} + m_{12} + m_{21} + m_{22}}. \tag{3}$$

The matrix $[M]$ is the ordered product of the matrices of the individual layers and completely represents the structure. The elements in the matrix of a symmetrical

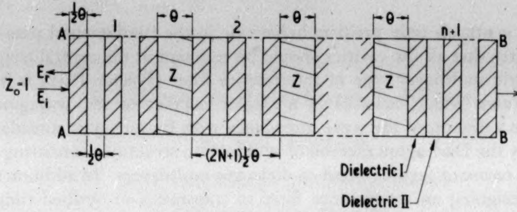

Figure 1. Arrangement of dielectric layers in a generalized filter. There are n half-wave layers of wave impedance $Z/Z_0 = z$. $\theta = \pi\omega/\omega_0$ where ω_0 is the central frequency of the pass-band of the filter. The multilayer systems numbered (1) and $(n+1)$, (2) and (n) etc. are identical. They consist of alternate quarter-wave layers of two dielectric materials. There are $N+1$ layers of the dielectric with the higher refractive index.

structure are related by $m_{11}m_{22}-m_{12}m_{21} = 1$ and $m_{11} = m_{22}$. The transfer matrix of a single layer is

$$\begin{bmatrix} \cos\phi & jz\sin\phi \\ \dfrac{j\sin\phi}{z} & \cos\phi \end{bmatrix}$$

when there is no absorption, ϕ being the optical thickness and z the normalized wave impedance. z is wholly real for dielectrics without absorption so that $m_{12} = jM_{12}$, $m_{21} = jM_{21}$, m_{11}, M_{12} and M_{21} all being real numbers.

The reflection and transmission coefficients of (2) and (3) can now be expressed more simply in this particular case by

$$\frac{\mathbf{E}_r}{\mathbf{E}_i} = \frac{j(M_{12}-M_{21})}{2m_{11}+j(M_{12}+M_{21})} \quad\text{and}\quad \frac{\mathbf{E}_e}{\mathbf{E}_i} = \frac{2}{2m_{11}+j(M_{12}+M_{21})} \tag{4}$$

so that the reflectivity and transmissivity are therefore

$$R = \left|\frac{\mathbf{E}_r}{\mathbf{E}_i}\right|^2 = \frac{(M_{12}-M_{21})^2}{4m_{11}^2+(M_{12}+M_{21})^2} = \frac{(M_{12}-M_{21})^2}{4+(M_{12}-M_{21})^2} \tag{5}$$

$$T = \left|\frac{\mathbf{E}_e}{\mathbf{E}_i}\right|^2 = \frac{4}{4m_{11}^2+(M_{12}+M_{21})^2} = \frac{1}{1+\frac{1}{4}(M_{12}-M_{21})^2}. \tag{6}$$

Either (5) or (6) is sufficient to represent the behaviour of the filter because $R+T = 1$ for no absorption. Equation (6) is more convenient to use than equation (5) and the expression for the reciprocal of the transmissivity, $1+\frac{1}{4}(M_{12}-M_{21})^2$, is widely used in the synthesis of electrical circuit filters free from energy loss. We will use it to predict the behaviour of the arrangement of multilayer resonant cavities shown in figure 1.

2.2. *The Transfer Matrix of the Filter*

2.2.1. *The reflecting multilayers.*

The transfer matrix of reflecting multilayers consisting of two dielectric materials I and II is

$$[M'] = \begin{bmatrix} \cos\frac{1}{2}\theta & jz_{\text{I}}\sin\frac{1}{2}\theta \\ \dfrac{j\sin\frac{1}{2}\theta}{z_{\text{I}}} & \cos\frac{1}{2}\theta \end{bmatrix} \underbrace{\begin{bmatrix} \cos\frac{1}{2}\theta & jz_{\text{II}}\sin\frac{1}{2}\theta \\ \dfrac{j\sin\frac{1}{2}\theta}{z_{\text{II}}} & \cos\frac{1}{2}\theta \end{bmatrix} \text{---}}_{N\text{ times}} \begin{bmatrix} \cos\frac{1}{2}\theta & jz_{\text{I}}\sin\frac{1}{2}\theta \\ \dfrac{j\sin\frac{1}{2}\theta}{z_{\text{I}}} & \cos\frac{1}{2}\theta \end{bmatrix} \tag{7}$$

where θ is the optical thickness of the half-wave layers. When the angular frequency ω is equal to the central frequency ω_0 the product $[M']$ reduces to

$$[M'] = \begin{bmatrix} 0 & jz_{\mathrm{I}}\left(\dfrac{-z_{\mathrm{I}}}{z_{\mathrm{II}}}\right)^N \\ \left(\dfrac{j}{z_{\mathrm{I}}}\right)\left(\dfrac{-z_{\mathrm{II}}}{z_{\mathrm{I}}}\right)^N & 0 \end{bmatrix}. \tag{8}$$

It is convenient to put

$$\frac{1}{z_{\mathrm{I}}}\left(\frac{-z_{\mathrm{II}}}{z_{\mathrm{I}}}\right)^N = r. \tag{9}$$

The matrix product of the structure shown in figure 1 must be simplified before equation (6) can be used for synthesis to a prototype transmission function. As a first step we can represent the reflecting multilayers by the matrix of equation (8)

$$\begin{bmatrix} 0 & j/r \\ jr & 0 \end{bmatrix}$$

at all frequencies within the fundamental pass-band of the filter. This approximation ignores two properties of the multilayer. The most important is that the optical thickness is subject to a frequency-dependent phase shift from the central value $(2N+1)\frac{1}{2}\pi$; the other is that the effective transformation ratio only reaches the value r when the phase shift is $(2N+1)\frac{1}{2}\pi$. A multilayer is more accurately represented by (8) for a band of frequencies centred on an angular frequency ω_0 by increasing r. An important consequence of the simplification of (8) is that the optical thicknesses of the half-wave layers become the only elements of the filter which are sensitive to frequency.

2.2.2. *The multilayer resonant cavities.*

The transfer matrix of a half-wave layer bounded by multilayers represented by the approximate matrix of (8) is

$$[M''] = \begin{bmatrix} 0 & j/r \\ jr & 0 \end{bmatrix} \begin{bmatrix} \cos\theta & jz\sin\theta \\ \dfrac{j\sin\theta}{z} & \cos\theta \end{bmatrix} \begin{bmatrix} 0 & j/r \\ jr & 0 \end{bmatrix}. \tag{10}$$

The matrix of the half-wave layers must be simplified before the product representing a sequence of resonant cavities can lead to equations in the parameter r which are capable of simple solution. By restricting the fundamental pass-band to about $0{\cdot}1\omega_0$ we can put $\cos\theta \simeq -1$ in (10) (in fact $\cos\theta$ will vary as about $(1-\omega/\omega_0)^2\pi^2/2-1$ near ω_0, $\cos\frac{1}{2}\theta$ in (7) will vary as about $(1-\omega/\omega_0)\pi/2)$. It is also necessary to put $\sin\theta \simeq 0$ in the 21 term in (10) which only increases the half-width of the Fabry–Pérot resonant cavity represented by (10) by a factor of about $r^2/(r^4-1)^{1/2}$, involving an error of less than 1% provided that r is greater than 2·5.

The matrix product which we therefore propose for an approximate band-pass synthesis is

$$[M] = \begin{bmatrix} m_{11} & jM_{12} \\ jM_{21} & m_{11} \end{bmatrix} \simeq \begin{bmatrix} 0 & j/r_1 \\ jr_1 & 0 \end{bmatrix} \begin{bmatrix} -1 & jz\sin\theta \\ 0 & -1 \end{bmatrix}$$

$$\times \begin{bmatrix} 0 & j/r_2 \\ jr_2 & 0 \end{bmatrix} \cdots \begin{bmatrix} -1 & jz\sin\theta \\ 0 & -1 \end{bmatrix} \begin{bmatrix} 0 & j/r_{n+1} \\ jr_{n+1} & 0 \end{bmatrix} \tag{11}$$

n is the number of cavities in the filter, $r_{n+1} = r_1$, $r_n = r_2$, etc.

2.3. *The Prototype Transmission Functions*

Equal ripple (Tchebyshev) and maximally flat (Butterworth) functions are used extensively as transmission functions in the synthesis of electrical filters. The transmissivity written in terms of these functions is

$$T = \frac{1}{1+[f_n(\bar{\omega})]^2} \tag{12}$$

where $\bar{\omega}$ is a transformed frequency variable.

The equal ripple function is

$$f_n(\bar{\omega}) = hT_n(\bar{\omega}) \tag{13}$$

where

$$T_n(\bar{\omega}) = \begin{cases} \cos(n \cos^{-1} \bar{\omega}) & \text{for } |\bar{\omega}| \leqslant 1 \\ \cosh(n \cosh^{-1} \bar{\omega}) & \text{for } |\bar{\omega}| \geqslant 1. \end{cases}$$

The Tchebyshev functions $T_n(\bar{\omega})$ are more conveniently expressed as polynomials which are valid for all values of $\bar{\omega}$, as follows

$$\left.\begin{aligned} T_n(\bar{\omega}) &= 1 & \text{for } n &= 0 \\ &= \bar{\omega} & n &= 1 \\ &= 2\bar{\omega}^2-1 & n &= 2 \\ &= 4\bar{\omega}^3-3\bar{\omega} & n &= 3 \\ &= 8\bar{\omega}^4-8\bar{\omega}^2+1 & n &= 4 \end{aligned}\right\} \begin{aligned} &T_n(\bar{\omega}) \text{ tends to } 2^{n-1}\bar{\omega}^n \text{ for} \\ &\text{large values of } \bar{\omega}. \end{aligned}$$

The maximally flat function is

$$f_n(\bar{\omega}) = (\bar{\omega}')^n. \tag{14}$$

The two functions are compared in figure 2 which shows $1/T$ plotted against $\bar{\omega}$ for $n = 2$, 3 and 4. The parameter h^2, which is the amplitude of the ripple, has been set equal to unity for the comparison making $\bar{\omega}'$ equal to $\bar{\omega}$. It should be noted that transmission of the equal ripple type is specified over the bandwidth for which T is not less

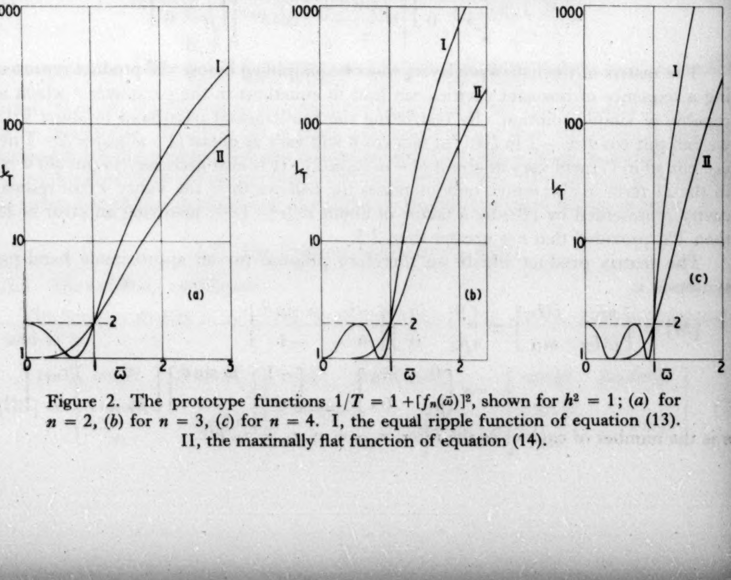

Figure 2. The prototype functions $1/T = 1+[f_n(\bar{\omega})]^2$, shown for $h^2 = 1$; (*a*) for $n = 2$, (*b*) for $n = 3$, (*c*) for $n = 4$. I, the equal ripple function of equation (13). II, the maximally flat function of equation (14).

than $1/(1+h^2)$, $\bar{\omega}$ having the values of ± 1 at the band edges. The bandwidth of the maximally flat function is specified in the same way but the value of $\bar{\omega}'$ at the band edges depends on the chosen value of h^2.

The requirements of any particular filter will determine which of the prototype functions is most suitable. If the transmissivity can have a value as low as $1/(1+h^2)$ at any frequency within the pass-band then the equal ripple function should be used since it has a more rapid transition from the pass-band than the maximally flat function. For large values of $\bar{\omega}$, $(T_n(\bar{\omega}))$ is increasing more rapidly than $\bar{\omega}^n$ by a factor of 2^{n-1}. In contrast the maximally flat function always shows complete transmission when $\bar{\omega}' = 0$ and T is nearly equal to unity for a large central part of the pass-band. The number of cavities which are necessary will be determined by the rate at which the transmissivity is required to fall with frequency outside the pass-band.

2.4. *Synthesis to the Prototype Functions*

The simplified product of (11) has been evaluated for filters consisting of two, three and four cavities; the terms in the matrix $[M]$ being summarized in table 1. Synthesis to the prototype functions requires that

$$\frac{1}{T}-1 = \tfrac{1}{4}(M_{12}-M_{21})^2 = [f_n(\bar{\omega})]^2. \tag{15}$$

$(M_{12}-M_{21})$ is a polynomial function containing the terms $\sin^n\theta$, $\sin^{n-2}\theta$, etc. with coefficients in the values of r. Since we have restricted (11) to filters of moderate bandwidth

$$\sin\theta = \sin\frac{\pi(\omega_0-\omega)}{\omega_0} \simeq \frac{\pi(\omega_0-\omega)}{\omega_0}. \tag{16}$$

The frequency variable in the equal ripple function $\bar{\omega}$ must equal ∓ 1 when $\omega = \omega_1$ or $2\omega_0-\omega_1$ where ω_1 defines the edge of the pass-band so that $\bar{\omega}$ can be defined in terms of ω as

$$\bar{\omega} = \frac{\omega-\omega_0}{\omega_0-\omega_1}. \tag{17}$$

The maximally flat function $(\bar{\omega}')^{2n}$ must have the value h^2 if T is specified to be $1/(1+h^2)$ when $\omega = \omega_1$ or $2\omega_0-\omega_1$ so that since $\bar{\omega}$, as defined in (17), is equal to ∓ 1 at these frequencies

$$\bar{\omega}' = h^{1/n}\bar{\omega} = h^{1/n}\frac{\omega-\omega_0}{\omega_0-\omega_1}. \tag{18}$$

$\sin\theta$ can be related to the variables $\bar{\omega}$ and $\bar{\omega}'$

$$\sin\theta \simeq \frac{\pi(\omega_0-\omega)}{\omega_0} = t\bar{\omega} \text{ or } t'\bar{\omega}' \tag{19}$$

where the scale factors t and t' are given by

$$t = \frac{-\pi(\omega_0-\omega_1)}{\omega_0} \quad \text{for the equal ripple function,}$$

$$t' = \frac{-\pi(\omega_0-\omega_1)}{h^{1/n}\omega_0} \quad \text{for the maximally flat function.}$$

4	$\left.\begin{aligned}&\pm\left(\frac{r_2^2}{r_1^2r_3}-\frac{r_3r_1^2}{r_2^2}\right)=0\\&\pm\left(2r_1^2r_3+\frac{r_1^2r_2^2}{r_3}-\frac{r_2^2r_3}{r_1^2}\right)=0\\&\pm(-r_3r_1^2r_2^2)=\frac{2}{z^4(t')^4}\end{aligned}\right\}\begin{aligned}r_1&=\pm\frac{(2-\sqrt{2})^{1/4}}{\sqrt{(-zt')}}\\r_2&=\pm\frac{2^{1/4}}{zt'}\\r_3&=\pm\left(\frac{r_2}{r_1}\right)^2\end{aligned}$	$\left.\begin{aligned}&\pm\left(\frac{r_2^2}{r_1^2r_3}-\frac{r_3r_1^2}{r_2^2}\right)=2h\\&\pm\left(2r_1^2r_3+\frac{r_1^2r_2^2}{r_3}-\frac{r_2^2r_3}{r_1^2}\right)=\frac{-16h}{z^2t^2}\\&\pm(-r_3r_1^2r_2^2)=\frac{16h}{z^4t^4}\end{aligned}\right\}\begin{aligned}r_1&=\pm\left(\frac{-2h}{ktz}\right)^{1/2}\\&\quad\times\{[2-(1/k)]+[(1/k)-2]^2+(k/h)^2]^{1/2}\}^{1/4}\\r_2&=\pm\frac{2\sqrt{k}}{zt}\\r_3&=\pm\frac{16h}{z^4t^4r_1^2r_2^2}\end{aligned}$

where $k = (h[\sqrt{(1+h^2)}-h]^{1/2}$

The polynomial functions in $M_{12}-M_{21}$ can now be written in terms of $t(\bar{\omega})$ or $t'(\bar{\omega}')$ by substituting for $\sin\theta$.

Synthesis to the equal ripple function is completed by equating the coefficients of $\sin^n\theta$ etc. with those of $(\bar{\omega}/t)^n$ etc. in the polynomial expansion for $hT_n(\bar{\omega}/t)$ given in (13). Synthesis to the maximally flat function requires that the polynomial function of $\sin\theta$ must equal $(\bar{\omega}')^n$ for all values of $\bar{\omega}'$. The coefficient of $\sin^n\theta$ in $M_{12}-M_{21}$ can therefore be put equal to $1/(t')^n$ and the coefficients of all lower powers of $\sin\theta$ put equal to zero.

The values of the parameter r in the synthesized filter are given in terms of h and t or t' by simultaneous equations obtained from equating the coefficients in (15). The equations and the unique real solutions for r are indicated in table 2 for $n = 2$, 3 and 4. The solutions are no longer simple when n is greater than 4 because the simultaneous equations contain mixed polynomials in r_1, r_2 and r_3. This problem does not arise in the synthesis of electrical ladder network filters because the values of the circuit elements are deduced from general recurrence formulae such as those given by Belevich (1952) and Orchard (1953); the synthesis of interference filters with more than four cavities requires the development of a general formula for r.

§ 3. APPLICATION OF THE THEORY

The accuracy of the synthesis described in § 2 is illustrated by comparisons between the exact transmission characteristics and the prototype functions of some particular filters. The examples are chosen to transmit an 8% bandwidth with a value of T not less than $1/1{\cdot}1$ (i.e. $h^2 = 0{\cdot}1$, $t = -0{\cdot}04\pi$). Two, three and four cavity filters have been synthesized to the specified equal ripple and maximally flat functions using the equations of table 2. The reflecting multilayers of the example filters have been assumed to consist of single layers. This restriction, as well as simplifying the calculations of the exact transmission characteristics, was imposed to demonstrate the effect of the variation with frequency in the optical thickness of the multilayers. The other approximations

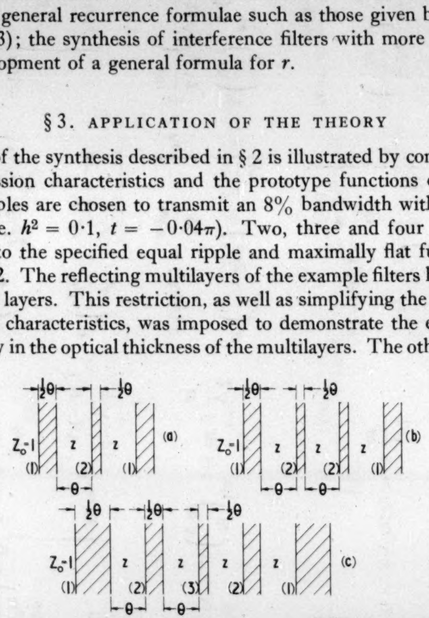

Figure 3. Details of the filters chosen to illustrate the synthesis. T is specified to be not less that $1/1{\cdot}1$ over an 8% bandwidth. The reflecting systems (1) etc. are assumed to consist of a single dielectric layer, the refractive index of which is given by the values of r_1 etc. shown below. $\theta = \pi\,\omega/\omega_0$

Filter	Values of r obtained from table 2 for $h^2 = 0{\cdot}1$, $t = -0{\cdot}04\pi$					
	Equal ripple			Maximally flat		
	r_1	r_2	r_3	r_1	r_2	r_3
(a) 2 cavities	3·22	7·68		2·50	6·30	
(b) 3 cavities	3·45	10·3		2·33	7·65	
(c) 4 cavities	3·52	11·0	13·4	2·13	7·07	11·0

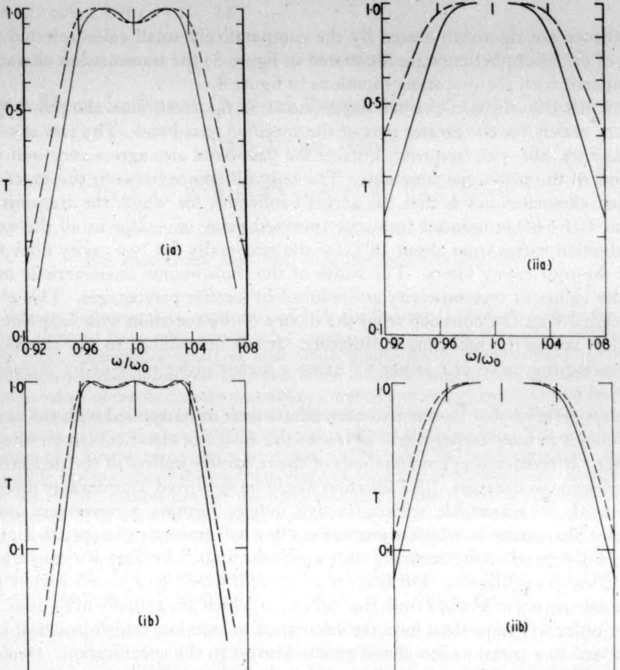

Figure 4. Transmission characteristics of filters chosen as examples, for which $h^2 = 0{\cdot}1$, $t = -0{\cdot}04\pi$. (*a*) 2 cavities, (*b*) 3 cavities, (*c*) 4 cavities. Broken line, prototype functions, $T = 1/(1 + [f_n(\bar{\omega})]^2)$, full line, exact transmission of filters represented in figure 3. (i) for equal ripple transmission, (ii) for maximally flat transmission.

in the theory are rigorously tested by the comparatively small value selected for h^2/t. Details of the example filters are illustrated in figure 3; the transmission characteristics are compared with the prototype functions in figure 4.

The exact transmission characteristics shown in figure 4 follow the prototype functions very closely for the greater part of the specified pass-band. The rate at which the transmissivity falls with frequency outside the pass-band also agrees very well with the behaviour of the prototype functions. The only difference between the exact and the simplified characteristics is that the actual bandwidth for which the transmissivity is less than $1/(1+h^2)$ is reduced from the specified value of $-2t/\pi$ in all the examples. The reduction varies from about 18% for the maximally flat two cavity filter to about 7% for the four cavity filters. The width of the transmission characteristic measured at smaller values of transmissivity are reduced by similar percentages. This effect can be associated with the omission from the theory of the variation with frequency in the phase shift across the reflecting multilayers. It can be reduced in any particular case by increasing the value of r either by using a higher order filter or by increasing the value of h^2/t.

It is appreciated that the method of synthesis cannot be applied with the same freedom of choice to interference filters as it is to the design of electrical circuit filters. The parameter r is restricted to combinations of the refractive indices of the dielectrics used in the reflecting multilayers. The situation would be improved considerably if more than two materials were available with refractive indices forming a convenient numerical sequence. The extent to which a particular filter will transmit the specified prototype function will depend on the accuracy with which the required values of r can be achieved with practicable multilayers. For two cavity filters it would be a simple matter to make a reverse calculation of h^2 and t from the values of r which are actually to be used. Filters of higher order will require an iterative calculation to ascertain which practicable values of r will lead to a transmission characteristic nearest to the specification. Decisions of this kind will be assisted by remembering that the transmissivity of any arrangement is easily calculated at $\omega = \omega_0$ by eliminating the half-wave layers. Further, a transmission characteristic intermediate to the equal ripple and maximally flat functions would be expected if the practicable values of r are intermediate to the synthesized values for both functions. The equations of table 2 will provide a quick assessment for the best deployment of quarter-wave layers in a particular filter when, for example, either the overall thickness or the number of layers is fixed.

Some Electrical and Optical Properties of InAs–In_2Se_3 and InSb–In_2Se_3 Alloys

By J. C. WOOLLEY and P. N. KEATING†

Department of Physics, The University, Nottingham

MS. received 9*th June* 1961, *in revised form* 27*th July* 1961

Abstract. Polycrystalline specimens of InAs–In_2Se_3 and InSb–In_2Se_3 alloys have been prepared by suitable annealing of ingots. Measurements have been made of the room temperature values of Hall effect, conductivity, thermoelectric power and infra-red absorption over the whole of the available range of solid solution, and hence values of carrier density n, mobility μ and optical energy gap E_g determined. It is found that the behaviour is similar to that of the corresponding In_2Te_3 alloys in that the alloys rich in $A^{III}B^{V}$ are n-type and highly degenerate. The observed values of n for the four systems concerned ($A^{III}B^{V}$–$A_2^{III}B_3^{VI}$) are compared, and possible explanations of the results in terms of solubility of tellurium and selenium in the $A^{III}B^{V}$ compounds, or the band structure of the $A^{III}B^{V}$ compounds are discussed. The use of thermoelectric power data to give values of the Fermi level is considered, and it is shown that to give consistent results in the composition range where ionized impurity scattering occurs, a scattering relation of the form $\tau \propto E^{+1/2}$ must be used. The results suggest that the InAs–In_2Se_3 system may show a change in conduction band minimum at a composition of low In_2Se_3 content.

§1. INTRODUCTION

UNLIKE THE compounds In_2Te_3, Ga_2Te_3 and Ga_2Se_3 which have a defect zinc blende structure, In_2Se_3 has a more complicated structure of lower symmetry. It has however a tendency towards the defect zinc blende structure, as is shown by the relatively large range of solid solution not only in the corresponding $A_2^{III}B_3^{VI}$ compounds but also in the zinc blende type $A^{III}B^{V}$ compounds such as InAs (Woolley and Keating 1961). Thus these alloys of In_2Se_3 with $A^{III}B^{V}$ compounds can be conveniently compared with the corresponding alloys between In_2Te_3 and $A^{III}B^{V}$ compounds and similar alloys of Ga_2Se_3.

The electrical and optical properties of the alloy systems InSb–In_2Te_3 (Woolley, Gillett and Evans 1960, to be referred to as I), InAs–In_2Te_3 (Woolley, Pamplin and Evans 1961, to be referred to as II), and GaAs–Ga_2Se_3 (Nasledov and Feltin'sh 1959, Feltin'sh 1960) have recently been described. It is found in each case that the addition of a small percentage of $A_2^{III}B_3^{VI}$ to the $A^{III}B^{V}$ compound produces an alloy which is n-type with a large carrier density ($\sim 10^{18}$–10^{20} cm^{-3}). In the case of InAs–In_2Te_3, where complete solid solution occurs at all compositions, it has been shown (II) that this large carrier density is retained until some 50 mol % In_2Te_3‡ is reached, but that for larger In_2Te_3 content the carrier density falls rapidly to a value of the order 10^{12} cm^{-3} for In_2Te_3 itself. The values of electron mobility in alloys of this system show a rapid fall from the value for InAs as small amounts of In_2Te_3 are added and then a slower rate of fall to the low value associated with In_2Te_3.

---

† Now at A.E.I. (Woolwich) Limited, Harlow, Essex.

‡ In calculating mol. % in systems composed of one $A^{III}B^{V}$ compound and one $A_2^{III}B_3^{VI}$ compound, the molecules have been taken as $A_3^{III}B_3^{V}$ and $A_2^{III}B_3^{VI}$, i.e. the percentage is strictly the percentage of B^{V} and B^{VI} atoms on the B sub-lattice.

In the case of InAs–In_2Se_3 alloys the range of solid solution from 0 to approximately 80 mol % In_2Se_3 enables a comparison to be made between the results obtained with the zinc blende type alloys of this system and those of the InAs–In_2Te_3 system. The InAs–In_2Se_3 results are presented here, together with those for the InSb–In_2Se_3 alloys, where only a very limited range of solid solution of In_2Se_3 in InSb occurs (~2·5 mol % In_2Se_3).

§ 2. PREPARATION OF SPECIMENS

The details of preparation of the alloys have already been given (Woolley and Keating 1961). The alloys were made by melting together appropriate amounts of the compounds concerned. The In_2Se_3 was prepared from 99·999% purity indium and commercial high purity selenium which had been repeatedly distilled to give better purity, the InAs was of high purity having approximately 10^{16}–10^{17} carriers/cm^3, and the InSb was zone refined material with approximately 3×10^{16} carriers/cm^3. All of the ingots were annealed under vacuum in solid form, the InAs–In_2Se_3 alloys for 350 hours at 720 °c and the InSb–In_2Se_3 alloys for 1000 hours at 490 °c, previous investigations having shown that these treatments gave good equilibrium material. The mechanical condition of the ingots varied with composition. Those with small In_2Se_3 content were solid and mechanically sound, containing no blow holes etc. In the InAs alloys the condition of the ingots became worse as the In_2Se_3 content increased, particularly in the range 40 to 60 mol % In_2Se_3, but the condition in the range close to 75 mol % In_2Se_3, where some type of ordering appears to occur, was good. With care however suitable specimens for measurement could be cut from the various ingots.

§ 3. METHODS OF MEASUREMENT AND RESULTS

Room temperature values of conductivity and Hall coefficient were obtained for alloys of various compositions, the methods used for the measurements being the same as those described previously for the In_2Te_3 alloys (I and II). For these highly degenerate materials, the electrical results are found to be independent of temperature, and hence the room temperature values were taken to be characteristic of the materials. For the InAs alloys, conductivity values were obtained out to 75 mol % In_2Se_3, but owing to the low conductivity of the In_2Se_3-rich alloys, values of Hall coefficient were obtained out to 50 mol % In_2Se_3 only. Similar conductivity and Hall coefficient measurements were made over the 2·5 mol % range of solid solution in the InSb system. The variations of carrier density n (assuming that $R_H = 1/ne$), conductivity σ, and Hall mobility μ ($= \sigma R_H$) obtained from these measurements are shown in figures 1–4.

Optical measurements were also made on various alloys to determine the value of optical energy gap E_g at room temperature, and again the method was the same as described previously (I). The variation of E_g with composition in the two systems is shown in figures 5 and 6.

Measurements were made also of the thermoelectric power Q of the alloys up to the limit of solid solution in each system, using the method described previously (II). In these highly degenerate materials Q would be expected to vary linearly with T. Measurements made in the range 100–400 °K with InAs–In_2Se_3 alloys containing

0·1 mol %, 10 mol % and 75 mol % In$_2$Se$_3$ respectively confirmed that this behaviour was obtained. With the other alloys, the value of Q/T required later was obtained from room temperature measurements only. Figures 7 and 8 show the variation of room temperature thermoelectric power with composition.

It is seen from figures 1–8 that the variation of the parameters n, μ, σ, E_g and Q with composition is very similar to the results for the corresponding In$_2$Te$_3$ alloys (I and II). Again for the InSb alloys and in the range 0–60 mol % In$_2$Se$_3$ of the InAs alloys, the material is highly degenerate and the results show a considerable filling of the conduction band. Thus in particular the optical results do not give the intrinsic energy gap, but this latter may be obtained in certain cases, if the optical data are combined with the results of the thermoelectric power measurements.

§ 4. DISCUSSION

If the results for alloys of low In$_2$Se$_3$ content are considered, it is seen that these agree with what seems to be a general result that, whenever defect $A_2^{III}B_3^{VI}$ compounds are alloyed with normal zinc blende type $A^{III}B^{V}$ compounds, a large electron density of the order 10^{19}–10^{20} cm^{-3} occurs in the conduction band at very low $A_2^{III}B_3^{VI}$ percentages. It appears that some of the B^{VI} atoms are acting as donors in the B sub-lattice and that the observed high carrier density is probably due to the fact that the number of lattice vacancies occurring in the A sub-lattice is considerably less than the value to be expected from the alloy composition. As indicated in the case of the In$_2$Te$_3$ alloys (I and II), the results at very low In$_2$Te$_3$ content are the same as those obtained by doping the $A^{III}B^{V}$ compound with tellurium, and it appears probable that when large amounts of tellurium are added to the $A^{III}B^{V}$ compound, some lattice vacancies occur similar to those in the $A^{III}B^{V}$–In$_2$Te$_3$ alloys. The same results are obtained when A^{III}B^{V}–In$_2$Se$_3$ alloys are compared with selenium-doped A^{III}B^{V} compounds. It is assumed that the excess arsenic or antimony atoms are segregated to grain boundaries or lost as a vapour phase, but this has not been experimentally confirmed. Recent work by Parrott (1961)† has shown that such behaviour in these alloys is to be expected on the basis of thermodynamic arguments.

As indicated in II, the maximum observed values of n may be determined by one of two factors. One possibility is that this value of n represents the limit of solid solubility of tellurium (or selenium) in the A^{III}B^{V} compound or the composition at which further addition of In$_2$Te$_3$ (or In$_2$Se$_3$) produces a stoichiometric number of lattice vacancies. Alternatively it is possible that this observed maximum value of n is determined by the band structure of the A^{III}B^{V} compound. In this latter case, it would be postulated that solid solution of tellurium (or selenium) continues beyond the value corresponding to $n_{\max}$ but that the electrons from these resulting donor atoms enter the conduction band in a region where they have considerably larger effective mass than the electrons in the normal band minimum, and hence would contribute very little to the Hall coefficient and would effectively not be observed. The maximum values of n observed are 9×10^{18} cm^{-3} for In$_2$Te$_3$ in InSb, 9×10^{18} cm^{-3} for In$_2$Se$_3$ in InSb, 5×10^{19} cm^{-3} for In$_2$Te$_3$ in InAs and 7×10^{19} cm^{-3} for In$_2$Se$_3$ in InAs. Although it is possible that the solid solubilities of tellurium and selenium in the A^{III}B^{V} compound are practically identical for both InAs and InSb, the close agreement in the values of $n_{\max}$ for a given A^{III}B^{V} compound would tend to support the second suggested explanation. As indicated in II, there is some evidence from density measurements to support this also. If, in terms of this band structure explanation, it is assumed that the electrons of larger effective mass are in subsidiary conduction band minima, then the height of the Fermi level above the main conduction band minimum when n is maximum should give some indication of the energy separation of the main and subsidiary conduction band minima. The method of estimating Fermi energies from thermoelectric power data is discussed below.

If the assumption that the observed maximum value of n is due to the effect of a second conduction band minimum is correct, the observed values of E_g at the corresponding composition should give an indication of the height of this minimum above the valence band maximum. The values obtained are:

InSb–In$_2$Te$_3$	0·44 ev	InSb–In$_2$Se$_3$	0·43 ev
InAs–In$_2$Te$_3$	0·85 ev	InAs–In$_2$Se$_3$	1·0 ev

Recent work by Cardona (1961, private communication) indicates that the energy spacing between the valence band maximum and ⟨111⟩ minima is about 0·5 ev for InSb and 0·8 ev for InAs. This gives very good agreement with the present results, the discrepancy in the InAs–In$_2$Se$_3$ value possibly being due to the effects discussed below.

For degenerate material the thermoelectric power Q is related to the absolute temperature T and the height of the Fermi level above the conduction band minimum, ζ, by the equation (Ehrenberg 1958)

$$Q = -\frac{k}{e}\frac{\pi^2}{2}\frac{kT}{\zeta}\left[1+\frac{2}{3}\left(\frac{E}{\tau}\frac{d\tau}{dE}\right)_{E=\zeta}\right]$$

and if it is assumed that

$$\tau \propto E^s$$

---

† Reported at the Institute of Physics and Physical Society Conference on Thermoelectricity, Durham, July 1961.

then

$$Q = -\left(\frac{3+2s}{6}\right)\frac{\pi^2k^2T}{e\zeta}. \tag{1}$$

The determination of ζ from Q thus requires a knowledge of s, which depends upon the particular scattering mechanism concerned. The two scattering mechanisms expected to predominate in these materials are ionized impurity scattering at low In_2Se_3 content and alloy scattering at higher In_2Se_3 content. The Brooks–Herring (Brooks 1955) and Conwell–Weisskopf (1950) analyses of ionized impurity scattering give $s = \frac{3}{2}$ while Sclar (1956) obtains $s = \frac{3}{2}$, $\frac{1}{2}$ or $-\frac{1}{2}$ under various conditions of concentration etc. For experimental determination of s, with pure semiconductors it is possible to write $E = kT$ and hence mobility–temperature measurements give s. But this method is not valid in the degenerate case. One method of determining s in this latter case is by comparison of thermoelectric and optical data using equation (1). This method has been used by Barrie and Edmond (1955) for InSb heavily doped with tellurium but large discrepancies were found between experiment and theory. Since, however, these discrepancies may well be due to the theoretical analysis, it was decided to attempt to use here the comparison of thermoelectric and optical data to find a satisfactory value of s.

A relation between Fermi level ζ and observed optical absorption edge E_g of the form

$$\zeta = E_g + 4kT - E_{g_0}, \tag{2}$$

where E_{g_0} is the intrinsic energy gap, has been assumed as in previous work (Barrie and Edmond 1955, Burstein 1954). The relation will not be accurate, as the $4kT$ term may differ from this value depending on the transition conditions, while the definition of E_g is somewhat arbitrary in the case of polycrystalline materials of unknown reflectivity (Woolley and Evans 1961). In the interpretation of the present optical results for the InSb alloys E_g was taken as the value corresponding to a change in absorption coefficient of 300 cm^{-1} above background, while for the InAs alloys a change of 100 cm^{-1} was used, these values being those required to give the accepted value for E_g in the corresponding pure $A^{III}B^{V}$ compounds. Even under these conditions it is considered that the inaccuracy in E_{g_0} should be well below 0·1 ev and therefore is sufficient here.

Using the above method for correlating the optical and thermoelectric data, values of E_{g_0} have been calculated for both InSb and InAs alloys containing up to 2 mol. % In_2Se_3 using the various values of s suggested for ionized impurity scattering. It has been assumed that over this range of composition little change in the intrinsic energy gap should occur, and hence the values of E_{g_0} should be close to that for the appropriate $A^{III}B^{V}$ compound. It is possible that this assumption is invalid in that the presence of an impurity band may greatly affect E_{g_0} or, as indicated by Aigrain (1961), the presence of a high density of donor atoms in the lattice may reduce E_{g_0}. Nevertheless the above assumption has been used to determine the best value of s over this composition range. It is found that for alloys with 10^{19}–10^{20} carriers/cm^3, the use of $s = \frac{3}{2}$ gives values of E_{g_0} very different from the value of the corresponding $A^{III}B^{V}$ compound, in some cases giving $E_{g_0} \simeq 0$, while the use of $s = -\frac{1}{2}$ gives results which are little better. Good agreement between alloys and compound is obtained however if s is taken as $+\frac{1}{2}$. It appears that within the limits of the assumptions made above $s = +\frac{1}{2}$ is the appropriate value to use for ionized impurity scattering in these alloys. The same result was obtained with the InAs–In_2Te_3 alloys (II). It is perhaps worthy of note that the Sclar resonance method gives $s = +\frac{1}{2}$ and that Domenicali (1960) has treated metal alloys at low temperatures by resonance methods.

For alloys of higher In_2Se_3 content, alloy scattering is assumed to apply. In this case a value of $s = -\frac{1}{2}$ is appropriate (Nordheim 1931, Brooks 1955) but the above method for checking is not available in this case since no values of E_{g_0} are known. However in the case of InAs–In_2Te_3 the use of $s = -\frac{1}{2}$ for the alloys of higher In_2Te_3 content were found to give consistent results out to the composition where the alloys were non-degenerate and the optical results gave a value of E_{g_0} directly.

For alloys of both the systems InAs–In_2Se_3 and InSb–In_2Se_3 values of ζ have been calculated, using $s = +\frac{1}{2}$ at lower In_2Se_3 content and, in the InAs alloys, $s = -\frac{1}{2}$ for higher In_2Se_3 content. These results are shown in figures 6 and 9. In the InSb alloys ionized impurity scattering is dominant throughout the limited range of solid solution, but in the InAs alloys it is apparent that between approximately 2 and 10 mol % In_2Se_3 neither scattering mechanism is dominant, and in this range an interpolated value of ζ is indicated. These values have then been used, together with the optical data, to give values of E_{g_0} from equation (2) and the resulting values of E_{g_0} are shown as a function of composition in figures 5 and 6.

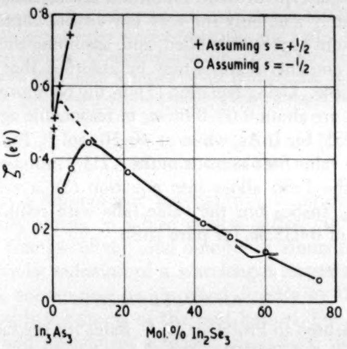

Figure 9. Variation of Fermi level ζ with composition for InAs–In_2Se_3 alloys.

The form of the E_{g_0}–composition curves are very different for the two In_2Se_3 systems concerned. With the InSb alloys, the value of E_{g_0} stays approximately constant at 0·17 ev to 1 mol % In_2Se_3 and then increases slowly to the limit of solid solution ($\sim$2·5 mol %). In the case of the InAs alloys however E_{g_0} rises rapidly from 0·33 ev at InAs to 0·60 ev at 4 mol % In_2Se_3 and then increases slowly up to 0·92 ev at 75 mol % In_2Se_3, the alloy of largest In_2Se_3 content for which measurements were made. The form of this curve is very similar to that for the Ge–Si system, where a change in slope in the E_{g_0}–composition curve occurs when the lowest conduction band minima change from the $\langle 100 \rangle$ minima characteristic of silicon to the $\langle 111 \rangle$ minima characteristic of germanium. This suggests that possibly a similar band change occurs in the InAs–In_2Se_3 alloys, where the discontinuity in the E_{g_0} curve at 4 mol. % In_2Se_3 would represent a change in lowest conduction band minimum from the 000 minimum characteristic of InAs to some other set of minima, possibly the $\langle 111 \rangle$ as in germanium. Extrapolation of the curve from compositions above 5 mol % In_2Se_3 would give a value of E_{g_0} for these minima in InAs itself of approximately 0·60 ev, a value rather lower than that quoted above. However, this suggestion that the second conduction band minimum in the InAs–In_2Se_3 alloys may fall below the 000 minimum is not inconsistent with the explanation put forward above for the maximum value of n observed with these alloys. Thus even when the 000 minimum is at a slightly higher energy than the other set of minima, provided the electrons in the 000 minimum have a much smaller effective mass, these would be the carriers observed by Hall effect measurements. The discrepancy in the values of E_{g_0} mentioned above could indicate that both sets of conduction band minima were filled to a considerable extent when maximum n occurs.

The density of states effective mass m_n is given by the relation

$$n = \frac{8\pi}{3}\left(\frac{2m_n}{h^3}\right)^{3/2}\zeta^{3/2}$$

where m_n is related to the effective mass tensor components by the equation

$$m_n = N^{2/3}(m_{ii}m_{jj}m_{kk})^{1/3},$$

N being the number of equivalent minima. This equation, however, only has meaning when electrons in a single type of band minimum are considered. Thus for the InAs alloys this is approximately true only for very low In_2Se_3 content where the 000 min mum is the only minimum appreciably filled, and, assuming the band change postulat above, at large In_2Se_3 content where it may be assumed that the contribution of t 000 minimum is negligible. Using equation (3), in the composition range 0 to 1 mol. In_2Se_3 the values of m_n are about 0·05–0·06 m_0 in reasonable agreement with the resu of Stern and Talley (1955) for InAs, while at 40–50 mol % In_2Se_3 $m_n \simeq 0{\cdot}30\ m_0$ whic is rather lower than the value for electrons in the $\langle 111 \rangle$ minima of germanium. Substituting the values for the InSb alloys into equation (3), a value of $m_n \simeq 0{\cdot}06\ m_0$ is obtained at 1·5 mol % In_2Se_3 but the value falls with reduced In_2Se_3 content and extrapolates to a value of 0·035 m_0 for pure InSb.

Growth and Decay of Luminescence Intensity under Cathode Ray Excitation

By M. SAYER

Department of Physics, University of British Columbia, Vancouver, B.C., Canada

MS. received 9th June 1961

Abstract. Expressions for the growth and decay of cathodoluminescence intensity are derived for phosphors which show exponential decay schemes under ultra-violet excitation. A model is used in which excitation of luminescence centres can take place either by direct interaction with primary electrons or indirectly by transfer of energy from excited lattice electrons. Two systems are considered: (i) with monomolecular recombination in the lattice and monomolecular recombination in the centres, (ii) with bimolecular recombination in the lattice and monomolecular recombination in the centres. Comparison between the theory and published experimental data indicates that such a model with bimolecular recombination in the lattice is compatible with many of the available experimental results.

§ 1. INTRODUCTION

RADIATION IS emitted by a luminescent material from luminescence centres situated at specific sites, or impurity atoms, in a host crystal lattice. In general, the number of such centres is a small fraction of the total number of atoms present. If the crystal is illuminated with ultra-violet radiation of a wavelength longer than that corresponding to the absorption edge, energy may be absorbed directly by the luminescence centres with little interaction with the atoms of the host lattice. For many materials such as zinc oxide, tungstates and manganese activated phosphors, this gives rise to a centre recombination process described by monomolecular kinetics, with exponential growth and decay processes of a time constant characteristic of the material.

Cathodoluminescence is again produced by the decay of excited centres, but for a particular phosphor, both the emission spectrum and the growth and decay processes may be altered significantly from those observed under ultra-violet excitation. Simultaneous changes in both emission spectrum and growth and decay processes may be explained in terms of the preferential excitation of different luminescence centres contained in the same material (Froelich 1953). However, a number of phosphors have been reported (Einstein 1957, Feinberg 1959, Arkangel'skaya and Tolstoy 1958) which show a considerable change in the growth and decay processes with no significant change in the emission spectrum. This applies both for a change from optical to electron excitation and for an increase in electron excitation. In the latter case, the primary electrons interact impartially with both lattice atoms and luminescence centres, producing ionization and excitation in both the lattice and the centres. The energy of the excited lattice atoms may be dissipated either by phonon generation, or by transfer to luminescence centres. If the latter process occurs, part of the total emission must be determined by the interaction between the host lattice and the luminescence centres. Thus a phosphor with a monomolecular type of growth or decay process under ultra-violet excitation may be expected to show a more complicated behaviour under cathode ray excitation. The characteristics to be expected from such a system are the subject of this paper.

2.1. *Theory*

The situation may be described in terms of a model originally proposed by Bril (1949). Figure 1 shows the transitions possible between energy levels of both the lattice and the centres. Suppose that there are N luminescence centres per cm^3 and a beam of electrons J A cm^{-2} is incident on the surface such that an electron density of I electrons per cm^3 is produced over the excited region.

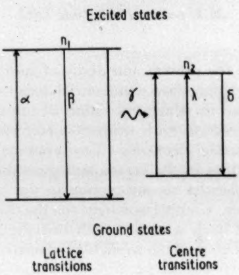

Figure 1. Model for the cathodoluminescence process.

A set of transition probabilities may be defined, viz. α the number of excited lattice atoms per incident primary electron, β the probability that the energy of an excited lattice electron is lost by phonon generation, γ the probability for energy to be transferred from a lattice electron to a centre, λ the number of luminescence centres excited directly by a primary electron and δ the probability for a radiative transition within the centre. To simplify the analysis, the probability for a non-radiative centre transition is assumed to be zero.

It will be assumed that all parameters are uniform over the excited region. This is a reasonable assumption for β, γ, N and δ, but it is less satisfactory for α, λ and I. The electron density I electrons per cm^3 at a distance d cm below the surface is given by an expression $I = (J/R)f(d/R)$ where J(A cm^{-2}) is the primary electron current at the surface, R is the range of electrons in the crystal, and $f(d/R)$ is a function describing the distribution of electrons with depth. Both this expression and those for the excitation probabilities α and λ are complex functions of electron energy, so that an exact calculation of the product αI presents severe difficulties. Errors may therefore be introduced from this source and the analysis can yield no accurate information regarding the luminescence characteristics as a function of electron energy. For changes in current density at constant primary electron energy, it will be assumed that I is proportional to J.

The recombination process in the centres is assumed to remain monomolecular and a lattice recombination of either monomolecular or bimolecular kinetics will be considered.

2.2. *Monomolecular Lattice—Monomolecular Centre*

Suppose that at a given time t there are n_1 excited lattice electrons and n_2 excited luminescence centres. To simplify the analysis, $n \ll N$ under all conditions.

2.2.1. *Rate equations.*

$$\frac{dn_1}{dt} = \alpha I - (\beta+\gamma N)n_1 \tag{1}$$

$$\frac{dn_2}{dt} = \lambda I + \gamma N n_1 - \delta n_2. \tag{2}$$

Solving equation (2) for n_1 and substituting

$$\frac{d^2n_2}{dt^2} + (\delta+\beta+\gamma N)\frac{dn_2}{dt} + \delta(\beta+\gamma N)n_2 = (\alpha I\gamma N + k\lambda I). \tag{3}$$

Writing

$$(\beta+\gamma N) = k \qquad \alpha I\gamma N = Z$$

equation (3) has a solution of the form

$$n_2 = \frac{(Z+k\lambda I)}{\delta k} + A\exp(-kt) + B\exp(-\delta t)$$

where A and B are constants.

2.2.2. *Growth process.*

Inserting boundary conditions and simplifying,

$$t = 0 \qquad n_1 = n_2 = 0$$

$$n_2 = \frac{Z}{\delta k}\left[\left\{1+\frac{\lambda k}{\alpha N\gamma}\right\} + \frac{\delta}{(k-\delta)}\exp(-kt) - \left\{\frac{k}{(k-\delta)} + \frac{\lambda k}{\alpha N\gamma}\right\}\exp(-\delta t)\right] \tag{4}$$

2.2.3. *Decay process.*

$$t = 0 \qquad n_2 = \frac{Z+k\lambda I}{\delta k}$$

$$n_2 = \frac{Z+k\lambda I}{\delta k}\left[\frac{k}{k-\delta}\exp(-\delta t) - \frac{\delta}{k-\delta}\exp(-kt)\right]. \tag{5}$$

The characteristics of the growth and decay processes described by the above equations may be summarized as follows:

(i) The overall process is a combination of two exponential components with time constants δ and $\beta+\gamma N$ sec^{-1} respectively.

(ii) For no direct excitation, the proportion of each component is inversely proportional to the time constant. If direct excitation is included, the proportion of the δ process is increased, and the time constant of the growth process is greater than that of the decay process.

(iii) Increase in current density introduces no changes in either the proportions or the time constants of either process.

2.3. *Bimolecular Lattice—Monomolecular Centres*

2.3.1. *Rate equations.*

$$\frac{dn_1}{dt} = \alpha I - (\beta+\gamma N)n_1^2 \tag{6}$$

$$\frac{dn_2}{dt} = \lambda I + \gamma N n_1^2 - \delta n_2. \tag{7}$$

2.3.2. *Growth process.*

Solving equation (6) for n_1

$$n_1 = n_0 \tanh n_0 kt$$

where

$$n_0 = \left(\frac{\alpha I}{k}\right)^{1/2} \qquad k = (\beta + \gamma N).$$

Substituting in equation (7)

$$\frac{dn_2}{dt} + \delta n_2 = \lambda I + \frac{\gamma N \alpha I}{k} \tanh^2 (\alpha I k)^{1/2}\, t. \tag{8}$$

Writing

$$(\alpha I k)^{1/2} = b \qquad \gamma N \alpha I = Z$$

the solution of equation (8) may be reduced to the form

$$n_2 = \frac{\lambda I}{\delta}[1 - \exp(-\delta t)] + \frac{Z}{k} \exp(-\delta t) \int_0^t \exp(\delta t) \tanh^2 bt\, dt. \tag{9}$$

The maximum value of n_2 is given when

$$\delta t = bt = \infty; \qquad \tanh^2 bt \to 1$$

i.e.

$$n_2 = \frac{Z + k\lambda I}{\delta k}.$$

2.3.3. *Decay process.*

Let $I = 0$ in the rate equations and solve (6) for n_1

$$n_1 = \frac{n_0}{1 + n_0 kt}.$$

Substituting into equation (7)

$$\frac{dn_2}{dt} + \delta n_2 = \frac{\gamma N \alpha I}{k}\left[\frac{1}{1 + (\alpha I k)^{1/2}\, t}\right]. \tag{10}$$

Solving for n_2 and introducing the boundary conditions

$$t = 0 \qquad n_2 = \frac{Z + k\lambda I}{\delta k}$$

$$n_2 = \frac{Z}{\delta k}\left[-\frac{\delta}{b(1+bt)} + \exp(-\delta t)\left\{\frac{\lambda k}{\gamma N \alpha} + 1 + \frac{\delta}{b} + \frac{\delta^2}{b} \int_0^t \frac{\exp(\delta t)}{1 + bt}\, dt\right\}\right]. \tag{11}$$

The integrals which occur in equations (9) and (11) have no analytical solution and were computed graphically. The solutions for the growth and decay processes are plotted in figures 2 and 3 respectively, calculated for a fixed value of δ and different values of b and assuming no direct excitation of luminescence centres ($\lambda = 0$).

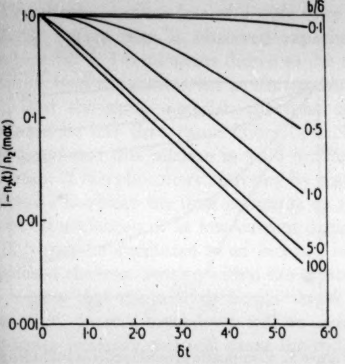

Figure. 2. Luminescence growth process for different values of parameter b/δ. Plotted as $1-n_2(t)/n_2(\max)$. No direct excitation of luminescence centres ($\lambda = 0$).

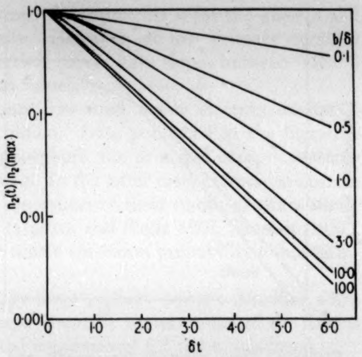

Figure 3. Luminescence decay process for different values of parameter b/δ. No direct excitation of luminescence centres ($\lambda = 0$).

2.4. *Summary*

The forms of both processes are determined by the relative magnitude of the parameters δ and b. If $b/\delta \gg 1$, both growth and decay are exponential with a time constant which approaches an upper limit δ as $b/\delta \to \infty$. If $b/\delta \lesssim 1$, the processes are non-exponential, the departure from the exponential form being greatest over the initial part of the curve and being greater for smaller values of b. This is most marked for the growth process and further examination of equation (8) indicates that the beginning of the curve over a small interval of time is proportional to the time squared. At larger times, both processes approximate well to an exponential form with a time constant less than $\delta\ \mathrm{sec}^{-1}$. The time constant most often measured experimentally ($1/\tau$, where τ is the time to attain $1/e$ of the maximum value) is shown as a function of b in figure 4. This indicates that the relation between the time constant and the current density is complex, although in the region where $b/\delta \lesssim 1$, the time constants for both processes are proportional to $\log b$ and hence $\log I$. The decay constant is seen to be greater than the growth constant over the same range.

The direct excitation of luminescence centres introduces an extra term

$$(\lambda k/\gamma N\alpha)\exp(-\delta t)$$

into equations (9) and (11). The importance of the additional term is again determined by the magnitude of b/δ. If $b/\delta > 1$, the term is effective over the entire growth and decay, which results in an approximately exponential process of time constant increased above that calculated for the lattice process above. If $b/\delta < 1$, the term is of most importance over the initial part of the growth and decay and if of sufficient magnitude, may replace the initial square law section predicted for the growth process by an exponential process of time constant approaching that of $\delta\ \mathrm{sec}^{-1}$. This is shown in figure 5. Note that an increase of electron density I increases the time constant of the lattice process. This may be interpreted experimentally as an increase in the proportion of the process due to direct centre excitation.

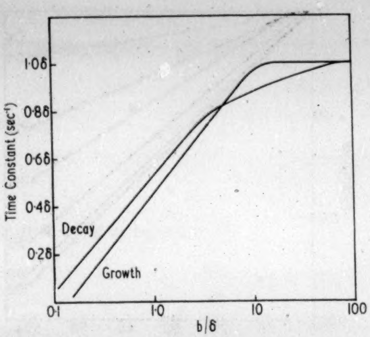

Figure 4. Time constant for growth and decay processes plotted against the parameter b/δ. Time constant measured as $1/\tau$, where τ is time to attain $1/e$ of maximum value. No direct excitation of centres ($\lambda = 0$).

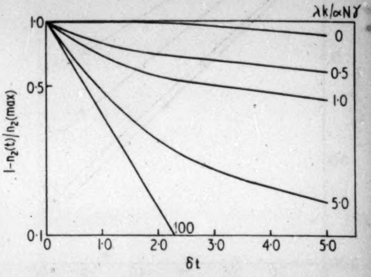

Figure 5. Composite growth process including excitation via the lattice and direct centre excitation. Curves plotted for $b/\delta = 0{\cdot}1$ and different values of $\lambda k/\alpha N\gamma$.

§ 3. DISCUSSION

Much of the experimental data reported in the literature may be explained in terms of this analysis. Many authors have shown that the growth and decay processes are non-exponential under electron excitation (Arkangel'skaya and Tolstoy 1958). Strange and Henderson (1946) have described the decay schemes of a range of materials in terms of two exponential processes—the A and B processes. On the present analysis, the A process is a result of the direct excitation of luminescence centres by primary electrons, the B process is due to indirect excitation via the lattice. The arbitrary classification of phosphors into two classes used by these authors is explicable if it is assumed that under the conditions of measurement:

Manganese class. (δ 10–10^3 sec^{-1}); $b/\delta \gg 1$, i.e. the overall time constants are fixed at the upper limit δ sec^{-1} and the B process alone is apparent.

Silver class. (δ 10^4–10^6 sec^{-1}); $b/\delta \lesssim 1$, i.e. the value of b/δ is small so that two components are observed. This suggests that the value of $\beta+\gamma N$ is about 10^5 sec^{-1} for most phosphors. The relative proportion of the A process was reported to increase with increased current density. It has been shown in a previous section that such an observation may be due to a change in the effective time constant of the lattice process.

Theoretically the characteristics of both growth and decay processes are determined by the parameter $(\alpha Ik)^{1/2}$. The overall lattice transition probability $k = \beta+\gamma N$ appears both in the above expression and in that for the maximum luminescence intensity $Z/\delta k$. Pfanhl (1961) has reported experimental data for zinc oxide phosphors which show that an increase in time constants is accompanied by a decrease in luminescence efficiency. Feinberg (1959) and Einstein (1957) have shown that the decay constant is less than the growth constant at low current densities in agreement with theory. Einstein has measured the time constants as a function of current density and has obtained a relation of the form $1/\tau = Ci^n$ where C is a constant and n is $0{\cdot}4$ for the growth process and $0{\cdot}3$ for the decay process. An attempt was made to fit these results to theoretical curves but it was not possible to obtain agreement over the entire range of observations.

The theory predicts less of a difference between the exponents n for the growth and decay curves than is observed experimentally. However, at low primary currents where $b/\delta < 1{\cdot}0$, tangents drawn to the theoretical curves have slopes between 0·2–0·3 which is of the same order as the experimental values.

For the same material, the time constants measured under electron excitation should be less than those under optical excitation. Data published in the literature indicate that this relation is valid for many phosphors, the principal exceptions being certain of the phosphors activated by manganese. In the latter case, increase in current density increases the time constants to values in excess of those obtained either under optical excitation or at low current densities (Garlick and Sayer 1961, Einstein 1957). This may be attributed to an increase in the centre transition probability δ due to increased electron density within the crystal.

Note that the analysis breaks down at very large primary current densities when $n_2 \simeq N$. Such a breakdown will be shown experimentally by saturation of the luminescence intensity and will cause the differential equations of § 2 to be non-linear.

§ 4. CONCLUSION

It has been shown that a relatively satisfactory model of the cathodoluminescence process may be set up if the mutual interaction and the recombination kinetics of both the host lattice and the luminescence centres are considered. A satisfactory description of the growth and decay processes as a function of current density is obtained, but a more complex treatment is required for a discussion of the voltage dependence.

Intensity Measurements in Emission on 29 Bands of the O_2 Schumann–Runge System

BY G. R. HÉBERT† AND R. W. NICHOLLS

Department of Physics, University of Western Ontario

MS. received 3rd July 1961

Abstract. Relative integrated photoelectric intensity measurements have been made upon each of the $v' = 0$, $v'' = 9$–19; $v' = 1$, $v'' = 8$–12; 16–20; $v' = 2$, $v'' = 7$–9, 15, 16, 19–21, bands of the Schumann–Runge System. These measurements have been interpreted, with the aid of Franck–Condon factors $q_{v'v''}$ and r-centroids $\bar{r}_{v'v''}$, to determine the variation of electronic transition moment $R_e(r)$ with internuclear separation r as

$$R_e(r) = \text{const.}\,(1 - 1{\cdot}1807r + 0{\cdot}35047r^2); \qquad 1{\cdot}44(\text{Å}) < r < 1{\cdot}76(\text{Å}).$$

A 'smoothed' array of relative vibrational transition probabilities

$$p_{v'v''} = R_e^2(\bar{r}_{v'v''})q_{v'v''}$$

and band oscillator strengths $f_{v'v''}$ have thereby been determined for all bands of the system between 2450 and 5000 Å.

§ 1. INTRODUCTION

THE SCHUMANN–RUNGE band system ($B^3\Sigma_u^- - X^3\Sigma_g^-$) of O_2 and its associated photodissociation continuum play an important part in the absorption spectrum of the atmosphere (Goldberg 1954) also in the emission spectrum arising from missile re-entry (Meyerott 1958) and possibly in the spectrum of high altitude nuclear explosions (Griggs and Press 1961) observed over long atmospheric path lengths. It has therefore been thought worth while to make photoelectric intensity measurements in emission on as many bands as are easily accessible in order to obtain an array of relative vibrational transition probabilities for the system.

Owing to the large change $\Delta r_e(\simeq 0{\cdot}4\,\text{Å})$ in equilibrium internuclear separation, the band system is very extensive. The bands lie between 1700 Å and 4500 Å and the photodissociation continuum lies between 1300 and 1750 Å. The bands are wide and severely overlapped. Their locations and structure are well known. (Lochte-Holtgreven and Dieke 1929, Curry and Herzberg 1934, Knauss and Ballard 1935, Feast 1948, 1949, 1950, Brix and Herzberg 1954, Hébert and Nicholls 1961).

Many of the studies upon the system have involved absorption through cold oxygen, although some work on absorption through hot oxygen (Garton and Feast 1950, Treanor and Wurster 1960) has been done, and studies have also been made on the emission spectrum of O_2 in high voltage high pressure arcs (Feast 1948, 1949, 1950).

Nearly all of the previous work on intensity measurements of the system has been concerned with intensity measurements upon the $v'' = 0$ progression in absorption. Ladenberg and Van Voorhis (1933) measured integrated absorption coefficients of the continuum between 1300 and 1750 Å using photographic photometry. Watanabe, Inn and Zelikoff (1953) made photoelectric measurements on absorption from 1050 to 1900 Å in oxygen. They specifically measured partial oscillator strengths of bands between 1750 and 1910 Å and the continuum between 1750 and 1300 Å. Ditchburn and Heddle (1953, 1954) made photographic intensity measurements upon the continuum and also upon the bands of the $v'' = 0$ progression assigning oscillator strengths to each. Bethke (1959) made an accurate photoelectric intensity measurement in absorption of bands lying between 1750 and 2000 Å with pressure broadening. He inferred oscillator strengths for each band and an effective oscillator strength for the whole system. Treanor and Wurster (1960) using flash absorption through shock heated oxygen and photoelectric photometry made oscillator strength measurements upon the bands $v' = 0$, $v'' = 10$–17; $v' = 1$, $v'' = 9$–12, 16–18; $v' = 2$, $v'' = 9$, 15, 16, and assigned an oscillator strength to the whole system.

---

† Now in Department of Physics, St. Francis Xavier University, Antigonish, Nova Scotia.

Very little work has been done on emission intensity measurements. Keck, Camm, Kivel and Wentink (1959) made photoelectric measurements by a number of repetitive experiments on shock excited air in emission over the wavelength range 3300 to 4700 Å. In view of the strong CN impurity features in their spectra the quantitative aspects of their results must be left in some doubt. They interpreted their measurements using Franck–Condon factors calculated upon the basis of a very crude approximation.

In the present work, photoelectric intensity measurements have been made in emission upon the bands $v' = 0$, $v'' = 9$–19; $v' = 1$, $v'' = 8$–12,16–20; $v' = 2$, $v'' = 7$–9, 15, 16, 19–21.

The bands studied lie between 2400 and 4500 Å. They are degraded towards the red and exhibit extensive overlapping due to the high gas temperature in the high voltage arc through oxygen at atmospheric pressure in which the system was excited. The triplet splitting of the lines was not resolved at the dispersions used, and the bands appeared to have a ${}^1\Sigma$–${}^1\Sigma$ structure.

The heavy overlap between adjacent bands precluded the use of simple intensity measurement techniques such as the fractional band intensity method or the method of 'separation of contour'. Thus the 'rotational line intensity intercept method' (Robinson and Nicholls 1961) which is described more fully below was used.

§ 2. THEORY

It is well known that the intensity $I_{v'v''}$ of a band may be represented by

$$I_{v'v''} = DN_{v'}E^4_{v'v''}R_e^2(\bar{r}_{v'v''})q_{v'v''} \tag{1}$$

where D is a constant associated with the units and the geometry, $N_{v'}$ is the population of the v' level, $E_{v'v''}$ is the energy quantum of the band, $R_e(r)$ is the electronic transition moment of the system (Fraser 1954), $q_{v'v''}$ is the Franck–Condon factor and $\bar{r}_{v'v''}$ is the r-centroid.

Provided that computed arrays of $\bar{r}_{v'v''}$ and $q_{v'v''}$ and measured values of $I_{v'v''}$ are available this equation may be used:

(i) To infer the variation of electronic transition moment with internuclear separation from plots of $(I_{v'v''}/q_{v'v''}E^4_{v'v''})^{1/2}$ against $\bar{r}_{v'v''}$ for each v'' progression, with appropriate rescaling to account for the variation of the $N_{v'}$ term.

(ii) To obtain a smoothed array of relative vibrational transition probabilities

$$p_{v'v''} = R_e^2(\bar{r}_{v'v''})q_{v'v''} \tag{2}$$

for the whole band system.

(iii) In some cases to obtain the variation of $N_{v'}$ with v' from the rescaling factors of (i).

This method has been previously applied to a number of band systems, most of which have exhibited unoverlapped bands so that measurements of $I_{v'v''}$ were not, in principle, difficult to make (see for example Nicholls 1956, 1958, Dixon and Nicholls 1958, Robinson and Nicholls 1958a, b). Bands of the O_2 Schumann–Runge system however, overlap strongly and thus recourse has been made in this work to the rotational line intensity intercept method to measure $I_{v'v''}$. The basis of the method is as follows.

The intensity ($I_{K'K''}$) in emission of an individual rotational line of a band is, assuming thermal equilibrium,

$$I_{K'K''} = \text{const}\frac{N_{v'}}{Q}\nu^4_{K'K''}S_{K'K''}R_e^2(\bar{r}_{v'v''})q_{v'v''}\exp\left(\frac{-E_{\text{rot}}}{kT_{\text{rot}}}\right) \tag{3}$$

where the constant depends upon the geometry and the units employed, Q is the rotational partition function of v', $\nu_{K'K''}$ is the wave number of the line, E_{rot} is the rotational energy term of the v', k is Boltzmann's constant and T_{rot} is the rotational temperature. Dividing equations (1) and (3),

$$\frac{I_{K'K''}}{I_{v'v''}} = \frac{S_{K'K''}}{Q}\exp\left(\frac{-E_{\text{rot}}}{kT}\right) \tag{4}$$

if the justifiable approximation $E_{K'K''} = E_{v'v''}$ be made (Fraser 1958). Thus if thermal equilibrium is maintained in the source, a plot of $\ln I_{K'K''}/S_{K'K''}$ against E_{rot} is linear, of slope $-1/kT$ and has a relative intercept on the ordinate axis of $\ln I_{v'v''}/Q$. If such a plot is made for each band of the system (using sufficient line intensity measurements to establish the plot for each band), relative integrated intensities $I_{v'v''}$ may be determined from relative differences on the ordinate scale.

For some band systems it is sufficient to use $B_vK(K+1)$ for E_{rot} in the above plots. For the Schumann–Runge system the more complete expression

$$B_vK(K+1)-D_vK^2(K+1)^2$$

was necessary.

The method has previously been used by Robinson and Nicholls (1958a, b, 1960) for the NO β and BO α, β systems and by Treanor and Wurster (1960) in absorption measurements on Schumann–Runge bands.

§ 3. EXPERIMENTAL PROCEDURES

3.1. *Excitation*

The band system was excited in a 900–1000 volt a.c. arc between 3/16 in. Pt–Rh electrodes in flowing oxygen at a pressure of a few millimetres above atmospheric in a 1 litre round-bottom flask. Tungsten rods were mounted in ball and socket joints attached at diametrical points to the flask and Pt–Rh tips were attached to the ends of the rods by barrel connectors. The current in the circuit was controlled by a Variac and limited to 400 mA by a 5000 ohm ballast resistance. At this current the electrode tips became white hot and emitted electrons thermionically. The spectrum was comparable in intensity to that of an iron arc at 2500 °K. The source was similar to that used by Feast (1950).

3.2. *Identifications*

A complete photographic survey was made of the spectrum of the source prior to making photoelectric intensity measurements on it. A Baird–Atomic 3 metre Eagle mounting grating spectrograph was employed and the spectrum of interest between 2480 and 4500 Å photographed in the second and third orders of a 15 000 lines in^{-1} concave grating at a reciprocal dispersion of about 2·7 and 1·7 Å mm^{-1}. They were photographed in three sections: λ2480–3000 Å, including the 0–10, 11; 1–9, 10, 11, 12: 2–7, 8, 9 bands, λ3000–3700 Å, including the 0–12, 13, 14, 15, 16; 1–11, 12, 16, 17; 2–15, 16 bands and λ3700–4500 Å including the 0–14, 15, 16, 17, 18, 19; 1–16, 17, 18, 19, 20; 2–20, 21 bands.

Identifications of individual lines were made from large scale prints of spectrograms with the aid of the analyses of Lochte-Holtgreven and Dieke (1929) and of Feast (1950). One previously unanalysed band, the (0, 9) at λ2763·4 Å has been analysed (Hébert and Nicholls 1961).

3.3. *Intensity Measurements*

After development of a stable source, and a complete identification of all of its spectral features, a calibrated Leeds and Northrup scanning spectrometer (Fastie 1952) was employed to measure relative intensities of lines in each of the bands mentioned in the previous section. The 1P28 photomultiplier of the instrument was sensitive over the wavelength range 2100 to 7000 Å. The instrument had a 10 μ entrance slit and a 20 μ exit slit.

The response of the instrument was calibrated with respect to a Philips tungsten strip filament lamp. Spectral emissivity $E_{\lambda,T}$ data of Larrabee (1959) and of de Vos (1954) were used respectively in the wavelength ranges 3500–4500 Å and 2400–3500 Å. The black body distribution tables of Lowan and Blanch (1940) were also used to rectify the response $R_{K'K''}$ (as read from the trace of the spectrometer record) into line intensity $I_{K'K''}$ through the equation

$$I_{K'K''} = R_{K'K''}E_{\lambda T}I_{\mathfrak{b}\lambda}/R_{w\lambda} \tag{5}$$

where $R_{w\lambda}$ is the response to the emission from the standard lamp at the line wavelength λ.

§ 4. RESULTS

4.1. *Line Intensities*

The spectral line profiles were planimetered for as many lines per band as were effectively non-overlapped. On the average, twenty to thirty lines per band were accessible. For each line, the resulting area under its profile was multiplied by the $E_{\lambda T}I_{\mathfrak{b}\lambda}/R_{w\lambda}$ from equation (5) to give the line intensity $I_{K'K''}$.

4.2. *Band Intensities*

Semi-logarithmic plots of $\ln I_{K'K''}/S_{K'K''}$ against $B_{v'}K'(K'+1)-D_{v'}K'^2(K'+1)^2$ were made for each of the 29 bands mentioned in § 1. The $B_{v'}$ and $D_{v'}$ values adopted were those of Curry and Herzberg (1934) and of Feast (1950). That is $B_0' = 0{\cdot}813$ cm^{-1}, $B_1' = 0{\cdot}798$ cm^{-1}, $B_2' = 0{\cdot}7845$ cm^{-1}, $D_{v'} = 4{\cdot}38\times10^{-6}$ cm^{-1} for $v' = 0, 1, 2$. $S_{K'} = K$ for the P branch and $K+1$ for the R branch. An example of the disposition of points on such a plot is shown on figure 1 for (1, 10). It has a clear linear trend. Straight lines could be fitted to the plots for all bands except (1, 16), (2, 16) and (2, 19) for each of which rather few isolated spectral lines could be measured. A best 'least squares' straight line was fitted to each of the other 26 bands using an I.B.M. 650 computer programme at the University of Western Ontario, Computation Centre. The slopes were almost identical, consistent with a rotational temperature of 2150 °K existing in the arc. This is some confirmation of the adequacy of the procedure.

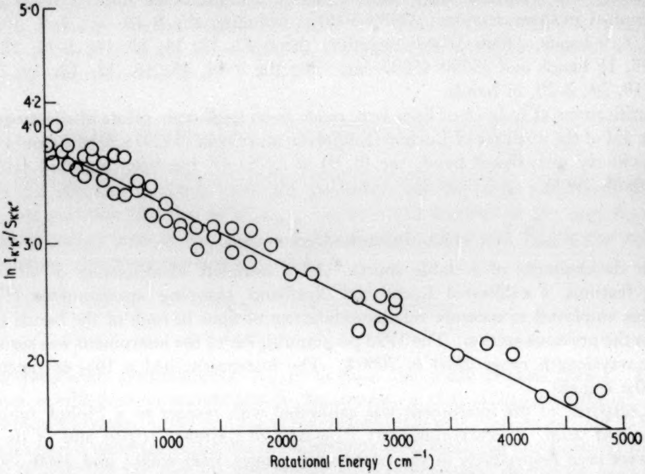

Figure 1. ln $I_{K'K''}/S_{K'K''}$ against $B_{v'}'K'(K'+1)-D_{v'}'K'^2(K'+1)^2$ for the (1, 10) band.

In the case of the (1, 16), (2, 16) and (2, 19) bands, severe line overlap prevented measurement of sufficient line intensities to yield enough points for a linear semi-logarithmic plot. The following procedure was therefore adopted. The centroid of the plotted points was calculated in each case and a straight line of the same slope as that determined for the other 26 bands, was placed through it.

The intercepts on the ordinate axis of each of the 29 linear semi-logarithmic plots were then measured and subtracted from that of the most intense (2, 8) band. In this way an array of relative $I_{v'v''}$ values were determined as described in § 2 and these are displayed in table 1. They are integrated relative vibrational intensities determined band by band.

4.3. *Electronic Transition Moment and Smoothed Relative Vibrational Transition Probabilities*

The set of $I_{v'v''}$ derived band by band in the manner described above can be interpreted as described in § 2 with the aid of the Franck–Condon factors $q_{v'v''}$ and *r*-centroids $\bar{r}_{v'v''}$ to provide information upon the variation of $R_e(r)$ with r, and thereby by use of equation (3) to provide a smoothed array of relative vibrational transition probabilities $p_{v'v''}$ for the whole band system.

Table 1

Measured Relative Integrated Band Intensities $I_{v'v''}$ for the O_2 Schumann–Runge System

Legend: λ(vac) band origin (calculated values in parentheses)
$r_{v'v''}$ (A) (Jarmain 1960)
$q_{v'v''}$ (Nicholls 1960)
$p_{v'v''}$ (Smoothed)

Note: The positive or negative number in some entries is the power of ten by which the preceding number is multiplied.

Franck–Condon factors $q_{v'v''}$ (Nicholls 1960) for the transition were computed for a Morse model by direct integration of the wave functions using an I.B.M. 704 computer at the U.S. National Bureau of Standards, Computation Laboratory. r-centroids were calculated by W. R. Jarmain. Both of these quantities are displayed in table 2.

A plot of $(I_{v'v''}\lambda^4_{v'v''}/q_{v'v''})^{1/2}$ against $\bar{r}_{v'v''}$ was made for bands of the $v' = 0, 1, 2$ progressions. Plots of $\log(I_{v'v''}\lambda^4_{v'v''}/q_{v'v''})^{1/2}$ against $\bar{r}_{v'v''}$ for each progression are shown in figure 2. It will be noted that the curves (one for each progression) are parallel. As is clear from equation (1) they are separated in relative ordinate by a factor which is proportional to $\log N_v{}^{1/2}$. The curves were 'rescaled' by simple linear displacement on the ordinate axis. The equivalent linear plot of $(I_{v'v''}\lambda^4_{v'v''}/q_{v'v''})^{1/2}$ against $\bar{r}_{v'v''}$ was then made of the rescaled points and is shown in figure 3. A best 'least squares' parabola of the form $R_e(r) = a+br+cr^2$ was fitted to the points and found to be

$$R_e(r) = \text{const}(1-1{\cdot}1807r+0{\cdot}35047r^2) \qquad 1{\cdot}44(\text{Å}) < r < 1{\cdot}76(\text{Å}). \tag{6}$$

No superlative accuracy is to be inferred from the large number of significant figures carried in the coefficients. They are required to overcome cancellation.

The array of smoothed relative vibrational transition probabilities

$$p_{v'v''} = R_e{}^2(\bar{r}_{v'v''})q_{v'v''}$$

or 'band strengths' derived from equation (3) are also displayed in table 2 together, for comparison, with values of intensities at infinite temperatures $I = p_{v'v''}/\lambda^4_{v'v''}$.

The relative displacements ($\log N_{v'}{}^{1/2}$) of the curves of figure 2, lead to the ratio $N_0 : N_1 : N_2 : 1000 : 57 : 26$, from which an effective vibrational temperature of 1460 °K can be inferred.

§ 5. DISCUSSION

The probable error in measured relative intensity of each band was estimated and the overall effect of this upon the plots leads to probable errors in $p_{v'v''}$ values of 5% for bands on the $v' = 0$ progression, 11% for bands in the $v' = 1$ progression and 12% for bands in the $v' = 2$ progression. Exceptions to these estimates were the (0, 10), (0, 17), (0, 18), (0, 19), (1, 16), (1, 17), (1, 18), (1, 20), (2, 18), (2, 22) bands for which estimated errors (%) are respectively 8, 6, 12, 14, 19, 19, 20, 24, 22, 18. Treanor and Wurster (1960), results of whose photographic photometry on the system are discussed below, estimate their error at 25%.

Treanor and Wurster (1960) inferred $R^2_{v'v''} = p_{v'v''} = R_e{}^2(\bar{r}_{v'v''})q_{v'v''}$ in absolute atomic units band by band in $v' = 0, 1, 2$ progressions from heterochromatic photographic absorption measurements upon lines of the Schumann–Runge system in shock heated oxygen. A band oscillator strength $f_{v'v''}$ can be derived from the equations

$$f_{v'v''} = \frac{8\pi^2 mc}{3he^2}\nu_{v'v''}R^2_{v'v''} = \frac{8\pi^2 mc}{3he^2}\nu_{v'v''}R_e{}^2(\bar{r}_{v'v''})q_{v'v''} \tag{7}$$

$$= \frac{302}{\lambda(\text{Å})}R_{v'v''}\,(\text{atomic units})^2. \tag{8}$$

They also took an average value for $\bar{R}_e{}^2$ of 0·51 atomic units from the bands which they studied and thereby assigned an 'effective' oscillator strength to the whole system

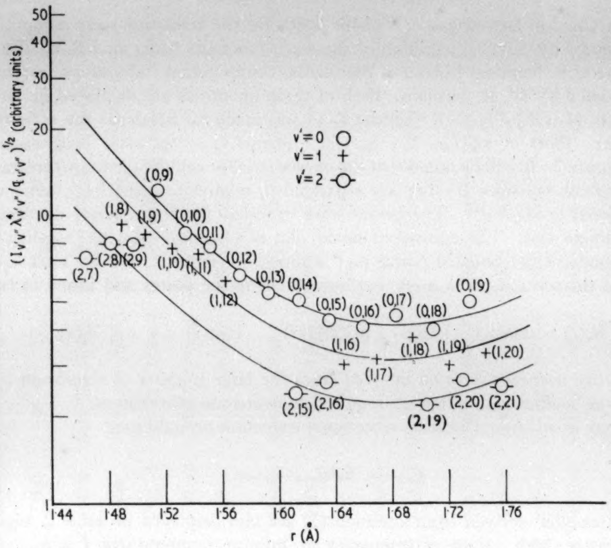

Figure 2. Comparative plots of $\ln(I_{v'v''}\lambda^4_{v'v''}/q_{v'v''})^{1/2}$ against $\bar{r}_{v'v''}$ for the $v' = 0, 1, 2$ progressions.

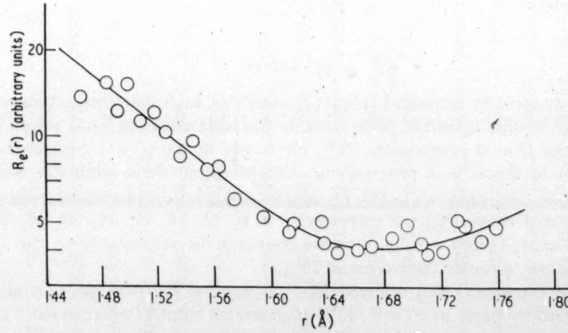

Figure 3. The electronic transition moment $R_e(r)$ as a function of r.

through the equation

$$f = \frac{8\pi^2 mc}{3he^2}\bar{R}_e^2 = 0{\cdot}048.$$

The limitations of the concept of an effective oscillator strength for a complete band system which should be treated with great caution and which has also been used by other workers, are discussed below.

A very useful comparison can be made between Treanor and Wurster's absolute values of $p_{v'v''}$, which were obtained band by band, and our smoothed relative values derived from measurements on the whole system. In figures 4, 5 and 6, in which are plotted $p_{v'v''}$ against v'' for $v' = 0, 1, 2$, the two sets of data are compared. Our measurements, on the whole show smooth, undulating variation of $p_{v'v''}$ with v'' as would be expected. Treanor and Wurster's data are a little more fragmentary, but show good general agreement in trend with ours for the $v' = 0$ progression. Agreement is poorer in the $v' = 1$, 2 progressions. Their points for small values of v'' (corresponding to wavelengths less than about 3000 Å) seem to be consistently low; possibly as an artefact of heterochromatic photographic photometry.

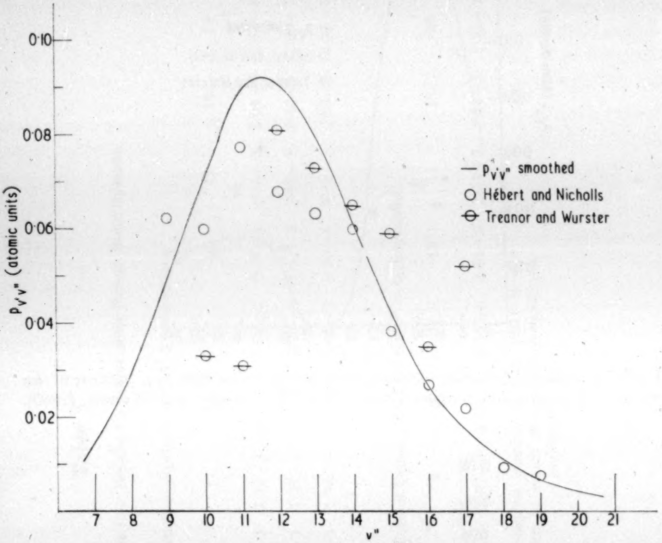

Figure 4. Smoothed relative vibrational transition probability $p_{v'v''}$ against v'' for the $v' = 0$ progression compared with $|R^2_{v'v''}|$ of Treanor and Wurster (1960).

It is possible to make our values absolute by scaling them to agree with Treanor and Wurster's over a large segment of the $v' = 0$ progression. The band oscillator strengths which can be assigned to Treanor and Wurster's measurements are

$$f_{v'v''} = 302 R^2_{v'v''}/\lambda(\text{Å})$$

and the scaling procedure when applied to our data gives smoothed band oscillator strengths

$$f_{v'v''} = 457 p_{v'v''}/\lambda(\text{Å}).$$

In table 3 are displayed the oscillator strengths thereby derived from our measurements scaled onto the $v' = 0$ progression of Treanor and Wurster. Bethke (1959) has made a study in absorption through cold oxygen of intensities of the $v'' = 0$ progression of bands and has also derived a series of oscillator strengths band by band for this progression. His data are also incorporated in table 3.

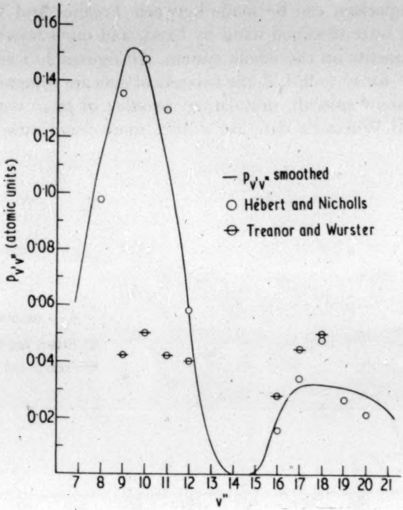

Figure 5. Smoothed relative vibrational transition probability $p_{v'v''}$ against v'' for the $v' = 1$ progression compared with $|R^2_{v'v''}|$ of Treanor and Wurster (1960).

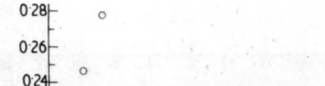

Figure 6. Smoothed relative vibrational transition probability $p_{v'v''}$ against v'' for the $v' = 2$ progression compared with $|R^2_{v'v''}|$ of Treanor and Wurster (1960).

Table 3

Band Oscillator Strengths $f_{v'v''}$ for the O_2 Schumann–Runge Band System

(a) Smoothed $f_{v'v''}$ for the $v' = 0, 1, 2$ progressions

v' \ v''	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
0	1·68 − 3	3·38 − 3	5·56 − 3	7·59 − 3	8·97 − 3	8·82 − 3	7·52 − 3	5·50 − 3	3·70 − 3	2·26 − 3	1·36 − 3	8·06 − 4	2·73 − 4	—	—
1	8·32 − 3	1·313 − 2	1·640 − 2	1·573 − 2	1·136 − 2	5·55 − 3	1·35 − 3	1·12 − 5	5·86 − 4	1·61 − 3	2·61 − 3	2·42 − 3	2·29 − 3	1·97 − 3	1·54 − 3
2	2·045 − 2	2·418 − 2	2·110 − 2	1·151 − 2	2·90 − 3	7·62 − 8	1·58 − 3	3·18 − 3	2·61 − 3	9·80 − 4	4·18 − 5	2·89 − 3	1·33 − 3	2·60 − 3	3·66 − 3

(b) Indivudual $f_{v'0}$ values of Bethke (1958) for the $v'' = 0$ progression

v'' \ v'	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
0	2·3 − 8	7·4 − 8	2·74 − 7	7·28 − 7	1·73 − 6	3·56 − 5	6·75 − 5	1·07 − 5	1·56 − 5	2·16 − 5	2·81 − 5	3·17 − 5	3·24 − 5	3·26 − 5	3·16 − 5	2·94 − 5

Note the negative number in each entry is the power of ten by which the preceding number is multiplied.

It was mentioned above that the results of the increasingly common process of averaging or summing in certain ways band oscillator strengths $f_{v'v''}$ to provide an effective electronic oscillator strength f_{el} for a complete band system, should be treated with some reserve. In such work the assumption is often made that

$$f_{\text{el}} = f_{v'v''}E_{00}/q_{v'v''}E_{v'v''}.$$

Weber and Penner (1957), Bethke (1959), Keck, Camm and Kivel (1958), Keck, Camm, Kivel and Wentink (1959) and others have used such a process to assign oscillator strengths to complete band systems in discussions of the molecular contribution to the emissivity of hot gases. The above relation may be formally derived by asserting that

$$f_{\text{el}} = \sum_{v'} f_{v'0}$$

performing the summation over v' in equation (7) and dividing equation (7) by the result.

The sweeping assumptions made in such a derivation are (i) constancy of $R_e(r)$ over the whole system, (ii) summability of $f_{v',0}$ and (iii) the adequacy of E_{00} to represent the average energy quantum of the whole transition. We have shown that $R_e(r)$ is by no means constant over the whole system. The adequacy of E_{00} as an average, particularly in extensive systems is also open to question.

Thus although the $f_{v'v''}$ are of great quantitative value in the interpretation of spectral intensities, the applicability of f_{el} to better than a rough order of magnitude guide is open to serious question.

Note added in proof.—It has been pointed out by J. W. Chamberlain of Yerkes Observatory in private conversation that $p_{v'v''}$ could properly be called 'band strength' rather than the cumbersome, dimensionally incorrect though conventional 'relative vibrational transition probability'.

Measurements of Quenching of Ortho-positronium in Gases

BY F. F. HEYMANN[†], P. E. OSMON[‡], J. J. VEIT[†][§], AND W. F. WILLIAMS[‡]

[†] University College, London

MS. received 28th June 1961

Abstract. Three photon annihilations of ortho-positronium in gases as a function of pressure have been investigated using a scintillation spectrometer technique. Quenching rates per atmosphere were determined for argon ($0{\cdot}035\lambda_0$), neon ($0{\cdot}024\lambda_0$), helium ($0{\cdot}014\lambda_0$), oxygen ($3\lambda_0$), nitric oxide ($400\lambda_0$), and carbon dioxide ($0{\cdot}08\lambda_0$), the last three being only very approximate. λ_0 is the natural annihilation rate of ortho-positronium, $0{\cdot}7\times10^7$ sec^{-1}. The high quenching rates in oxygen and nitric oxide are attributed to ortho-to-para conversion by electron exchange. The order of magnitude of the smaller quenching rates is understandable if the positronium atom annihilates with an electron of a gas molecule during collision (pick-off quenching).

§ 1. ANNIHILATION PROCESSES

TWO KINDS of annihilations of positrons emitted into a gas are possible: (i) free annihilations, or annihilations in flight, (ii) bound annihilations, i.e. from the bound states of an electron–positron pair (positronium). In both cases the spins of the pair may be parallel (triplet) or anti-parallel (singlet).

It follows from invariance under charge conjugation that the singlet state of a pair annihilates into an even number of photons and the triplet state into an odd number. Conservation of energy and momentum require that at least two photons are created per annihilation. The probability of annihilation decreases very rapidly the greater the number of photons created. Therefore for all practical purposes singlet states decay into two photons, triplet states into three. The cross section for free singlet annihilations between unpolarized electrons and positrons has been shown (Dirac 1930) to be

$$^1\sigma_{2\gamma} = \pi r_0{}^2\frac{c}{v}$$

for free positrons of non-relativistic velocity v, where r_0 is the classical electron radius.

After allowing for the greater statistical weight it is found (Dirac 1930, Radcliffe 1951) that annihilations from the free triplet state are $1115/3 \simeq 372$ times less likely and can therefore be ignored in what follows.

The rate of free annihilations in a gas is therefore

$$\Lambda_f = n_e{}^1\sigma_{2\gamma}v$$

where n_e is the electron density in the path of the positron. If N = Loschmidt's number, p = pressure in atmospheres, and K = effective number of electrons per atom, $n_e = KNp$ and $\Lambda_f = \pi KpNr_0{}^2c$. (High energy positrons are repelled by the field of the atom so that $K < Z$, the atomic number; slow positrons polarize the atom so that $K > Z$.)

[§] Now at Physics Department, University of British Columbia.

It is convenient to define λ_f the free annihilation rate per atmosphere of gas

$$\lambda_f = \pi K N r_0^2 c = \frac{\Lambda_f}{p}.$$

The annihilation rates from the bound states of positronium can also be calculated: (i) From singlet or para-positronium

$$\lambda_p = 4n_e{}^1\sigma_{2\gamma}v$$

where n_e is again the density of electrons in the path of the positron, and so

$$\lambda_p = (4|\Psi_{r=0}|^2)\,{}^1\sigma_{2\gamma}v.$$

For S states with quantum number n this reduces to

$$\lambda_p = \frac{1}{\pi}\left(\frac{me^2}{2n\hbar^2}\right)^3 4\pi r_0^2 \frac{c}{v} v$$
$$= 0{\cdot}8\times 10^{10} n^{-3}\ \text{sec}^{-1}.$$

(ii) From triplet or ortho-positronium the annihilation rate is 1115 times smaller

$$\lambda_0 = \frac{1}{1115}\lambda_p$$
$$= 0{\cdot}7\times 10^{7} n^{-3}\ \text{sec}^{-1}.$$

In a two-photon annihilation the total energy of the pair is shared equally between the photons. If annihilation is from rest the photons are emitted in opposite directions; alternatively the angle between the emitted photons is a measure of the momentum of the pair before annihilation. In the three-photon case Ore and Powell (1949) have calculated the energy spectrum of the photons, which are coplanar for annihilation from rest.

§ 2. QUENCHING

The term 'quenching' was initially applied to the conversion of ortho-positronium to para-positronium. As the latter, singlet, form has a lifetime so much shorter, this effectively resulted in the destruction or quenching of the positronium. The term is here applied more generally to any process whereby two-photon annihilation replaces three. There are a number of possible quenching processes.

(i) *Exchange quenching*. Atoms and molecules with an unpaired electron (e.g. atomic hydrogen, alkali atoms, nitric oxide) may exchange an electron with a positronium atom during a collision, and in some of these exchanges ortho- to para- will occur. The probability of conversion is one per four collisions (as the statistical weights of triplet and singlet states are in the ratio 3:1) and the cross section for quenching is therefore one quarter of the elastic cross section. (The energy difference between the ground states of ortho- and para-positronium is $8{\cdot}5\times 10^{-4}$ ev which is negligible compared with the kinetic energy of the positronium atom even at thermal energies.) The exchange quenching cross section is therefore energy dependent, increasing rapidly at low positronium energies (Massey and Mohr 1954).

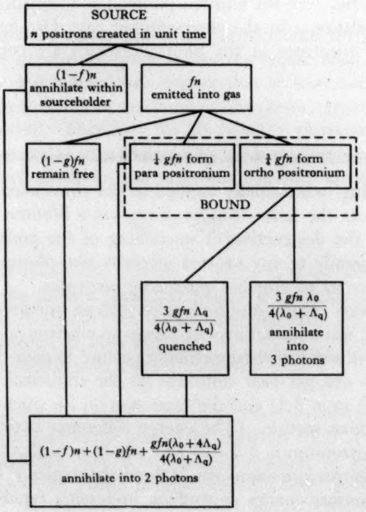
(ii) *Angular momentum processes.* It has been suggested (Gittelman and Deutsch 1955–1956) that one of the quenching processes effective in oxygen (in addition to spin exchange) may be triplet–singlet conversion of the positronium atom with a reorientation of the angular momentum of the oxygen molecule.

(iii) *Chemical quenching.* This is the enhanced annihilation rate of ortho-positronium when it is bound to another atom to form a molecule. The observed high quenching cross section of chlorine (Deutsch 1953) is believed to occur in this way. A related process is the attachment of free positrons which is believed to have been observed in freon (CCl_2F_2) (Deutsch 1953).

(iv) *Pick-off quenching.* During any collision between a positronium atom and a gas molecule the positron of the former is temporarily in a region of higher electron density and so is more likely to annihilate. The time spent in the region of higher electron density is inversely proportional to the velocity of the positronium atom (assuming no scattering) and so also, therefore, will be the pick-off quenching cross section, while the quenching rate will be velocity independent. It is possible to make crude estimates of pick-off quenching rates similar to the free annihilation rate estimate above.

(v) *Spin reversal.* Reversal of spin of either component of the positronium atom during a collision by interaction with the magnetic moment of the gas molecule is possible but is expected (Massey and Mohr 1954) to have a cross section at least an order of magnitude smaller than those observed.

A quenching rate $\Lambda_q = Np\sigma_q v$ can be defined for each of the above processes, the rates being additive where more than one process is taking place. For the particular case of pick-off quenching which occurs universally (though it is masked by the much more effective exchange quenching where this occurs) the quenching rate is expected to be nearly independent of positronium energy. Since quenching rate is proportional to gas pressure it is appropriate to express experimental results as quenching rates per atmosphere of gas λ_q.



SOURCE
n positrons created in unit time
$(1-f)n$ annihilate within sourceholder
fn emitted into gas
$(1-g)fn$ remain free
$\frac{1}{4}gfn$ form para positronium
$\frac{3}{4}gfn$ form ortho positronium
BOUND
$\frac{3gfn\Lambda_q}{4(\lambda_0+\Lambda_q)}$ quenched
$\frac{3gfn\lambda_0}{4(\lambda_0+\Lambda_q)}$ annihilate into 3 photons
$(1-f)n+(1-g)fn+\frac{gfn(\lambda_0+4\Lambda_q)}{4(\lambda_0+\Lambda_q)}$
annihilate into 2 photons

Figure 1. Fate of positrons in a gas (simplified).

For a mixture of gases the quenching contributions from the different gases are additive so that the resulting quenching rate for the mixture is

$$\Lambda_q = p\lambda_q = p_1\lambda_1+p_2\lambda_2+ \ldots$$

where the p's are the partial pressures in atmospheres of the gases and the λ_q's their quenching rates per atmosphere.

Figure 1 is a block diagram to show the fates of positrons emitted into a gas.

§ 3. METHOD

The purpose of the observations reported in this paper was to measure quenching rates in a variety of gases in order to provide evidence for the existence of at least two distinct quenching mechanisms.

Two possible distinct methods are available: (A) The multiplicity of the annihilation radiation can be observed either by using counters in coincidence (DeBenedetti and Siegel 1952, Wheatley and Halliday 1952, Pond 1952) or by measuring the energies of the photons (Deutsch 1953, Lewis and Ferguson 1953, Hughes, Marder and Wu 1954). (B) Alternatively the lapse of time between the creation of a positron (which must be marked by the emission of a nuclear gamma ray) and its annihilation can be measured by using counters in delayed coincidence (Deutsch 1953, Lewis and Ferguson 1953, Daniel and Stump 1959). Three mean lifetimes should be distinguishable: (i) the free positron lifetime inversely proportional to gas pressure and equal to Λ_f^{-1}; (ii) the para-positronium mean lifetime of $\lambda_p^{-1} \sim 10^{-10}$ sec, which is negligibly short for our purposes; (iii) the ortho-positronium mean lifetime $\Lambda_0^{-1} = (\lambda_0+\Lambda_q)^{-1}$ which is pressure dependent.

Both 'multiplicity' and 'lifetime' methods have been used by other workers. In this paper the work described has all been carried out using the multiplicity method.

The source of positrons was approximately $\frac{1}{4}$ mc of sodium 22 sandwiched between two mica sheets 6 mg cm^{-2} thick and 2 cm in diameter and held in the centre of the gas chamber (figure 2). Sodium 22 emits 1·3 MeV gamma rays and 560 kev positrons and has a half-life of 2·6 years. Referring to figure 1, if n nuclei decay per second, fn positrons escape into the gas, gfn form positronium, $\frac{3}{4}gfn$ being ortho-positronium, and if a

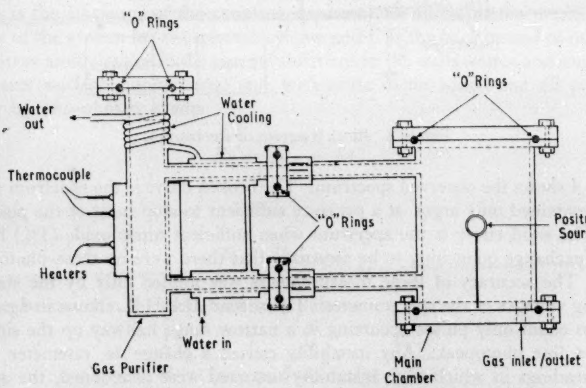


Figure 2. Diagram of the pressure chamber and gas purifier.

proportion η only is detected the rate of three photon annihilations detected by the counter system would be $\frac{3}{4}gfn\eta$ without quenching. When there is quenching at a rate Λ_q the fraction of ortho-positronium annihilating by three-photon emission is

$$\frac{\lambda_0}{\lambda_0+\Lambda_q} = \frac{\lambda_0}{\Lambda_0}$$

and the observed three-photon rate is

$$\begin{aligned} R &= \tfrac{3}{4}gfn\eta\lambda_0\Lambda_0{}^{-1} \\ &= \eta A\left(1+p\frac{\lambda_q}{\lambda_0}\right)^{-1} \quad \text{where } A = \tfrac{3}{4}gfn. \end{aligned}$$

g is constant for a particular gas or mixture of gases; f is constant for the source used; n was effectively constant in these measurements. It follows that

$$\frac{1}{R} = \frac{1}{\eta A}\frac{\lambda_q}{\lambda_0}p + \frac{1}{\eta A}. \tag{1}$$

If η is independent of p a graph of $1/R$ against p should be a straight line with an intercept $-\lambda_0/\lambda_q$ on the pressure axis and intercept $1/\eta A$ on the $1/R$ axis.

The experimental problem is to measure R, i.e. to separate three photon events from the background. The authors employed a sodium iodide scintillation spectrometer technique (block diagram figure 3). The positron source was mounted at the centre of an aluminium alloy cylindrical gas chamber 6 in. long × 4 in. diameter × $\frac{1}{8}$ in. wall thickness. The scintillation counter (1 in. thick × $1\frac{3}{4}$ in. diameter sodium iodide (Tl) crystal optically coupled to an EMI 6260 photomultiplier) was placed sufficiently far, 60 cm, from the gas chamber for its detection efficiency for an annihilation event to be sensibly independent of where in the chamber the event occurs. This is necessary in order that η should be independent of p.

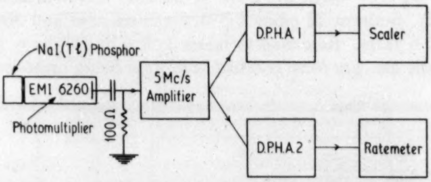

Figure 3. Block diagram of electronics.

Figure 4 shows the observed spectrum. The broken curve is the spectrum when the chamber contained only argon at a pressure sufficient to stop most of the positrons in the gas. The solid curve is the spectrum when sufficient nitric oxide (3%) had been added for exchange quenching to be so strong that there were no three-photon events observed. The accuracy of these measurements was limited only by the stability of the defining voltages of the spectrometer. The second D.P.H.A. shown in figure 3 was arranged to count only pulses occurring in a narrow range halfway up the side of the annihilation line photopeak. Any instability caused a change in ratemeter reading. Series of readings in which such instability occurred were abandoned, the apparatus readjusted, and a fresh series commenced.

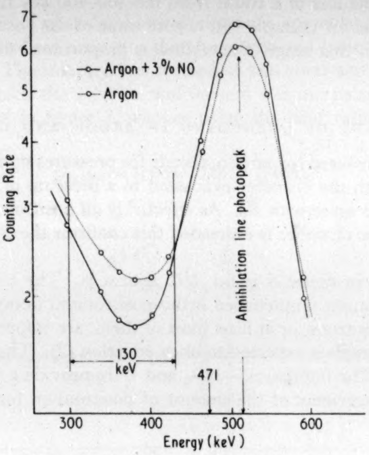

Figure 4. Scintillation spectrum of annihilation radiation.

It is apparent from the two curves that the addition of the nitric oxide has removed three-photon annihilation counts from the region between 300 kev and 440 kev and produced a corresponding increase in the photopeak. The apparatus was adjusted to record only pulses with heights in a range corresponding to 300 – 440 kev. If R_p is the counting rate in the gas at pressure p and R_0 is the rate in the same gas contaminated with 3% nitric oxide, then $R = R_p - R_0$ is a measure of the amount of ortho-positronium decaying by three-photon emission in uncontaminated gas. Since

$$R_p = \eta_3 A \frac{\lambda_0}{\Lambda_0} + \eta_2 \frac{A}{3}\left(\frac{3\Lambda_q}{\Lambda_0} + 1\right) + C$$

where η_3 is the efficiency of the counting apparatus for three-photon events, η_2 is the efficiency of the system for two-photon events, and C is the background of other events (free positron annihilations in the gas, annihilations in the walls source and sourceholder, and 1·3 MEV nuclear gamma rays) and, with nitric oxide added and all positronium decaying by two-photon events

$$R_0 = \eta_2 \, \frac{4A}{3} + C$$

we find

$$R = A(\eta_3 - \eta_2)\frac{\lambda_0}{\Lambda_0}$$

which can be stated in the same form as (1) above:

$$\frac{1}{R} = \frac{1}{(\eta_3 - \eta_2)A}\,\frac{\lambda_q}{\lambda_0}\,p + \frac{1}{(\eta_3 - \eta_2)A}. \qquad (2)$$

The similarity between equations (1) and (2) is to be expected. While quenching does not always result in the loss of a count from the 300–400 kev range (double Compton scattering in the crystal for example will restore some of the possible losses) the change in the counting rate in this range is nevertheless proportional to quenching rate.

§ 4. MEASUREMENT OF QUENCHING IN ARGON AND CARBON DIOXIDE

R_p and R_0 were measured for carbon dioxide for pressures up to twenty atmospheres. The counting rate with the chamber evacuated to a pressure of 10^{-2} mm Hg was also observed and found to agree with R_0. As effectively all positrons annihilate in the aluminium walls when the chamber is evacuated this confirms the efficacy of the 3% nitric oxide in quenching.

The curve shown in figure 5 is for $1/R$ against p. The minimum in any curve corresponds to a maximum unquenched ortho-positronium decay rate and presumably occurs when all the positrons, or at least most of them, are stopped within the gas. For higher pressures the graph is expected to obey equation (2). The best straight line was fitted to this region. The intercepts $-\lambda_0/\lambda_q$ and $1/A\eta$ provide a value of λ_q in terms of λ_0 and a relative measurement of the amount of positronium formed. In this way we find $(\lambda_q)_{CO_2} = 0{\cdot}08\,\lambda_0$.

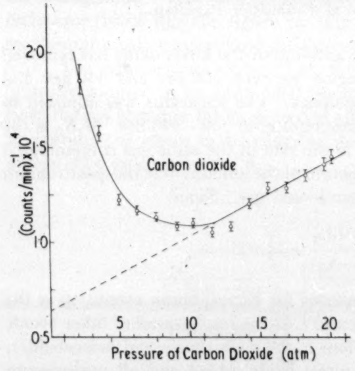

Figure 5. Quenching in carbon dioxide.

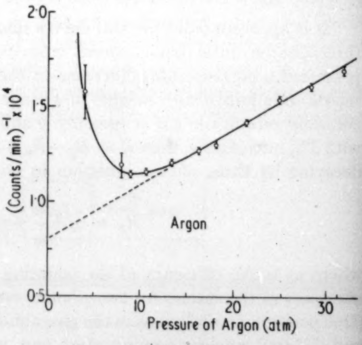

Figure 6. Quenching in argon.

At this stage in the work considerable improvement of the apparatus was carried out. A more stable counting system (enabling the second D.P.H.A. and ratemeter to be dispensed with), better resolution, a strengthened gas vessel (permitting pressures up to 32 atmospheres) and a cleaner system with faster pumping and better ultimate vacuum (less than 5 microns Hg pressure) were developed. With this improved apparatus revised data for argon were obtained and are shown in figure 6. The best straight line was fitted to the points for pressures above 16 atmospheres, and the intercepts calculated by the method of least squares. The standard deviation of the pressure intercept (±2%) was also calculated by the method of least squares giving

$$(\lambda_q)_A = 0{\cdot}0352\lambda_0 \text{ atm}^{-1} \pm 2\%.$$

§ 5. MEASUREMENT OF QUENCHING IN NEON AND HELIUM

The stopping power of neon for $\frac{1}{2}$ MeV positrons is appreciably smaller than that of argon. A quenching rate for neon was therefore extracted from a measured rate for a neon–argon mixture. The mixture was formed of two parts argon and one part neon. The accuracy with which the mixture was formed was estimated to be to about 2%. The results are plotted in figure 7, whence using the later value of $(\lambda_q)_A$ determined above we find

$$(\lambda_q)_{Ne} = 0{\cdot}024\lambda_0 \text{ atm}^{-1} \pm 40\%.$$

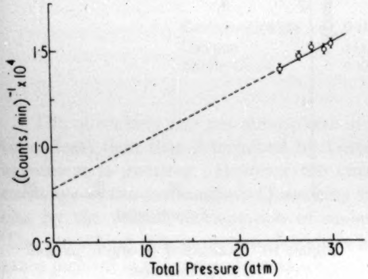

Figure 7. Quenching in neon $(\frac{1}{3})$ argon $(\frac{2}{3})$ mixture.

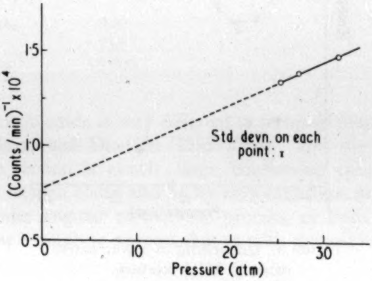

Figure 8. Quenching in helium $(\frac{1}{3})$ argon $(\frac{2}{3})$ mixture.

Similarly quenching by a mixture 2 parts argon, 1 part helium was measured. The results are shown in figure 8 and from the intercepts we find

$$(\lambda_q)_{He} = 0{\cdot}014\lambda_0 \text{ atm}^{-1} \pm 50\%.$$

§ 6. MEASUREMENT OF QUENCHING IN NITRIC OXIDE AND OXYGEN

Nitric oxide and oxygen quench too powerfully for the same method to be used. Instead very weak constant proportion mixtures of these gases with argon were used. In each case sufficient of the strong quencher was added to argon to reduce the three-photon rate by about one-half (0·03% nitric oxide, 1·6% oxygen). Curves of $1/R$ against p were obtained from these mixtures (figures 9, 10) and quenching rates for the strong quenchers alone extracted from those obtained for the mixtures using the value for argon:

$$(\lambda_q)_{NO} = 400\lambda_0 \text{ atm}^{-1}$$

$$(\lambda_q)_{O_2} = 3\lambda_0 \text{ atm}^{-1}.$$

All the gases used, with the exception of the nitric oxide which was produced in the laboratory, were British Oxygen Company commercial gases.

§ 7. DISCUSSION

The method essentially measures λ_q in terms of λ_0 where λ_0 is the natural or unquenched annihilation rate of ortho-positronium. Ore and Powell (1949) and Radcliffe

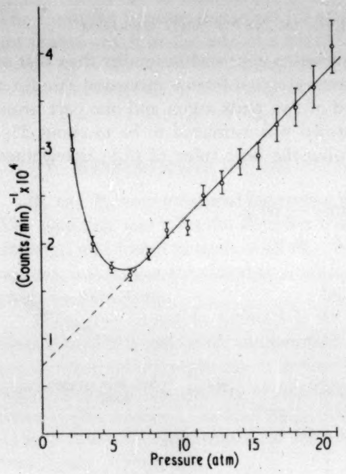

Figure 9. Quenching in argon, nitric oxide (0·03%) mixture.

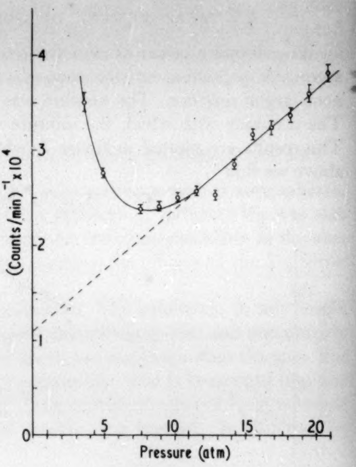

Figure 10. Quenching in argon, oxygen (1·6%) mixture.

(1951) have calculated the natural annihilation rate from the ground state of ortho-positronium (λ_{01}), and if we assume that all our positronium is in the ground state before annihilating we can then use $\lambda_0 = \lambda_{01} = 0{\cdot}7 \times 10^7$ sec^{-1} and we can write down the absolute value for λ_q. In addition, by making an assumption about the energy distribution of our positronium atoms at annihilation we can deduce a mean cross section for quenching σ_q from λ_q. Assuming that the positronium has reached thermal equilibrium with the quenching gas we can take mean positronium speed to be $6{\cdot}6 \times 10^6$ cm sec^{-1}, leading to the results in table 1.

Table 1

	λ_q	$\sigma_q \times 10^{21}$(cm^2)
Helium	$0{\cdot}014\lambda_0$	$0{\cdot}62 \pm 50\%$
Neon	$0{\cdot}024\lambda_0$	$1{\cdot}1 \pm 40\%$
Argon	$0{\cdot}0352\lambda_0$	$1{\cdot}55 \pm 2\%$

The helium result is in agreement with that found by Daniel and Stump (1959) using a lifetime method ($0{\cdot}0093\lambda_0$). The argon quenching rate is appreciably lower than that found with this apparatus in its original form (unpublished) and we believe that the previously higher quenching rate must be attributed to residual oxygen. The fact that we were able to observe the lower quenching rates of helium and neon suggests that any oxygen remaining is having only a very small effect.

The observed increase in quenching rate with atomic size is good evidence in support of the pick-off process as the important quenching mechanism in the inert gases. For more quantitative evidence we need calculations of pick-off quenching cross sections and measurements of the distribution of positronium energies at annihilation.

The results obtained for carbon dioxide, oxygen and nitric oxide are clearly only provisional and give an indication of order only. These measurements are being repeated with the improved apparatus and will be published when complete together with estimates of the relative yields of positronium in the various gases and gas mixtures. Again assuming thermal equilibrium, these provisional results can be summarized as in table 2.

Table 2

	λ_q	$\sigma_q \times 10^{21}(\text{cm}^2)$
Carbon dioxide	$0{\cdot}08\lambda_0$	3·5
Oxygen	$3\lambda_0$	130
Nitric oxide	$400\lambda_0$	18 000

The quenching rate per atmosphere in nitric oxide is very different (a factor of fifty times less) than that determined by Gittelman and Deutsch (1955–1956). This disagreement is puzzling. However the cross section is clearly large, confirming spin exchange as the mechanism. Quenching in oxygen could also be by spin exchange, or else by the related reorientation of molecular angular momentum process, or both. The quenching rate in carbon dioxide is low enough to suggest that as with the noble gases pick-off is the major process.

Radiation Damage in Well Oriented Pyrolytic Graphites

BY L. C. F. BLACKMAN,† G. SAUNDERS AND A. R. UBBELOHDE

Department of Chemical Engineering and Chemical Technology,
Imperial College of Science and Technology, London, S.W.7

MS. received 28th March 1961

Abstract. Graphite formed by cracking methane under various conditions has been exposed to neutron irradiation. Changes in electronic properties were measured: (i) after radiation damage by neutron doses of the order 10^{17} neutrons/cm^2, (ii) after 'mild' annealing around 470 °C, and (iii) after 'strong' annealing at 2200 °C and above. Effects of radiation damage are proportionately greatest in specimens whose properties are initially nearest to those of ideal graphite. Some discrimination can be made between the types of disorder originally present, and the disorder added by irradiation.

Changes of thermoelectric power of graphite in the direction of the *c* axis show 'latent' increases attributed to disorder frozen in until after mild annealing.

§ 1. INTRODUCTION

WELL-ORIENTED pyrolytic graphites have certain properties close to those of ideal crystals. When conventional X-ray methods become insufficiently sensitive to give detailed information about crystal disorder for such near-ideal specimens, various electronic properties still give much information, although effects of disorder can be quite complex. Crystal disorder inherent in graphites prepared at different cracking temperatures has been discussed elsewhere (Blackman, Saunders and Ubbelohde 1961). The present paper deals with the additional disorder introduced in a series of well oriented specimens by exposure to neutron irradiation.

Previous studies on effects of neutron irradiation on graphite have mainly dealt with polycrystalline specimens (cf. Hennig and Hove 1956). The density of such materials (1·5 to 1·8 g cm^{-3}) involves up to 35% porosity and an extensive internal surface. The primary effect of neutron irradiation is to displace carbon atoms from network sites into interstitial positions, leaving network vacancies, but various locations are possible for the displaced atoms. This complicates both structural and electromagnetic consequences of neutron irradiation in polycrystalline graphites. By using well-oriented graphites, as in the present work, fewer alternative sites are available at intercrystalline boundaries or surfaces of internal pores for the displaced atoms, and the effects of damage are perceptible for much smaller irradiation than is normally used, and should be more readily interpreted. Two main consequences of disorder are the creation of electron traps, and a general increase in scattering of charge carriers. By comparing effects of neutron damage on various electronic properties for a series of specimens of different inherent disorder some discrimination between the main consequences becomes possible in the predominant direction of the *a* axis. As is discussed below, effects in the predominant direction of the *c* axis are at present less easily interpreted partly because a satisfactory theory of electronic properties of graphite in this direction is not yet available.

§ 2. EXPERIMENTAL

Pyrolytic graphites were prepared by cracking gaseous methane at 10 cm Hg pressure, using a flat former of polycrystalline graphite (Morgan EY9A) heated electrically at controlled temperatures in the range 1950–2200 °C. This gives graphites whose crystallites have the predominant direction of their *a* axes parallel to the flat surface of the former, and of their *c* axes perpendicular to it. As the temperature of the preparation is raised, various measurements described elsewhere (Blackman, Saunders and Ubbelohde 1961) show that the disorder becomes progressively less. The resistivity can be used as an approximate measure of this disorder. Recrystallization at 2700 °C of pyrolytic deposits formed at 2200 °C gives graphites even nearer to ideal single crystals in their physical and electronic properties.

For electrical measurements in the predominant direction of the *a* axes, specimens 2 cm × 0·5 cm × 0·05 cm were cut from the pyrolytic deposits with three side arms so as to permit measurements of the Hall effect. To minimize mechanical action on the specimens, cutting was effected by a jet of powdered corundum (airbrasive). In the predominant direction of the *c* axes, circular specimens were cut similarly 0·5 cm × 0·05 cm; four contact measurements of the resistance and measurements of thermoelectric power were made using methods previously described (Blackman, Mathews and Ubbelohde 1960, Blackman, Dundas and Ubbelohde 1960). Densities were greater than $2{\cdot}2\ \mathrm{g\ cm^{-3}}$ in all cases which indicates a bulk porosity of less than 3%. At room temperature specific resistances in the direction of the *a* axis ranged from 33 to ·8 × 10^{-5} ohm cm. They are used as an empirical parameter to characterize crystal disorder in what follows, and to display the results in a convenient manner graphically.

Neutron irradiation was carried out in a hollow fuel element in the reactor BEPO for seven days. Specimens sealed *in vacuo* in a silica vessel received a total dose of about 3×10^{17} neutrons $\mathrm{cm^{-2}}$ (thermal velocity) and 2×10^{17} neutrons $\mathrm{cm^{-2}}$ (fast, above 1 MeV energy). This amount of irradiation is considered to be approximately equivalent to a dose of 1 Mwd (cf. Hennig and Hove 1956). In accordance with previous findings (Bacon and Warren 1956) the interlayer spacing of a near-ideal specimen increased only slightly from $3{\cdot}3538 \pm 0{\cdot}0003$ Å to $3{\cdot}3545 \pm 0{\cdot}0005$ Å.

In the direction of the *a* axis measurements of the electrical resistivity, magnetoresistance and Hall coefficient were carried out (cf. Blackman, Saunders and Ubbelohde 1961) at the two temperatures 293 and 77 °K. Measurements of the thermoelectric power were made at various temperatures down to 77 °K. In the direction of the *c* axis measurements were carried out on electrical resistivity and thermoelectric power.

Annealing operations were carried out under a pressure of less than 10^{-3} mm Hg to minimize any attack by oxygen on carbon atoms made labile by neutron damage (Montet, Hennig and Kurs 1956), and on the graphite network itself. From exploratory trials, it was found that annealing of damaged specimens at around 470° led to changes that reached limiting values in a convenient period of time, about 20 hours. This temperature was therefore used in 'mild' annealing operations; to permit more profound structural reorganization ('strong' annealing), specimens were heated for a few minutes to temperatures above 2000 °C in a rapidly acting induction furnace (Blackman, Dundas, Moore and Ubbelohde 1961). After this treatment only changes in the direction of the *c* axis could still be measured conveniently, since each successive measurement on the same piece of graphite weakened it mechanically, particularly in the direction of the *a* axis.

§ 3. RESULTS

For graphites of various initial resistivities, results in the direction of the *a* axis of the specimens are presented in figures 1, 2 and 3. Measurements of thermoelectric power are given in the table for both crystal directions. The variation of *c*-axis resistivity with temperature, plotted in the form log ρ against $1/T$ for a typical sample of well-oriented graphite is given in figure 4.

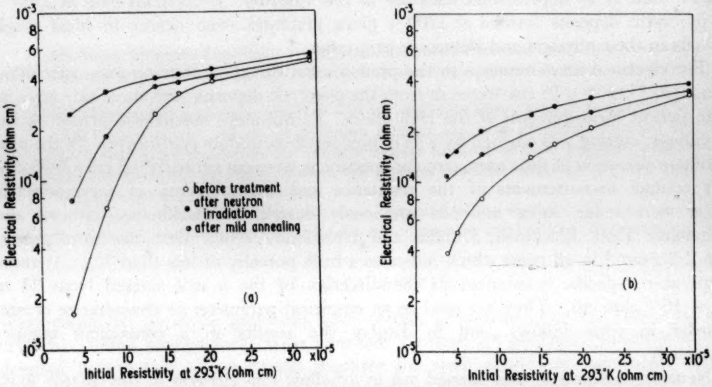

Figure 1. Electrical resistivity of graphites before treatment, after neutron irradiation and after subsequent mild annealing, plotted as a function of the initial room temperature electrical resistivity: (*a*) at 77 °K, (*b*) at 293 °K.

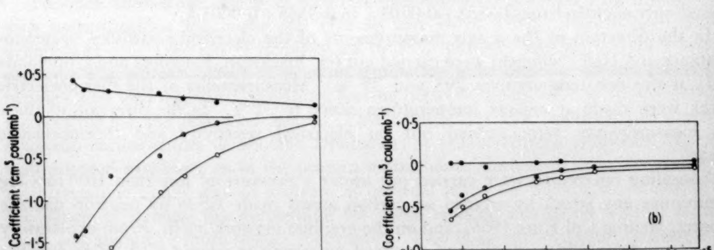

Figure 2. Hall coefficient of graphites before treatment, after neutron irradiation, and after subsequent mild annealing, plotted as a function of the initial room temperature electrical resistivity: (*a*) at 77 °K, (*b*) at 293 °K. Key as figure 1.

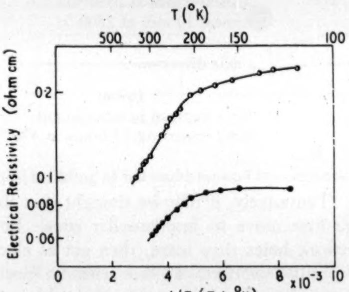

Figure 4. *c*-axis electrical resistivity of a near-ideal graphite (initial *a*-axis resistivity $3 \cdot 8 \times 10^{-5}$ ohm cm) measured after neutron irradiation and after subsequent mild annealing, plotted as a reciprocal function of absolute temperature. Key as figure 1.

§ 4. DISCUSSION

For any particular specimen of graphite the sequence of measurements, untreated, annealed after damage and neutron-irradiated, may be expected to give results for increasing defect concentration. The Hall coefficient is affected primarily by the number and sign of the charge carriers. From figure 2 it follows that in the annealed samples the number and sign of the charge carriers must lie quite close to their original values. Radiation damage produces a large increase in positive carriers, but most of these are removed by mild annealing. This increase of defects is most pronounced in the specimens whose resistivity is nearest to ideal graphite, to the left of the figures. From the illustrative example in the table, it will be seen that changes of thermoelectric power in the direction of the *a* axis are reversed by mild annealing in a similar way to

changes in the Hall effect. Tentatively, it may be thought that the carbon atoms displaced by neutron damage first move to interlamellar sites. Both the interlamellar carbon atoms, and the network holes they leave, then act as electron traps and thus increase the proportion of positive carriers. In this sense an electron trap is any disturbance which reduces the number of mobile carriers in the π band, through alterations in the binding energy where the resonance of ideal graphite is decreased. This includes effects due to buckling of the layers. On mild annealing these traps are reduced in number. A proportion of the interlamellar atoms probably migrates to the edges of the crystallites leaving the network holes, and the remainder return to the original sites thereby closing up network holes.

The electrical resistance of graphite is affected both by changes in the number of carriers, and, to a more marked extent than the Hall effect, by changes in the scattering probability. Inspection of the behaviour of the resistivity (figure 1) shows that scattering makes a marked contribution to the effects of neutron damage in the near-ideal graphites, which is not removed to any great extent by the reduction of traps on mild annealing.

This conclusion is confirmed by measurements of the magneto-resistance which is even more strongly dependent on the scattering probability (approximately as the inverse square according to some theories); figure 3 shows that most of the increased scattering due to neutron damage remains unaffected by the mild annealing.

Before discussing the findings in the direction of the *c* axis, which are less extensive because of physical difficulties in making certain types of measurement with the specimens available, it seems useful to outline a model for damage that could help to interpret results in the direction of the *a* axis. When a carbon atom is displaced from a network site, the networks will buckle locally (i) to accommodate the interstitial atom between them, and (ii) to allow for any bond rearrangements at a network 'hole' (cf. Ubbelohde 1957).

Figure 5 illustrates schematically that buckling of the network, for example at a network hole, need not involve major pushing aside of the neighbouring networks, since their normal distance of separation (3·4 Å) is quite large. On the other hand, to accommodate extra atoms between the networks requires a considerable local expansion of the normal separation between networks. Both network holes and interstitial carbon atoms act as traps, but the interstitial atoms are much more labile since their bonding is not stabilized by resonance. On mild annealing, those interstitial atoms which have not been removed too far by neutron damage can return to the original sites and heal the network. Others that are more remote from their origins preferentially migrate to sites where they can form cross links between the edges of macro-aromatic networks, with bonding types well known in organic chemistry. Through the removal of the interstitial atoms the number of valency defects (and hence positive carriers) is diminished, but scattering irregularities due to network holes are stabilized. These can only be removed by strong annealing above 2000 °c, which permits rearrangements of aromatic C–C bonds.

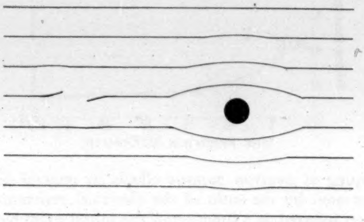

Figure 5. Sketch of buckling of networks around the network hole and an interstitial atom.

Types of disorder originally present in the pyrolytic graphites involve disturbances of crystal regularity and the presence of traps, which have been stabilized at the high temperatures of formation. Although consequences of such original disorder are formally similar to those arising from the disorder produced by neutron damage with or without mild annealing, geometrical aspects obviously differ. As the proportion of original defects increases, the distinctive role of neutron damage defects discussed in this paper rapidly becomes less prominent and becomes swamped beyond a limit for initial resistivities greater than about $1{\cdot}5 \times 10^{-4}$ ohm cm (figure 6).

In the direction of the *c* axis, near-ideal samples *decrease* in resistivity and show a less steep negative temperature coefficient after neutron bombardment (figure 4). The thermoelectric power also becomes more positive (table). If it is assumed that the carriers in this direction are mainly positive these changes are consistent with the model described above; the effect of mild annealing is relatively greater on the resistivity than on the thermoelectric power, but interpretation of this peculiarity awaits a satisfactory band model for the *c*-axis direction in graphite.

Brief comment may also be made about two further aspects of these experimental results.

The table illustrates the fact that for less perfect specimens of pyrolytic graphite, the maximum increase in positive thermoelectric power, resulting from neutron damage remains latent until after mild annealing. If the proposed model is used to interpret this unusual result, it would imply that in the direction of the *c* axis scattering effects due to interstitial carbon atoms mask increases in thermoelectric power resulting from an increase in positive carriers to an exceptionally strong degree. This could arise if contributions from lattice vibration to thermoelectric power, such as phonon drag and especially Umklapp processes, are particularly prominent in the direction of the *c* axis in graphite. Verification of this suggestion awaits the development of alternative means of studying lattice vibration contributions, such as measurements of thermal conductance which are being made.

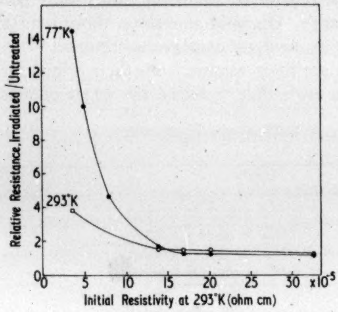

Figure 6. Swamping of neutron damage effects by general disorder in pyrolytic graphites as illustrated by the ratio of the electrical resistance after and before neutron irradiation (plotted as a function of the initial room temperature electrical resistivity).

Calculations can be made of the approximate number of additional positive carriers created in near-ideal pyrolytic graphite by the production of electron traps, following procedures outlined by McClure (1958). In a typical example, it is found that originally there are $4{\cdot}5 \times 10^{18}$ negative and $1{\cdot}5 \times 10^{18}$ positive carriers per cm^3.

After neutron irradiation, the specimen gave a Hall coefficient at 77 °K of $0{\cdot}43$ cm^3 coulomb^{-1} which did not vary with field strength. This indicates that conduction is wholly by positive carriers whose concentration is estimated as 17×10^{18} per cm^3. This may be compared with estimates for neutron damage in polycrystalline graphite made by Hennig (1958), which yield approximately 9×10^{-5} traps per atom or 10×10^{18} traps per cm^3 per MWd.

ACKNOWLEDGMENTS

Thanks are due to the Research Council of the Electricity Council for their support of this research and to the Atomic Energy Research Establishment, Harwell, for their collaboration in producing samples with neutron damage.

Determination of the Fierz Interference Term From the K-Capture/β^+ Ratio for the Pure Gamow–Teller Decay of ^{58}Co

By B. R. JOSHI and G. M. LEWIS

Department of Natural Philosophy, The University, Glasgow

MS. received 8*th May* 1961

Abstract. A direct determination has been made of the Fierz interference term b for the pure Gamow–Teller decay of ^{58}Co. The K/β^+ ratio has been determined by an internal source scintillation counter coincidence method. The value obtained was $4{\cdot}92 \pm 0{\cdot}09$. This may be compared with the recent predicted value of 4·87. Allowing for the variation in the theoretical value arising from β^+ end point uncertainty this yields a value for b of $(+0{\cdot}6 \pm 2{\cdot}3)\%$. Two interpretations of the result are possible on the basis of two-component neutrino theory. If, as is customarily assumed, $C_A = C_A'$, $C_T = -C_T'$, then b should vanish identically; and the small experimental value for b confirms the theory. If alternatively, $C_A = C_A'$, $C_T = +C_T'$ then the experimental result requires that C_T, C_T' be very small.

§ 1. INTRODUCTION

THE SIGNIFICANCE of the Fierz interference term b has changed in recent years, following the introduction of the two-component neutrino theory and the increase in β-decay data. Experimental studies of allowed β-spectral shapes and K/β^+ ratios have shown that b is not large. The subject has been reviewed by Konopinski (1958). Two-component neutrino theory and recent data now demand either that b should vanish identically or that the scalar and tensor coupling constants C_S, C_S', C_T, C_T' should be small.

The expression for b which arises from the combination of different coupling constants can be written

$$b = 2\mathscr{R}\,\frac{[C_S C_V^* + C_S' C_V'^*]|F|^2 + [C_T C_A^* + C_T' C_A'^*]|G|^2}{[|C_S|^2 + |C_V|^2 + |C_S'|^2 + |C_V'|^2]|F|^2 + [|C_T|^2 + |C_A|^2 + |C_T'|^2 + |C_A'|^2]|G|^2} \tag{1}$$

where F and G are the Fermi and Gamow–Teller matrix elements (cf. De Groot and Tolhoek 1950, Lee and Yang 1956, 1957).

For the determination of b the experimental K/β^+ ratio can be compared with the theoretical value $(\mathrm{K}/\beta^+)_{b=0}$ by the relation

$$\frac{\mathrm{K}}{\beta^+} = \frac{1+b}{1-\gamma b(1/W)_{\mathrm{av}}}\left(\frac{\mathrm{K}}{\beta^+}\right)_{b=0} \tag{2}$$

where

$$\gamma = \left\{1 - \left(\frac{Z}{137}\right)^2\right\}^{1/2}$$

and W is the β^+ energy.

Restricting attention at this stage to Gamow–Teller transitions, the experiments by Herrmannsfeldt *et al.* (1958) on ^{6}He have shown that $[|C_A|^2 + |C_A'|^2]$ is large compared with $[|C_T|^2 + |C_T'|^2]$. For time inversion invariance the coupling coefficients will be real.

For the two-component neutrino theory to hold consistently with polarization experimental data, the relation $C_A = +C_A'$ holds for the dominant coupling coefficients. Both $C_T = -C_T'$ and $C_T = +C_T'$ are consistent with two-component neutrino theory. The combination of the coupling constants in the form $C_A = C_A'$, $C_T = -C_T'$ requires the identical vanishing of b while the form $C_A = C_A'$, $C_T = +C_T'$ does not.

Experimental values of b are therefore necessary to establish the validity of the two-component neutrino theory if $C_T = -C_T'$, or to delimit the maximum magnitude of C_T and C_T' if $C_T = +C_T'$. It is also perhaps relevant to point out that for electron polarization methods designed to determine the validity of the theory, the expression for the electron polarization contains b explicitly (cf. Jackson, Treiman and Wyld 1957). It is therefore desirable, from this view point too, that b be specified experimentally.

The magnitude of b obtained from beta-spectral shape studies is not as closely defined as that from the K/β^+ ratio work. The theoretical K/β^+ ratios have been recalculated by Perlman, Welker and Wofsberg (1958) and, more recently, with second order corrections for the positron wave functions, by Nguyen–Khac (Depommier, Nguyen-Khac and Bouchez 1960). The experimental work on the ratio of orbital capture to positron emission has been reviewed extensively by Perlman, Welker and Wofsberg (1958), Konijn *et al.* (1958), and Depommier, Nguyen-Khac and Bouchez (1960). The majority of the experiments have been done by indirect methods. These generally involve considerable instrumental uncertainties, such as the assessment of detection efficiencies with solid external sources. Further, to estimate the K/β^+ ratio, a knowledge of $(L+M+\ldots)/K$ capture ratios has to be presumed. In many cases the Fermi Gamow–Teller admixtures of the nuclei investigated are unknown. In order that the results on b can be readily interpreted it is desirable to consider transitions that are either pure Fermi or pure Gamow–Teller.

The first assessment of b from the K/β^+ ratio for the Gamow–Teller radiator ^{22}Na was made by Sherr and Miller (1954) by an indirect technique. They found b to be $(-2\pm4)\%$. A direct observation of the K/β^+ ratio, free from escape effects, was carried out by Drever, Moljk and Scobie (1956) for the Gamow–Teller transition ^{18}F. They used a gaseous source and a wall-less proportional counter technique, and this gave $b = (0{\cdot}8\pm4)\%$. A similar technique was used by Scobie and Lewis (1957). They obtained $b = (-3\pm10)\%$ for the predominantly Fermi transition ^{11}C.

A direct experimental measurement of the K/β^+ ratio, free from escape effects, can readily be made for intermediate and high Z nuclei with an internal source scintillation counter technique. This method permits coincidence counting to be used, and this helps to eliminate background effects. The K-capture and β^+ events are separately recorded, and the K/β^+ ratio follows directly. The present paper reports an experiment carried out by this method to measure the K/β^+ ratio for the allowed decay of ^{58}Co which leads directly to the first excited state (810 kev) of ^{58}Fe. The recorded K-capture and β^+ events were observed in coincidence with the 810 kev γ-ray of ^{58}Fe. The result was used to find an upper limit to the value of b.

The decay scheme of ^{58}Co is shown in figure 1 (cf. Frauenfelder *et al.* 1956). The predominant decay process which proceeds to the first excited state at 810 kev of ^{58}Fe has been shown to be essentially pure Gamow–Teller by the alignment experiments of Dagley *et al.* (1958), with a Fermi admixture of less than $\frac{1}{2}\%$. The spectrum of positrons for this main branch has been investigated by Deutsch and Elliott (1944) and Cheng, Dick and Kurbatov (1952). They found the positron end-point at 470 ± 15 kev and 472 ± 6 kev respectively. These give a log *ft* value of approximately 6·6. The K/β^+ ratio was calculated to be 4·87 by Nguyen-Khac (Depommier, Nguyen-Khac and Bouchez 1960), assuming a 472 kev end point energy. Previous experimental results on the total electron capture/β^+ ratio of ^{58}Co by external source methods are shown in table 1.

Table 1

Author	Total electron capture to β^+ ratio
Good, Peaslee and Deutsch 1946	5·8 ±0·2
Cook and Tomnovec 1956	5·9 ±0·2
Grace, Jones and Newton 1956	6·7 ±1·3
Konijn *et al.* 1958	5·67 ±0·16
Ramaswamy 1959	5·48 ±0·25

To derive a value for the K/β^+ ratio from these results, it is necessary to use either the predicted value of the ratio of L-capture to K-capture, 0·092 (Brysk and Rose 1958) or the recent measured value of this ratio, 0·108 ± 0·004 (Moler 1961).

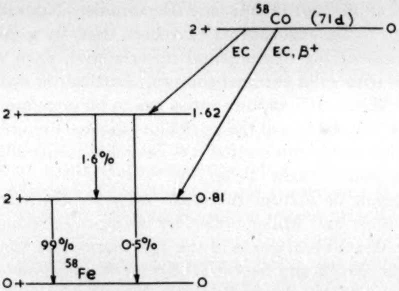

Figure 1. Decay scheme of ^{58}Co.

§ 2. EXPERIMENTAL PROCEDURE

The ^{58}Co was prepared by the ^{58}Ni (n, p) reaction, and was supplied by the Amersham authorities as a separated carrier free chloride. The ^{60}Co content was specified as less than 0·5%. In order to establish the purity of the source, the γ-radiations were checked, using an external source and 2 in. diameter × 2 in. NaI(Tl) scintillation counter with a C.D.C. multichannel pulse height analyser. Aluminium sheet was used to absorb the β^+ radiations, and the source–detector gap kept at 3 in. Except for the two prominent peaks at 810 kev and 510 kev, no other radiations were observed in the region from 100 kev to 2 Mev. To confirm still further the absence of ^{60}Co, an external source was examined in a 2 in. diameter × 2 in. well-type NaI(Tl) crystal. It was found that the ^{60}Co activity was certainly less than 0·1% of the total activity.

In order to analyse the K-capture and β^+ events, a thallium-activated sodium iodide crystal approximately 1 cm diameter × 1¼ cm was grown with a trace of the source by the Bridgman method (1925). Harshaw NaI(Tl) chippings were used. To help to eliminate possible surface effects, the crystal was cut and polished to an area of 4 mm × 8 mm and a thickness of 2 mm, and mounted in an aluminium container fitted with a thin glass window, with magnesium oxide as reflector. An E.M.I. 9514S phototube was used. The K capture events produced K x-rays and K Auger electrons which would be almost wholly absorbed in the active crystal. The β^+ particles would be, mostly, wholly absorbed in the crystal. A few per cent of these liberated near the surface would be recorded in the crystal before being absorbed in the crystal assembly. This would not affect the total β^+ counting rate. After amplification in a non-overloading amplifier, the pulses from this counter were fed by delay cable into a gating unit. This gate was controlled by the γ-ray counter described below. Pulses from the activated crystal which were in coincidence with the peak of the 810 kev radiation in the γ-ray counter, were passed to a multichannel kicksorter.

The γ-ray counter consisted of a 2 in. diameter × 2 in. NaI(Tl) scintillator mounted on another E.M.I. 9514S phototube. A gap of 3 in. lay between this scintillator and the small active crystal. Amplified pulses from the γ-ray counter led to an I.D.L. single-channel kicksorter with the channel set to receive the 810 kev peak. The limits of this channel are shown by the arrows in figure 2. The output of the single channel kicksorter was passed to a univibrator which generated a 5μsec gating pulse. Those

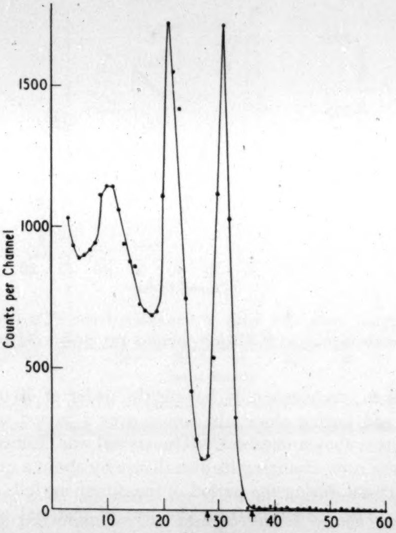

Figure 2. Total gamma ray spectrum of ^{58}Co in a 2 in. diameter × 2 in. NaI(Tl) crystal obtained in coincidence with K-capture and β^+ events in the thin active crystal.

K-capture and β^+ events from the small crystal which were in coincidence with the 810 kev peak were displayed in separate runs. The stability of the system was checked throughout the runs at regular intervals. This was done by noting the counting rate at the single channel output and by taking the spectrum of the γ-ray gating pulses; no gain shifts were observed.

Typical spectra of K-capture and β^+ events in coincidence with 810 kev radiation are shown in figures 3 and 4 respectively. The β^+ spectrum is of course distorted, in particular by partial absorption in the crystal of the associated annihilation radiation.

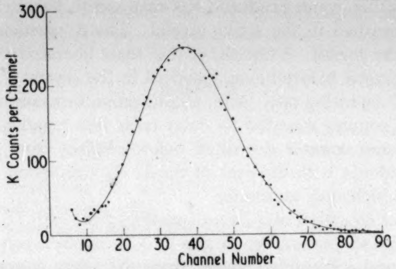

Figure 3. K-capture peak of ^{58}Co (with an internal source) in coincidence with 810 kev gamma ray peak. (1 hour run).

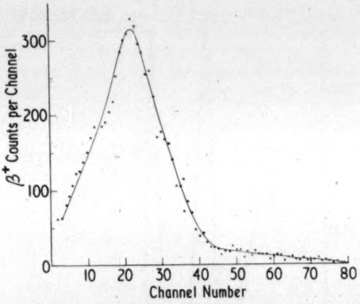

Figure 4. Spectrum associated with β^+ emission from ^{58}Co (with an internal source) in coincidence with 810 kev gamma ray peak. (4½ hours run).

Several runs were taken, each generally having the order of 10 000–20 000 K-events and 5000 β^+ events and lasting about six hours, over a period of three weeks. The consistency of the runs is shown in table 2. The crystal was cleaned and polished twice during the course of the runs, changing its overall size by about a quarter. The strength of the source in the crystal during the period of measurement fell, due to natural decay and loss of material. The reduction from the loss of material was about a quarter. This, and the consistency of the runs, substantiated the absence of surface effects from the source distribution. The random coincidence count was assessed by inserting appropriate delay cable in the main channel. The random rate was 2% and did not affect the observed ratio. There was no contribution from noise and afterglow effects. There were no losses due to dead time.

Table 2

Observed Uncorrected K/β^+ Ratio

Run	1	2	3	4	5	6	7	8
K/β^+ ratio	4·94	4·97	4·95	4·91	4·91	4·93	4·93	4·96

It was necessary to estimate the error arising in the main run owing to the arrival of $\frac{1}{2}$ MeV annihilation radiation simultaneously with 810 keV radiation in the γ-ray crystal, which would affect the β^+ contribution. To this end the γ-spectra in coincidence with the K-capture and β^+ events were analysed separately in the 2 in. scintillator by gating with the K-capture peak and the β^+ spectrum in the active crystal respectively, with the counter arrangement otherwise unchanged. The correction for this effect was then determined and found to be small (0·2%).

A small correction arises from the fact that an 810 keV γ-ray associated with a K-capture event can occasionally produce a low energy (10–100 keV) Compton electron in the 2 mm-thick source crystal and a scattered γ-ray which has a chance of recording in the 810 keV gate. Such an event will then be wrongly recorded as a β^+ event. The source was shown by subsidiary measurements to be distributed symmetrically about the appropriate central face of the crystal so that on average the γ-ray traverses 1 mm thickness of crystal. From γ-ray absorption tables, a 1% correction had to be applied for this effect.

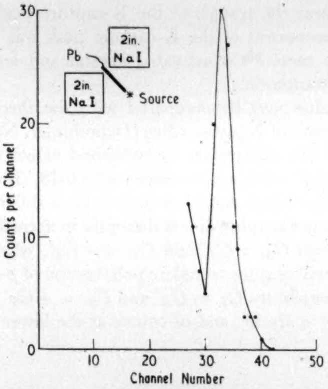

Figure 5. Investigation of the weak capture branch: Peak in the 800 keV region obtained by gamma–gamma coincidence measurements. The inset diagram shows the experimental set-up.

It was necessary to make allowance for the small number of unwanted K-capture x-rays emitted in the transition to the 1·62 MeV level, which would be observed in coincidence with the γ-ray of either of the 810 keV transitions. More accurate data than given in figure 1 were required. This could be readily investigated here because any source strength could be compared with that of the active crystal whose K-capture rate was known. The experimental arrangement for this ancillary measurement is shown in figure 5 (inset). The two counters were fitted with NaI(Tl) crystals, approximately 2 in. diameter × 2 in. On one side a single-channel kicksorter with the window set at the 810 keV peak was used, and on the other side a discriminator set at 700 keV was employed. The two outputs led to a coincidence unit. Pulses from the coincidence unit operated a gate and the associated spectrum from either side could be displayed on the multichannel kicksorter. Figure 5 shows the spectrum from the counter which had the bias set at about 700 keV. The fraction of the weak electron capture branch to the 1·62 MeV state which subsequently proceeded to the 0·81 MeV level by γ emission was found to be (1·25 ± 0·1)% of the K electron events in the main branch. Allowing for the L-capture contribution in this weak branch, a correction of 2·2% had therefore to be made in assessing the K/β^+ ratio for the main branch.

§ 3. RESULTS AND DISCUSSION

The experimental value of the K/β^+ ratio after applying the small corrections for the simultaneous arrival of ½ Mev and 810 kev radiation in the γ-ray crystal, for the Compton escape, and for the weak branch, all referred to above, was $4{\cdot}92 \pm 0{\cdot}09$. The error limit was partly associated with statistics, but mainly with the assessment of the low energy end of the K-capture peak. The random rate, as has been mentioned, was low at all energies observed. The rise at low energy is associated with L-capture events. The K-capture peak was fitted by a statistical distribution to assess the scintillation counter efficiency. The L-capture peak expected at 850 ev would then occur in the region of single electron emission from the photocathode; it would contribute to the low energy rise and to the region near the trough of the K-capture peak. (Further confirmation of the validity of this assessment of the K-capture peak was obtained through studies recently made with the same ^{58}Co activated crystal and an E.M.I. photomultiplier having a still better photocathode.)

The experimental value may be compared with the theoretical value of K/β^+ of 4·87 based on the calculation of Nguyen-Khac (Depommier, Nguyen-Khac and Bouchez 1960). Because of the 6 kev uncertainty in published values for the β^+ end point, the theoretical value of the K/β^+ ratio will become $4{\cdot}87 \pm 0{\cdot}18$. Inserting the value $(1/W)_{\text{av}} = 0{\cdot}75$ in equation (2), the Fierz term is found to be $+0{\cdot}006 \pm 0{\cdot}023$.

Within the stated limits the value of b is therefore in accord with the two component neutrino theory in the form $C_A = C_A'$ and $C_T = -C_T'$, where b vanishes identically. In this form, the theory will require complete polarization of β-particles at high momentum. If the alternative possibility $C_A = C_A'$ and $C_T = +C_T'$ holds instead, then from relation (1), $0 \leq |C_T/C_A| < 0{\cdot}015$; and of course at the lower limit the two interpretations are identical.

ACKNOWLEDGMENTS

The authors would like to thank Professor P. I. Dee for his interest in the work. One of us (B.R.J.) is grateful to the Colombo plan authorities for a Research Fellowship and to the Government of Nepal for its sponsorship.

The Lifetime of the 673 kev Level in ^{132}Xe

By W. D. HAMILTON†

The Department of Physics, The University of Birmingham

Communicated by P. B. Moon; MS. received 13th July 1961

Abstract. The resonant scattering cross section for the 673 kev electric quadrupole transition in ^{132}Xe was directly determined for a particular arrangement of source, scatterer, and detector. The resonant scattering condition was provided by the persistence of nuclear recoil following a preceding transition when the source was in the gaseous phase. The differential cross section for a mean scattering angle of 149° was evaluated as $\sigma(149°) = 1{\cdot}75 \times 10^{-26}$ cm^2 sterad^{-1}, and the value $\tau = (9{\cdot}7 \pm 3{\cdot}0) \times 10^{-12}$ sec was found for the mean-life of the level. This result is in good agreement with that obtained from a Coulomb excitation measurement. The enhancement of the E2 transition probability when represented by the ratio $B(\mathrm{E2}; 0 \rightarrow 2)/B(\mathrm{E2})_{\mathrm{S.P.}}$, has the value 20; this is consistent with the results for even–even nuclei which have characteristic vibrational spectra.

§ 1. INTRODUCTION

THE EVEN–EVEN nuclei in the atomic weight region of xenon are expected to have a well defined spherical equilibrium shape and a spectrum, particularly for the lower excited states, characteristic of quadrupole vibrations about this shape. In the review article by Alder, Bohr, Huus, Mottelson and Winther (1956) a general discussion is given on the spectra of such spherical nuclei. The E2 transition probability, as a result of the quadrupole vibrations, is enhanced compared with the single particle estimate, and in the present case the enhancement for the ground-state transition in ^{132}Xe may be estimated from a determination of the mean-life of the 673 kev level. Furthermore, the first excited states of many of the xenon isotopes, including ^{132}Xe, have been Coulomb-excited in experiments by Pieper, Anderson and Heydenburg (1958), and the relative values for the reduced upward transition probabilities, B(E2), have been determined. It should thus be possible to compare the value of B(E2) with that obtained from resonant scattering and perhaps to assess the validity of the relative values of the Coulomb excitation results.

The first excited state in ^{132}Xe, which is at 673 kev, is populated by the electron capture transition in ^{132}Cs, and also following the β-decay of ^{132}I. In each case the preceding transition has a greater momentum than the ground state γ-ray and is thus capable of providing the resonant scattering condition. The systematics of E2 transitions in even–even nuclei (Goldhaber and Sunyar 1951) indicate that the order of the mean-life of the 673 kev level will require the resonant radiation to be emitted by nuclei in the gas phase in order to permit the persistence of nuclear recoils free from collisions.

§ 2. CHOICE OF SOURCE

The production of ^{132}Cs by the (p, n) reaction will only proceed to any appreciable extent for bombardment energies exceeding 20 MeV, as found by Bhatki, Gupta and Jha (1956) who used 25 MeV protons and obtained ^{132}Cs only in low specific activity.

---

† Now at the Physics Institute, Uppsala University, Sweden.

As an alternative method of production, the (d, α) reaction was tried, and barium oxide was bombarded with 20 MeV deuterons in the Nuffield cyclotron at Birmingham University. Cesium carrier was added to the barium target, and after the barium had been removed by the perchlorate method (Saraf 1954) the Cs was precipitated as $CsClO_4$. From the trial bombardment only a small fraction of the activity could be attributed to ^{132}Cs and it did not appear possible to produce a source strength of the order 10 mc as would be required, even if a target enriched in the ^{134}Ba isotope was used.

The alternative source, ^{132}I, is the β-decay product of the pile-produced ^{132}Te isotope, which may be obtained in high specific activity. The decay scheme of ^{132}I, which is shown in figure 1, is that proposed by Finston and Bernstein (1954), who confirmed the spin assignment of 2^+ to the first excited state from a measurement of the K-electron internal conversion coefficient. The spin sequence 0^+, 2^+, 4^+ and the energy ratio of 2.2 between the second and first excited states are typical of a quadrupole vibrational spectrum.

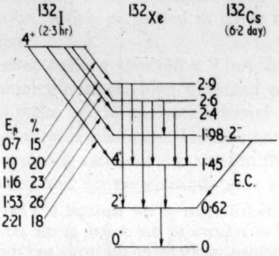

Figure 1. The excited states in ^{132}Xe populated following the β-decay of ^{132}I as proposed by Finston and Bernstein, and the electron capture transition from ^{132}Cs. The percentage intensities of the β-decay modes are listed, and the β- and γ-ray energies are expressed in MeV.

The 2·8 hour half-life of ^{132}I was too short for the present resonant scattering experiment, and for convenience the source was maintained in secular equilibrium with its parent, ^{132}Te, which has a half-life of 77 hours. The chemical form of the source was limited by the boiling point and suitability of the tellurium compound and the choice fell upon tellurium tetrachloride which has a boiling point of 414 °C at standard temperature and pressure.

The 20 mc source was contained in a conical ampoule of Pyrex glass which had an approximate volume of 3 ml. The ampoule fitted inside a metal container, the temperature of which could be controlled. When the ampoule was being filled 0·1 mM of hydrogen was included, and since ICl_4 readily dissociates when gaseous a large fraction of the source should exist as hydrogen iodide. During the preparation of the source several milligrams of solid material were also unavoidably included in the ampoule. This was believed to be mostly stannous chloride from which any occluded iodine should be easily liberated when the source was heated, while the presence of the additional material was not expected to affect the behaviour of the source.

§ 3. EMISSION LINE PROFILE

The decay of ^{132}I by five β-transitions of comparable intensity, and the many γ-cascades which lead to the 673 kev level will greatly complicate the calculation of the line shape of the emitted radiation. The enhancement of the E2 transition probabilities will require that the mean-life of the 1·45 Mev level be short compared with the collision time when the source is gaseous, and will further increase the difficulties.

In constructing the profile of the broadened emission line, transitions from the upper levels to the 1·45 Mev and 673 kev states were considered to have been emitted by nuclei at rest. The recoil momentum distribution in figure 2 then arises from a β–γ cascade, and several γ–γ cascades and single γ-transitions. It was assumed that only the xenon atom accepted the recoil momentum. This would appear to be justified since a large fraction of the source should exist as hydrogen iodide and furthermore since the β–γ cascades have several γ-components it would be expected that the xenon nucleus should be free from any influence of the original $TeCl_4$ molecule before the final stages of the cascades occurred. The fraction of γ-rays which energetically satisfy the resonant condition has the value $F_0(E) = 6{\cdot}4 \times 10^{-2}\ \mathrm{ev}^{-1}$. This would be slightly reduced if all transitions were considered to contribute to the final recoil distribution.

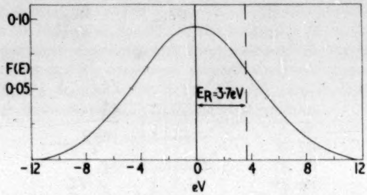

Figure 2. The energy distribution of the emitted 673 kev γ-ray. The absorption line is displaced by 3·7 ev relative to the centre of the emission line as a result of conservation of linear momentum between the γ-ray and the absorbing and emitting nuclei. The area under the curve is normalized to unity and the abscissa $F(E)$ represents the fraction of γ-rays within a unit energy interval.

The effects arising from thermal motion within the source and scatterer can be considered together, and since their contribution to the line broadening will widen the line profile by only a few per cent and have a negligible effect on $F(E)$ in the region of interest, they were neglected in the present case. No account was taken of the angular correlations between the different components of the cascades in view of the other uncertainties; their inclusion could either reduce or increase the fraction of γ-rays which satisfy the resonant condition but probably not to an appreciable extent.

§ 4. EXPERIMENTAL METHOD

The xenon scatterer was the same as that used in previous resonant scattering experiments (Hamilton 1961), but the volume of the xenon gas which was solidified into the container was increased to 12·5 litres at standard temperature and pressure. The intensity of the 673 kev Rayleigh scattered radiation, for which the cross section may be calculated, could not be distinguished above the background with sufficient accuracy to allow it to be compared with that of the resonant scattering, and thus it was impossible to estimate the cross section for the latter from such a comparison. Rather, it was necessary to determine absolutely the number of resonantly scattered γ-rays for a particular geometrical arrangement of source, scatterer and detector. The resonant scattering intensity was obtained from the difference in counting rates when the source was gaseous and solid, since, when the total mean-life of a level is of the order 10^{-11}–10^{-12} sec, it is longer than the collision time within a solid source and there will be no significant resonant scattering.

The small change in effective source position, when it was in the gaseous or solid phases, was conveniently determined by using a comparison scatterer. Iodine was a suitable material for this purpose and 65 g of iodine crystals were packed into a copper cylinder which had the same dimensions as the xenon container and which was also covered with styrofoam. No attempt was made to match the scatterers accurately since the amount of xenon which could be solidified varied up to 10% for different runs, although for any particular run the amount of xenon in the container could be accurately estimated. It was impossible to replace the solid xenon by the iodine scatterer since the xenon container was rigidly attached to an associated pumping system, and the scatterers were placed, as shown in figure 3, on each side of the detector and symmetrical with respect to it and the source. The source–scatterer and detector–scatterer separations were 22·5 cm and 11 cm respectively, and the mean scattering angle was 149°. The radiation incident on either scatterer could be cut off by inserting about 6 cm of heavy alloy between it and the source, which permitted in effect the scatterers to be rapidly and conveniently interchanged.

The scattered radiation after passing through a 3 mm lead filter was detected by a NaI(Tl) crystal $1\frac{1}{2}$ in. diameter by 2 in. long mounted on a 6295 DuMont photomultiplier. A single-channel pulse height analyser selected for recording the radiation which was accepted by a 3 volt wide channel. This channel width which included at least 70% of the photopeak counting rate was also used in the source calibration so that the absolute detection efficiency and source strength were not required.

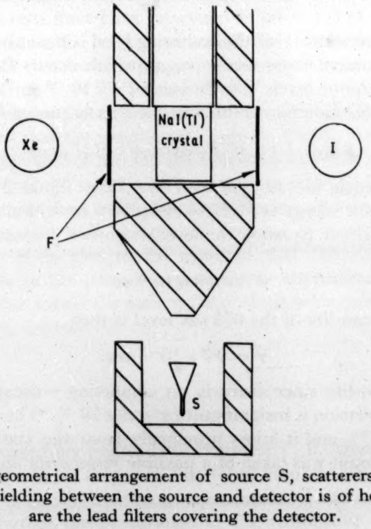

Figure 3. The geometrical arrangement of source S, scatterers, I and Xe, and detector. The shielding between the source and detector is of heavy alloy, and *F* are the lead filters covering the detector.

§ 5. EXPERIMENTAL RESULTS

The mean value of four independent results after correction for source decay and the fraction of xenon scatterer present was $9{\cdot}6 \pm 2{\cdot}4$ resonantly scattered γ-rays per minute. Each of the results was derived from sets of observations in which the counting rates were recorded for a number of 10 minute periods, when the source was hot and cold, and when the scatterer was alternatively iodine and xenon. The 25% statistical error in the mean value arose because of the large background.

Direct calibration of the source at a distance of 50 cm from the axis of the detector and perpendicular to it, gave a counting rate of $1{\cdot}48 \times 10^6$ counts per min when corrected with respect to source decay; the 3 mm lead filter was in position as before. The relative detection efficiencies corresponding to the source–detector separations at which the source was calibrated, and at which the scattered radiation was detected were determined experimentally since the radiation was perpendicular to the crystal axis and the tabulated theoretical coefficients, which are for a source on the detector axis, were not applicable in the present case. It was found that the resonant scattered counting rate when compared with the source calibration counting rate had to be increased by the factor 1·05 to compensate for the decrease in detector efficiency. A further correction to this counting rate was made for the self-absorption of the resonant scattered radiation within the xenon.

The differential resonant scattering cross section which, for a mean scattering angle of 149°, was determined as

$$\sigma(149^\circ) = 1{\cdot}75 \times 10^{-26}\ \mathrm{cm}^2\ \mathrm{sterad}^{-1}$$

is usually represented by an equation having the form (cf. Metzger 1959).

$$\sigma(\theta) = \sigma_{\max}\frac{\pi}{2}F_0(E)\Gamma\frac{f(\theta)}{4\pi}\ \mathrm{cm}^2\ \mathrm{sterad}^{-1}.$$

In the present case the width Γ of the scattering level is the only unknown in the above expression. The maximum cross section $\sigma_{\max}$, which occurs for complete overlap of the emission and absorption levels, has the value $2{\cdot}7 \times 10^{-20}$ cm². The angular distribution function $f(\theta)$ for E2 radiation emitted in the spin sequence 0^+, 2^+, 0^+ is given by

$$f(\theta) = 1 + 0{\cdot}357P_2(\cos\theta) + 1{\cdot}143P_4(\cos\theta),$$

and for a scattering angle of 149°, $f(\theta) = 1{\cdot}19$. From figure 2 the fraction of γ-rays which have the resonant energy is $F_0(E) = 6{\cdot}4 \times 10^{-2}\ \mathrm{ev}^{-1}$. Following the substitution of these terms in the above equation the level width was evaluated as

$$\Gamma = 6{\cdot}8 \times 10^{-5}\ \mathrm{ev}.$$

The corresponding mean-life of the 673 kev level is then

$$\tau = 9{\cdot}7 \times 10^{-12}\ \mathrm{sec}.$$

This is the total mean-life since there is no competing γ-decay mode to the ground state and internal conversion is insignificant ($\alpha < 3 \times 10^{-3}$). The probable error on the mean-life was set at 30% and it arises principally from the statistics of the recorded counting rates; no account was taken of a possible large error in $F_0(E)$ as it could not readily be assessed.

§ 6. DISCUSSION

In the Coulomb excitation experiments by Pieper, Anderson and Heydenburg (1958) the B(E2) values were determined relative to the assignment of the value $B(\mathrm{E2}) = 0{\cdot}48 \times 10^{-48}\ e^2\ \mathrm{cm}^4$ to the 535 kev transition in ^{130}Xe. They based this assignment on the systematics of the B(E2) values for even–even nuclei in the region of xenon, and no error was quoted for the results. Their values of B(E2) for ^{131}Xe (364 kev) and ^{132}Xe (673 kev) and the associated downward transition probabilities and mean-lives are given in the table together with the results of the present resonant scattering experiment, and the one previously reported on ^{131}Xe (Hamilton 1961). It was assumed that the total internal conversion coefficient was negligible in each case, and that the transitions were pure E2.

E_γ(kev)	B(E2)	$T(\text{E2}; I_f \to I_i)$	τ(E2) (sec)	$\tau_{\text{R.S.}}$ (sec)
364(^{131}Xe)	2·07	$8{\cdot}7 \times 10^{10}$	$1{\cdot}14 \times 10^{-11}$	$(2{\cdot}0 \pm 0{\cdot}5) \times 10^{-11}$
673(^{132}Xe)	0·32	$1{\cdot}04 \times 10^{11}$	$9{\cdot}6 \times 10^{-12}$	$(9{\cdot}7 \pm 3{\cdot}0) \times 10^{-12}$

The mean-life from Coulomb excitation of the 364 kev level in ^{131}Xe is some 40% smaller than the experimentally determined value, while for the 673 kev level, there is very good agreement between the values derived from the Coulomb excitation measurements and from the resonant scattering cross section. It perhaps might be a better test if the ratios of the mean-lives as determined by two methods were compared, since this should remove any possible systematic experimental errors in either of the methods. From the values listed in the table it can be seen that these ratios agree to within the error associated with the resonant scattering measurements.

The vibrational spectra have been studied in a number of cases by Coulomb excitation and many of the results have been presented in table V.6 of the review article by Alder *et al.* (1956). In this, for the purpose of comparison, the reduced upward transition probability, $B(\text{E2};0 \to 2)$, has been expressed in terms of a single particle transition probability given by $B(\text{E2})_{\text{S.P.}} = 3 \times 10^{-5} A^{4/3}\ 10^{-48}\ e^2\,\text{cm}^4$. The present result for ^{132}Xe, which yields 20 for this factor, compares favourably with the tabulated values.

It may be considered that the assignment made by Pieper, Anderson and Heydenburg (1958) to the B(E2) value of the 535 kev transition in ^{130}Xe is justified since there is good agreement between the ratios of the mean-lives of levels in ^{131}Xe and ^{132}Xe as obtained from resonant scattering and Coulomb excitation, and since the 673 kev transition probability is consistent with the general features of vibrational spectra in this atomic weight region. It is also to be expected that the value of $F_0(E)$ used in evaluating the mean-life in the present experiment is approximately correct but it is not possible to say to what extent the assumptions which were made, when constructing the emission line profile, are true.

ACKNOWLEDGMENTS

It is a pleasure to record my gratitude to Professor P. B. Moon who supervised the work. I am grateful to Dr. G. F. Pieper of The Johns Hopkins University for enlightening comments on the Coulomb excitation experiments. I am much indebted to Dr. J. D. Jenkins who undertook the preparation of the radioactive source at the Radiochemical Centre, Amersham, and also to Dr. K. F. Chackett who was most helpful with the ^{132}Cs preparation at Birmingham. I gratefully acknowledge the receipt of a Research Studentship from the Ministry of Education for N. Ireland during the course of the above work.

The Lifetime of the 638 kev level in ^{131}Xe

By W. D. HAMILTON†

Department of Physics, The University of Birmingham

Communicated by P. B. Moon; *MS. received* 13*th July* 1961

Abstract. A nuclear resonant scattering method was used to estimate the mean-life of the 638 kev level in ^{131}Xe. The result of 4×10^{-13} sec, when compared with the Weisskopf estimate, is consistent with an enhanced E2 transition or a retarded M1 transition. However, in reported Coulomb excitation experiments there is no evidence for an E2 transition probability consistent with the present mean-life, and it is suggested that the transition may be predominantly M1.

§ 1. INTRODUCTION

THE SPIN and parity of the 638 kev level in ^{131}Xe do not yet appear to have been conclusively established. The shell model predictions are not necessarily applicable to a level of such high energy, and indeed, it is thought unlikely that the state could be represented by a single particle configuration (Verster, Nijgh, van Lieshout and Bakker 1951). The level is populated by the 335 kev β-transition from ^{131}I, and has a log $ft = 6{\cdot}7$. This value is typical of an allowed or l-forbidden transition for this A-region, and since the ground state of ^{131}I is $7/2^+$, the 638 kev level may have a spin of 5/2 or 7/2 and positive parity. There is a wide range of values for the K-electron conversion coefficient and these indicate that the transition could be E1 or E2 as has been mentioned by Bell (1955) in his survey of the many ^{131}I decay scheme studies. The deviations, to a large extent, are removed when account is taken of the relative abundances of the ^{131}I decay modes as used in the different determinations. The results are then in general agreement and indicate that the transition is electric quadrupole.

§ 2. EXPERIMENTAL METHOD

The mean-life was determined from a measurement of the nuclear resonant scattering cross section. The experimental arrangement of source scatterer and detector was the same as that used in the investigation of the resonant scattering of the 364 kev γ-ray also in ^{131}Xe (Hamilton 1961). The resonant scattering condition for the 638 kev γ-ray was provided by the persistence of nuclear recoil following the β-decay which populated the state when the source was gaseous. If it is assumed that the xenon alone accepts the total recoil momentum then the 335 kev β-transition imparts to the nucleus a maximum recoil momentum of 1·32 mc which is adequate to compensate the 1·25 mc lost by the 638 kev γ-ray. The number of γ-rays $F_0(E)$ which have the resonant energy is $4{\cdot}2 \times 10^{-3}$ ev^{-1}, but there may be a large error in this value since the absorption line occurs near the extremity of the emission line's energy distribution of which the profile was determined by a graphical method.

It was not possible to make a direct measurement of the number of γ-rays resonantly scattered, since it was not possible to estimate accurately the fraction of emitting nuclei which satisfied the resonant scattering condition when the source was gaseous. Rather, since this condition was expected to be the same for both the 364 kev and 638 kev transitions, the intensities of these resonantly scattered γ-rays were compared when the source was solid and gaseous. It was expected that only for the latter condition would the resonant scattering be significant so that the measurement with the solid source should indicate the background. These intensities and the corresponding transition probabilities are proportional to the resonant scattering cross section, and since this has been determined for the 364 kev γ-ray, it might then be obtained for the 638 kev transition.

---

† Now at the Physics Institute, Uppsala University, Sweden.

A 100 mc source of ^{131}I in the form of 4×10^{-3} mM molecular iodine was enclosed together with approximately 0·05 mM of hydrogen in a pyrex glass ampoule, which had a volume of 3·5 ml., and as before it was possible to control its temperature. A mean scattering angle of 119° was selected and all spectra were recorded when a 3 mm lead filter covered the $1\frac{1}{2}$ in. diameter by 1 in. NaI(Tl) crystal. The spectra, which were displayed on a 100-channel analyser, were taken when the source was gaseous and solid, and when the xenon scatterer was alternatively in position and absent. The correction for the change in effective source position when in the different phases was made as described in the earlier experiment. Resonant scattering was found to occur only when the source was gaseous. The areas below the curves representing the 364 kev and 638 kev resonantly scattered γ-rays were corrected for the self-absorption within the scatterer and with respect to the relative abundance and detection efficiency of the transitions which were found from the direct spectrum.

§ 3. RESULTS AND DISCUSSION

The 364 kev resonant scattering intensity after applying the above corrections was found to exceed that of 638 kev by the factor 1·87. The partial mean-life of the 364 kev level had previously been determined as $(2{\cdot}0 \pm 0{\cdot}5) \times 10^{-11}$ sec and the corresponding resonant scattering cross section is $\sigma(119^\circ) = 2{\cdot}4 \times 10^{-26}\ \mathrm{cm}^2\ \mathrm{sterad}^{-1}$. From the intensity ratio of the resonantly scattered γ-rays, the cross section for the 638 kev γ-ray is $\sigma(119^\circ) = 1{\cdot}08 \times 10^{-26}\ \mathrm{cm}^2\ \mathrm{sterad}^{-1}$. If it is assumed that the 638 kev γ-ray arises from the spin change $\frac{7}{2}^+ \rightarrow \frac{3}{2}^+$ then the peak value of the resonant scattering cross section is $\sigma_{\max} = 12{\cdot}08 \times 10^{-21}\ \mathrm{cm}^2$. The mean-life of the level may be evaluated from an appropriate expression for the differential resonant scattering cross section (cf. Metzger 1959) and has the value $\tau = 3{\cdot}9 \times 10^{-13}$ sec. If a collision time of $t = 2 \times 10^{-14}$ sec is assumed for the source nuclei when in the solid phase (Ofer and Schwartzchild 1959), then the fraction of recoils persisting after the time $\tau = 4 \times 10^{-13}$ sec is $A = 1 - \exp(t/\tau) \simeq 5\%$, and for the present experiment, resonant scattering should only be observable when the source is gaseous, or possibly liquid for which the collision time may also be sufficiently long.

The statistical error in this determination of the mean-life is less than 30%, but the result cannot be considered to be more than a good estimate since there is a large uncertainty in $F(E)$. Furthermore, the effect of thermal broadening has been ignored, for although small compared with the width of the emission line profile due to β-decay, it should have been included in the total line broadening, since the absorption level overlaps the emission level near its extremity where small effects may not be completely negligible. However, the absence of observable resonance scattering for the solid source does indicate that the mean-life cannot be shorter than about 10^{-13} sec. The transition probability is some 140 times greater than the Weisskopf estimate for a single particle E2 transition.

The Coulomb excitation experiments by Pieper, Anderson and Heydenburg (1958), did not indicate any γ-rays which could be attributed to this transition. A value of 4×10^{-13} sec for the mean-life of the 638 kev level would give a reduced upward transition probability of $B(\mathrm{E2}) = 3{\cdot}87$, and Dr. Pieper, in a private communication, mentioned that they should have been able to detect 638 kev γ-rays corresponding to 10% of this value for $B(\mathrm{E2})$. A possible explanation for the absence of Coulomb excitation is that the 638 kev level does not de-excite principally by E2 radiation. The E1 multipolarity of the transition may be excluded on the basis of the values for the K electron conversion coefficient. However, α_K and the K/L ratio are not particularly sensitive to an admixture of M1 with the E2 radiation, even to a considerable degree. Such a mixed transition could occur if the spin and parity of the 638 kev level is $\frac{5}{2}^+$. This assignment is in agreement with the β-transition being l-forbidden ($g_{\frac{7}{2}^+} \rightarrow d_{\frac{5}{2}^+}$), and with $\log ft = 6{\cdot}7$.

The above value of the mean-life must now be slightly adjusted to take into account the change in the factor which represents the statistical weight of the transition and enters into the expression for $\sigma_{\max}$ through the ratio $(2J_i+1)/(2J_f+1)$, where J_i and J_f are respectively the spins of the excited and final states. Also, the angular distribution function of the resonantly scattered radiation is now based on the new spin sequence $\frac{3}{2}^+$, $\frac{5}{2}^+$, $\frac{3}{2}^+$, and should be dependent on the E2:M1 mixing ratio. If it is assumed that the 638 kev level is de-excited by a pure M1 transition, the mean-life then has the value $\tau \simeq 3 \times 10^{-13}$. The Weisskopf estimate for a 638 kev M1 transition is $1{\cdot}4 \times 10^{-13}$ sec, and if the M1 transition probability is relatively unhindered, the experimentally determined mean-life is also consistent with a large M1 admixture.

Thus, while the mean-life of the level, as would be expected, is not particularly sensitive to the M1 admixture, a value of the order 4×10^{-13} sec may be considered to be a good estimate which is essentially independent of the E2:M1 admixture and spin of the level. This value and the absence of Coulomb excited 638 kev γ-rays suggest an appreciable M1 admixture. It may be hoped that the L_{I}:L_{II}:L_{III} ratios are more sensitive to the multipolarity of the radiation, but results for such measurements have not yet been reported.

Note added in proof.—The electric hfs alignment of ^{131}I nucleus was made recently by Johnson, Schooley and Shirley (1960), who concluded from their measurements of the γ-ray angular distribution that the 637 kev level had spin $\frac{5}{2}^+$ and de-excited by pure E2 radiation. The latter is inconsistent with the results of Coulomb excitation and the present resonant scattering experiment.

ACKNOWLEDGMENTS

I wish to express my gratitude to Professor P. B. Moon under whose supervision the work was carried out. I am indebted to Dr. G. F. Pieper of The Johns Hopkins University for his helpful comments on the Coulomb excitation experiment and to Dr. J. D. Jenkins at the Radiochemical Centre, Amersham, who prepared the source. I am also pleased to acknowledge the receipt of a Research Studentship from the Ministry of Education for N. Ireland.

New Bands in the Second Negative System of Oxygen

Communicated by P. K. Carroll

The molecular spectrum of O_2^+ consists of two well-known systems: the First Negative system whose strongest bands lie in the visible and infra-red region of the spectrum and the Second Negative system which extends throughout the visible and near ultra-violet. In this laboratory a complete survey of the O_2^+ spectrum from 7000 Å to 400 Å has recently been made in a search for new transitions. No new systems were in fact found; but a considerable extension of the Second Negative system was observed and it was thought worth while reporting briefly the measurements of the new bands.

The source employed in the experiments was a high frequency discharge through pure oxygen. Spectra of the region 2800–400 Å were taken with a new 3-metre vacuum spectrograph (dispersion 2·5 Å mm^{-1}) using Ilford QII plates. The region 7000–2800 Å was photographed on a Hilger E 478 prism spectrograph using both the glass and quartz optics over their appropriate ranges. A complex group of bands at about 4350 Å was photographed in the second order of the 21 ft grating spectrograph. Ilford Zenith and Astra III plates were used in these experiments.

† Vacuum wavelengths. These heads are difficult to locate due to many-line band structure.
‡ Weak and somewhat uncertain bands.

The wavelengths and vibrational assignments of the new bands are given in the table. Previous data on the vibrational structure of the system are due to Johnson (1924) who reported all the stronger bands and Feast (1950) who identified a considerable number of weaker bands. In the same region as the Second Negative system Johnson had observed a number of other features which he attributed to O_3. Feast however identified most of the 'O_3' bands as either new bands of the second negative system or atomic lines of OII.

While the present observations are in agreement with Feast where 'O_3' features are identified as weaker O_2^+ bands, they suggest that the identification of some of Johnson's 'O_3' bands as OII lines is less certain. Most of these features appear on the present plates with a band-like structure and in some cases they can be identified as further O_2^+ bands. Thus the features reported by Johnson at 4464·7 Å, 4333·3 Å and 4316·5 Å can be identified from the table as the R_1 heads of the 3–11, 2–10 and 4–11 bands respectively while the feature at 4276·9 Å is probably the R_2 head of the 11–14 band. The two features at 3378·4 (identified by Feast as the OII line 3377·2 Å) and 3374 appear on the present plates as band heads of moderate strength, although it has not been possible to assign them convincingly to the second negative system. The features at 3284·6 Å and 3278·1 Å, identified by Feast as the OII lines 3287·59 Å and 3277·69 Å respectively, appear as weak and somewhat confused band structure.

An interesting aspect of the present work is the appearance of high members of the $v' \rightarrow 0$ progression. It should be pointed out that in this progression the band heads for higher v' values become difficult to locate and the last band which could be identified with any confidence was the 23–0 band at 1942 Å. Beyond this point to about 1870 Å there appeared a considerable amount of close line-like structure. As the dissociation limit for the $A^2\Pi$ state is the same as for the $X^2\Pi$ state, $O(^3P) + O^+(^4S)$ at 53 600 cm^{-1}, (Watanabe and Marmo 1956) it follows that the structure observed at 1870 Å (53 500 cm^{-1}) must be due to transitions from levels lying very close to the dissociation limit. The investigation of this region under considerably higher resolution should therefore enable a very accurate and direct determination of the dissociation energy of 0_2^+ to be made. It would also provide information on the structure of the $A^2\Pi$ state near its dissociation limit. Brix and Herzberg (1954) have observed pronounced changes in the spin splitting of the $B^3\Sigma$ state of O_2 as the dissociation limit is approached. It is possible that an analogous change occurs in the structure of the $A^2\Pi$ state. This could account for the many-lined appearance of the O_2^+ spectrum in the 1870–1950 Å region.

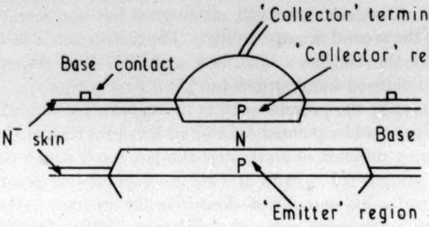
Excess High-frequency Noise in Junction Transistors

For ideal diffusion transistors there is ample experimental evidence to support the accepted theoretical model for low-level noise behaviour at high frequencies (Guggenbühl and Strutt 1957, van der Ziel 1959). A statistical investigation of a large batch of commercial p–n–p alloy-type transistors of normal asymmetrical construction showed, however, that many produced excess noise. Metallurgical cross-sectioning indicated that the excess noise was associated with non-alignment of the emitter–collector axes. In the worst cases a large part of the emitter junction extended beyond the periphery of the collector junction and was therefore opposite the surface of the base adjacent to the collector. It seemed likely that the excess noise was associated with this surface. For proof, the normal roles of emitter and collector of an ideal asymmetrical transistor were interchanged. In this way about half the 'emitter' junction area overlaps the surface of the base around the collector.



Schematic representation of 'reversed' asymmetrical transistor.

Note. P, N used here, corresponding to the normal use p, n.

The transistor chosen was first shown to produce theoretical noise for emitter currents i_E up to 4mA when connected normally. When reversed the transistor had a cut-off frequency of 1·3 Mc/s and a low frequency near-short-circuit current transfer coefficient in common base of 0·89 at i_E† = 1·0 mA. Measurements of noise figure were made over a wide range of source resistance R_0 for emitter currents from 100 μA to 5 mA and for frequencies between 100 kc/s and 8 Mc/s. There was little difference between measured noise figure F_m and calculated theoretical noise figure F_t at the lower frequencies.

Excess noise figure, $\Delta F \equiv F_m - F_t$, became detectable below 500 kc/s and increased with frequency thereafter. For 'collector' currents i_C up to 2 mA, ΔF increased as i_C^2 but somewhat less rapidly at higher currents. There was a linear dependence of ΔF on R_0 at high R_0. Under extreme conditions (high i_C, R_0 and frequency) values of ΔF considerably greater than F_t itself were determined.

As far as device performance is concerned the excess noise figure can be accounted for by an additional noise source represented by a noise current generator i_{cs} in parallel with the normal shot noise generator at the 'collector'–base junction. Above 500 kc/s the spectral density of this additional noise source is invariant with frequency.

The purpose of this letter is to put forward a possible model to account for this extra noise. An N$^-$ exhaustion layer is assumed to exist on the surface of the base as shown in the figure. Where the 'emitter' and 'collector' junctions meet the surface

---

† Upper case suffixes refer to direct current components, lower case to small-signal and noise components.

PN^- junctions will exist. Only that at the 'collector' need be considered. At the surface the PN^- junction takes up some of the applied 'collector'-base bias voltage; the remainder produces a radial drift field in the N^- surface skin and biases the NN^- junction in reverse. The PN 'collector' junction produces full shot noise of the current i_{CN} collected by it. The remainder of the collector current $i_{CS} = i_C - i_{CN}$ flows to the 'collector' terminal through the PN^- junction via the NN^- junction. Hole–electron pairs pass randomly from the base into the N^- region and drift with ambipolar drift velocity towards the PN^- junction at the 'collector'. While drifting they produce concentration–fluctuation noise similar to generation–recombination noise in a filament. The holes which finally reach the PN^- junction carry the current i_{CS} and produce full shot noise. This may be included in the usual way in the shot noise generator at the collector.

The excess noise associated with the concentration fluctuations in the surface skin may be represented by a voltage generator e_s in series with r_s. It should have the spectral form of equation (1)

$$\overline{e_s^2} = K r_s^2 i_{CS}^2 \frac{\tau}{(1+\omega^2\tau^2)}. \qquad (1)$$

Here K is a constant, r_s is the resistance of the skin, τ is the lifetime of hole–electron pairs in it and ω is angular frequency. If the ambipolar drift time is comparable with τ, the frequency dependence of $\overline{e_s^2}$ is only slightly modified. Effectively r_s is in series with c_{cs}, the depletion-layer capacitance of the PN^- junction. It is expected that $r_s \ll 1/j\omega c_{cs}$ so that the voltage generator e_s may be replaced by a current generator i_{cs} across c_{cs}, i.e. in parallel with the total collector capacitance c_c. The form of $\overline{i_{cs}^2}$ is

$$\overline{i_{cs}^2} = K r_s^2 i_{CS}^2 \omega^2 c_{cs}^2 \frac{\tau}{(1+\omega^2\tau^2)}. \qquad (2)$$

At low frequency ($\omega\tau \ll 1$) this increases as ω^2 and at high frequency ($\omega\tau \gg 1$) is independent of frequency. This can explain the dependence of ΔF on frequency if τ is about 0·5 μsec, which is a reasonable value. If τ is independent of i_{CS} then $\overline{i_{cs}^2}$ is proportional to i_{CS}^2. An increase of τ under high-level conditions will weaken this dependence as is required. There will be some correlation between e_s and the 'emitter' noise generator, but in view of the extra transit time for holes at the surface this will be weak and can be ignored to a first order at high frequencies.

It is proposed to test the validity of this model further by controlling the surface conditions using a field electrode and gaseous ambients (Beale, Thomas and Watkins 1958). A low resistivity surface skin should not produce significant excess noise.

Cyclotron Resonance at 4 mm Wavelength

Cyclotron resonance absorption from hole carriers has been investigated in high purity p-type germanium at 4·3 mm wavelength over the temperature range 10 to 100 °K. A modified 8 mm microwave spectrometer was employed for these measurements using a substantially non-resonant cavity system with the 4 mm power derived from a crystal doubler. The hole carriers were obtained by thermal ionization of the shallow acceptor impurities ($\sim 3\times10^{12}$ cm^{-3}).

The results obtained with this spectrometer have extended the measurements recently reported by Bagguley, Stradling and Whiting (1961). In particular, the new absorption line found by these authors in the [110] crystallographic direction has been established beyond reasonable doubt as arising from a hole carrier with a true effective mass of $0{\cdot}26_5 m_e$. The greater resolution which has been obtained at 4·3 mm wavelength has allowed this new absorption line to be observed at temperatures up to 60 °K. These observations verify the suggestion that the absorption line arises from the motion of a classical particle. It is not related to the quantum mechanical fine structure which is found at very low temperatures (Fletcher, Yager and Merritt 1955).

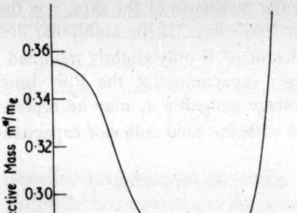

Figure 1. The variation of effective mass in the heavy hole band of germanium calculated as a function of **k**H in the [110] direction.

A numerical calculation shows that, for the heavy mass band in the [110] direction, the cyclotron effective mass has a minimum value for those carriers which have a translational energy in the direction of the magnetic field roughly one half of the maximum value possible on any given energy surface. Carriers in this region of wave vector space will have effective masses which are slowly varying functions of the wave vector, $\mathbf{k}_H$, in the direction of the magnetic field. There will be a definite lower limit for the effective mass of these carriers and a spread on the high mass side. This is evident in the recorded absorption line which has a sharp leading edge and a 'tail' on the high field side.

The variation of the effective mass with the wave vector $\mathbf{k}_H$ calculated for the [110] direction is shown in figure 1. The values for the constants in the equation for the energy surface

$$E(\mathbf{k}) = Ak^2 \pm [B^2k^4 + C^2(k_x{}^2k_y{}^2 + k_y{}^2k_z{}^2 + k_z{}^2k_x{}^2)]^{1/2}$$

(Dresselhaus, Kip and Kittel 1955) used in this calculation were $A = -13{\cdot}2$, $|B| = 8{\cdot}7$, $|C| = 11{\cdot}6$. These values differ slightly from those given previously by Bagguley, Stradling and Whiting (1961), for the same germanium crystal (G.E.b.1). With the present values, however, it is possible to fit not only the anisotropy of the heavy-mass hole but also the new absorption line without making any further assumptions. The discrepancy arises because of the approximations involved in relating the measured effective masses to the constants in the energy equation. A numerical calculation shows that the relation given by Dresselhaus, Kip and Kittel (1955) is less accurate than had been anticipated in the [100] direction.

The light-mass hole increases in mass as the temperature increases as shown in figure 2. This increase in mass is in the opposite direction to that which would arise from the decrease in energy gap with temperature, but is in good agreement with the theory of Kane (1956) where the change in mass arises from the change in curvature of the energy bands away from the origin in **k** space. From the published curves given by Kane we estimate that the light-mass hole in germanium will have an effective mass of the order

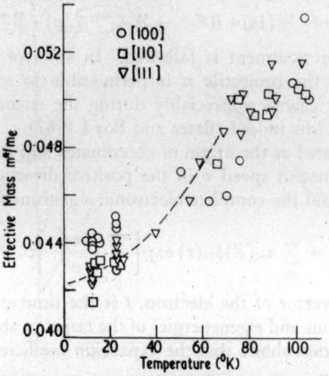

Figure 2. The temperature dependence of the light-mass hole in germanium. ▽, □, ○, experimental points obtained at 4·3 mm wavelength; – – – – – mean of the results obtained at 8·5 mm wavelength.

$$\frac{m^*}{m_e} = \frac{1}{24 - 2\times 10^{-12}k^2}$$

over the temperature range covered by our experiments. This leads to a value of about 0·05 m_e at 100 °K in agreement with our results.

Distortion Approximation to Cross Sections for Excitation of 1s–2p Transition of Hydrogenic Ions by Bare Nuclei

Little theoretical work has been done on inelastic collisions between charged atomic systems and no detailed quantal calculations on the cross sections have been reported. This note describes the application of the distortion approximation (Bates 1959) to the study of the excitation of a target hydrogenic ion with nucleus of charge $\mathscr{Z}_t e$ from the 1s to the 2p level by a projectile nucleus of charge $\mathscr{Z}_p e$:

$$\mathrm{A}^{(\mathscr{Z}_t-1)+}(1\mathrm{s})+\mathrm{B}^{\mathscr{Z}_p+} \rightarrow \mathrm{A}^{(\mathscr{Z}_t-1)+}(2\mathrm{p})+\mathrm{B}^{\mathscr{Z}_p+}. \tag{1}$$

An impact parameter treatment is followed. In spite of the Coulomb repulsion between the target and the projectile it is permissible to suppose that the relative velocity vector does not change appreciably during the encounter unless the relative energy of motion is very low indeed (Bates and Boyd 1962).

Let the target be located at the origin of coordinates and let the projectile, position vector $\mathbf{R}$, move with constant speed v in the positive direction along a line distant ρ from the Z axis. Expand the complete electronic eigenfunction according to

$$\Psi(\mathbf{r}, t) = \sum_m a_m(Z)\phi_m(\mathbf{r}) \exp\left[-\frac{i\epsilon_m Z}{v} \right], \quad Z = vt \tag{2}$$

where $\mathbf{r}$ is the position vector of the electron, t is the time and $\phi_m(\mathbf{r})$ and ϵ_m are the unperturbed eigenfunctions and eigenenergies of the target in atomic units. Substitution in the Schrödinger equation shows that the expansion coefficient must satisfy

$$i\frac{\partial a_n(Z)}{\partial Z} = \frac{1}{v}\sum_m a_m(Z)U_{nm}(\mathbf{R}) \exp\left[-\frac{i(\epsilon_m-\epsilon_n)Z}{v} \right] \tag{3}$$

where $U_{nm}(\mathbf{R})$ is the matrix element with respect to states m and n, of the interaction potential arising from the projectile. This set of coupled differential equations is effectively exact. A scaling law may be derived which enables results on a family of processes like (1) to be presented compactly.

Introducing

$$\mathbf{R}' = \mathscr{Z}_t\mathbf{R}, \qquad Z' = \mathscr{Z}_t Z \tag{4}$$

and noting that the interaction matrix elements may be written

$$U_{nm}(\mathbf{R}) = \mathscr{Z}_t\mathscr{Z}_p U_{nm}'(\mathbf{R}'), \tag{5}$$

where $U_{nm}(\mathbf{R}')$ does not involve $\mathscr{Z}_t$ or $\mathscr{Z}_p$, and that

$$\epsilon_m = \mathscr{Z}_t^2\epsilon_m', \tag{6}$$

where ϵ_m' is a constant, it may be seen from (3) that

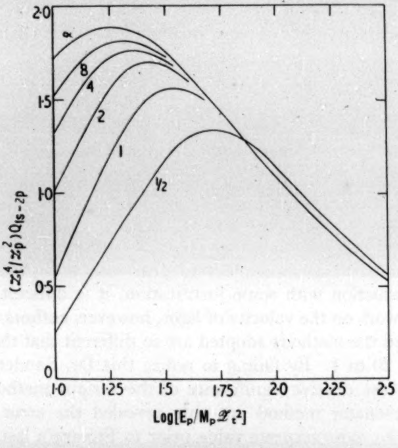
$$i\frac{\partial a_n(Z')}{\partial Z'} = \frac{\mathscr{Z}_p}{\mathscr{Z}_t}\left(\frac{\mathscr{Z}_t}{v}\right)\sum_m a_m(Z')U_{nm}'(\mathbf{R}') \exp\left[-i(\epsilon_m'-\epsilon_n')Z'\frac{\mathscr{Z}_t}{v} \right]. \tag{7}$$

Hence $a_n(\infty)$ depends on $\mathscr{Z}_t\rho$, $\mathscr{Z}_t/\mathscr{Z}_p$ and $v/\mathscr{Z}_t$ only. Since the excitation cross section is given by

$$Q_{0n} = 2\pi\int_0^\infty \rho|a_n(\infty)|^2\,d\rho \tag{8}$$

it follows that $\mathscr{Z}_t^2 Q_{0n}$ may be expressed in terms of two parameters $\mathscr{Z}_t/\mathscr{Z}_p$ and $v/\mathscr{Z}_t$, or instead of the latter $E_p/M_p\mathscr{Z}_t^2$ where E_p and M_p are the energy and mass of the projectile.

Using the distortion approximation, the cross section $Q_{1s,2p}$ for (1) was computed for selected values of $\mathscr{Z}_t/\mathscr{Z}_p$ and over a range of values of $E_p/M_p\mathscr{Z}_t^2$ (all such that the effect of the Coulomb repulsion is utterly negligible). The formulae which arise need not be displayed since they are obvious generalizations of formulae contained in an earlier paper on the excitation of the same transition in atomic hydrogen (Bates 1961).



Excitation of the 1s–2p transition in a target hydrogenic ion with nucleus of charge $\mathscr{Z}_t e$ by a projectile nucleus of charge $\mathscr{Z}_p e$. The value of $\mathscr{Z}_t/\mathscr{Z}_p$ is indicated on each curve. The distortion approximation cross section Q_{1s-2p} is in units of $\pi a_0^2 (8 \cdot 8 \times 10^{-17}\ \mathrm{cm}^2)$; the energy E_p of the projectile nucleus is in kev and the mass M_p is on the chemical (^{16}O) scale.

The results are presented in the figure, the dependent variable being taken to be $(\mathscr{Z}_t^4/\mathscr{Z}_p^2)Q_{1s,2p}$ since this combination depends only on the independent variable $E_p/M_p\mathscr{Z}_t^2$ in the case of the first Born approximation. As would be expected the curves tend to a limit as $\mathscr{Z}_t/\mathscr{Z}_p$ approaches infinity. They do so rather slowly at low energies.

This investigation has been supported by the U.S. Office of Naval Research under Contract No. N.62558–2637. It is a part of Project 'Defender' sponsored by the Advance Research Projects Agency Department of Defence.

REVIEWS OF BOOKS

The Fundamental Atomic Constants, by J. S. SANDERS. Pp. 88. (London: Oxford University Press, 1961.) 10*s*.

There is an increasing interest in the values of fundamental atomic constants, among which it is usual to include the velocity of light, because they are now being used in practical applications as standards of measurement. Some of them are related to the units of mass, length and time by direct measurement but others can be obtained only indirectly by combining a number of experimental results. It is the experimental results that are important and in this attractively produced little volume Dr. Sanders gives a most readable and useful introduction to this aspect of the subject.

The methods of measuring the Faraday, e/m, h/e and the Rydberg constant are briefly but clearly outlined. The longest section is devoted to some recent determinations of the velocity of light and fairly full descriptions are given of the measurement of the gyromagnetic ratio of the proton, and the proton magnetic moment.

One of the most difficult problems facing an experimenter is the assessment of the accuracy of his result, but if the values are used as standards of measurement or to assist in the determination of other fundamental constants the question of accuracy is of first importance. Dr. Sanders has chosen not to deal with this problem because, as he explains in the introduction with some justification, it is difficult to decide what the limits represent. In work on the velocity of light, however, authors do explain how they obtain their limits and the methods adopted are so different that they could change the limits by more than 20 to 1. By failing to notice this Dr. Sanders gives a somewhat wrong impression of the relative significance of the various methods of measurement used. The cavity resonator method not only revealed the error in Birge's adopted value but also gave the most accurate value prior to Froome's last determination.

L. ESSEN.

Quantum Theory of Atomic Structure, Vol. II, by J. C. SLATER. Pp. ix+439. (London: McGraw-Hill, 1960.) £5 15*s*.

Professor Slater disarms the critic, in his preface to this volume, by pointing out that while the first volume of this book was designed as a textbook, this second one is much more a work of reference for readers already versed in the simpler aspects of atomic theory.

The content of the book extends from an introduction of the Hartree–Fock method to a discussion of hyperfine structure. A lucid treatment of group theory introduces the heavy discussion of combination of angular momenta, and there are chapters on Dirac's theory of spin, the magnetic behaviour of complex atoms and radiation transition probabilities. It might have been profitable to the reader to have had more on density matrix methods, and perhaps some discussion of the effects of perturbing fields of, for example, cubic symmetry. The latter topic belongs more to the theory of the solid state but is illuminating for atomic theory.

This is an easier book in several ways than Condon and Shortley's classic. The author gives much more discussion of the historical motivation for various steps in the theory, and also makes admirable heuristic use of classical arguments wherever these are applicable. The inevitably high price will restrict sales to individuals, but this is a very valuable work of reference. The production, as usual with this series, is excellent.

THE RUTHERFORD MEMORIAL LECTURE 1958†

Reminiscences of the Founder of Nuclear Science and of Some Developments Based on his Work

By NIELS BOHR

It has been a pleasure for me to accept the invitation from the Physical Society to contribute to the series of Rutherford Memorial Lectures in which, through the years, several of Rutherford's closest collaborators have commented on his fundamental scientific achievements and communicated reminiscences about his great human personality. As one who in early youth had the good fortune to join the group of physicists working under Rutherford's inspiration, and owes so much to his warm friendship through the many succeeding years, I welcome the task of recalling some of my most treasured remembrances. Since it is impossible, of course, in a single lecture to attempt a survey of the immense and many-sided life-work of Ernest Rutherford and its far reaching consequences, I shall confine myself to periods of which I have personal recollections and to developments I have followed at close hand.

I

The first time I had the great experience of seeing and listening to Rutherford was in the autumn of 1911 when, after my university studies in Copenhagen, I was working in Cambridge with J. J. Thomson, and Rutherford came down from Manchester to speak at the annual Cavendish Dinner. Although I did not on this occasion come into personal contact with Rutherford I received a deep impression of the charm and power of his personality by which he had been able to achieve almost the incredible wherever he worked. The dinner took place in a most humorous atmosphere and gave the opportunity for several of Rutherford's colleagues to recall some of the many anecdotes which already then were attached to his name. Among various illustrations of how intensely he was absorbed in his researches, a laboratory assistant in the Cavendish was reported to have noted that, of all the eager young physicists who through the years had worked in the famous laboratory, Rutherford was the one who could swear at his apparatus most forcefully.

From Rutherford's own address I especially remember the warmth with which he greeted the latest success of his old friend C.T.R. Wilson who by the ingenious cloud chamber method had just then obtained the first photographs of tracks of α-rays exhibiting clear cases of sharp bends in their usual remarkably straight path. Of course, Rutherford was thoroughly acquainted with the phenomenon which only a few months before had led him to his epoch-making discovery of the atomic nucleus, but that such details of the life history of α-rays could now be witnessed directly by our eyes, he admitted to be a surprise, causing him extreme pleasure. In this connection Rutherford spoke most admiringly of the persistence with which Wilson already during their comradeship in the Cavendish had pursued his researches on cloud formation with ever more refined apparatus. As Wilson later told me, his interest in these beautiful phenomena had been awakened when as a youth he was watching the appearance and disappearance of fogs as air currents ascended the Scottish mountain ridges and again descended in the valleys.

---

† The present text is an elaborated version, completed in 1961, of the lecture delivered without a prepared manuscript at a meeting of The Physical Society of London at the Imperial College of Science and Technology on 28th November 1958.

A few weeks after the Cavendish Dinner I went up to Manchester to visit one of my recently deceased father's colleagues who was also a close friend of Rutherford. There, I again had the opportunity to see Rutherford who in the meantime had attended the inaugural meeting of the Solvay Council in Brussels, where he had met Planck and Einstein for the first time. During the conversation, in which Rutherford spoke with characteristic enthusiasm about the many new prospects in physical science, he kindly assented to my wish to join the group working in his laboratory when, in the early spring of 1912, I should have finished my studies in Cambridge where I had been deeply interested in J. J. Thomson's original ideas on the electronic constitution of atoms.

In those days, many young physicists from various countries had gathered around Rutherford, attracted by his genius as a physicist and by his unique gifts as a leader of scientific cooperation. Although Rutherford was always intensely occupied with the progress of his own work, he had the patience to listen to every young man, when he felt he had any idea, however modest, on his mind. At the same time, with his whole independent attitude, he had only little respect for authority and could not stand what he called ' pompous talk '. On such occasions he could even sometimes speak in a boyish way about venerable colleagues, but he never permitted himself to enter into personal controversies, and he used to say: " There is only one person who can take away one's good name, and that is oneself!"

Naturally, to trace in every direction the consequences of the discovery of the atomic nucleus was the centre of interest of the whole Manchester group. In the first weeks of my stay in the laboratory, I followed, on Rutherford's advice, an introductory course on the experimental methods of radioactive research which under the experienced instruction of Geiger, Makower and Marsden was arranged for the benefit of students and new visitors. However, I rapidly became absorbed in the general theoretical implications of the new atomic model and especially in the possibility it offered of a sharp distinction as regards the physical and chemical properties of matter, between those directly originating in the atomic nucleus itself and those primarily depending on the distribution of the electrons bound to it at distances very large compared with nuclear dimensions.

While the explanation of the radioactive disintegrations had to be sought in the intrinsic constitution of the nucleus, it was evident that the ordinary physical and chemical characteristics of the elements manifested properties of the surrounding electron system. It was even clear that, owing to the large mass of the nucleus and its small extension compared with that of the whole atom, the constitution of the electron system would depend almost exclusively on the total electric charge of the nucleus. Such considerations at once suggested the prospect of basing the account of the physical and chemical properties of every element on a single integer, now generally known as the atomic number, expressing the nuclear charge as a multiple of the elementary unit of electricity.

In the development of such views, I was encouraged not least by discussions with George Hevesy who distinguished himself among the Manchester group by his uncommonly broad chemical knowledge. In particular, as early as 1911, he had conceived the ingenious tracer method which has since become so powerful a tool in chemical and biological research. As Hevesy has himself humorously described, he was led to this method by the negative results of elaborate work undertaken as a response to a challenge by Rutherford who had told him that "if he was worth his salt" he ought to be helpful by separating the valuable radium D from the large amount of lead chloride extracted from pitchblende and presented to Rutherford by the Austrian government.

My views took more definite shape in conversations with Hevesy about the wonderful adventure of those Montreal and Manchester years, in which Rutherford and his collaborators, after the discoveries of Becquerel and Madame Curie, had built up the science of radioactivity by progressively disentangling the succession and interconnections of radioactive disintegrations. Thus, when I learned that the number of stable and decaying elements already identified exceeded the available places in the famous table of Mendeleev, it struck me that such chemically inseparable substances, to the existence of which Soddy had early called attention and which later by him were termed 'isotopes', possessed the same nuclear charge and differed only in the mass and intrinsic structure of the nucleus. The immediate conclusion was that by radioactive decay the element, quite independently of any change in its atomic weight, would shift its place in the periodic table by two steps down or one step up, corresponding to the decrease or increase in the nuclear charge accompanying the emission of α- or β-rays, respectively.

When I turned to Rutherford to learn his reaction to such ideas, he expressed, as always, alert interest in any promising simplicity but warned with characteristic caution against overstressing the bearing of the atomic model and extrapolating from comparatively meagre experimental evidence. Still, such views, probably originating from many sides, were at that time lively discussed within the Manchester group and evidence in their support was rapidly forthcoming, especially through chemical investigations by Hevesy as well as by Russell.

In particular, a strong support for the idea of the atomic number as determining the general physical properties of the elements was obtained from spectroscopic investigations by Russell and Rossi of mixtures of ionium and thorium, which pointed to the identity of the optical spectra of these two substances in spite of their different radioactive properties and atomic weights. On the basis of an analysis of the whole evidence then available, the general relationship between the specified radioactive processes and the resulting change of the atomic number of the element was indicated by Russell in a lecture to the Chemical Society in the late autumn of 1912.

In this connection it is interesting that, when after further research especially by Fleck, the radioactive displacement law in its complete form was enunciated a few months later by Soddy working in Glasgow, as well as by Fajans in Karlsruhe, these authors did not recognize its close relation to the fundamental features of Rutherford's atomic model, and Fajans even regarded the change in chemical properties evidently connected with the electron constitution of the atoms as a strong argument against a model according to which the α- as well as the β-rays had their origin in the nucleus. About the same time, the idea of the atomic number was independently introduced by van den Broek in Amsterdam, but in his classification of the elements a different nuclear charge was still ascribed to every stable or radioactive substance.

So far, the primary object of the discussions within the Manchester group was the immediate consequences of the discovery of the atomic nucleus. The general programme of interpreting the accumulated experience about the ordinary physical and chemical properties of matter on the basis of the Rutherford model of the atom presented, however, more intricate problems which were to be clarified gradually in the succeeding years. Thus in 1912, there could only be question of a preliminary orientation as to the general features of the situation.

From the outset it was evident that, on the basis of the Rutherford model, the typical stability of atomic systems could by no means be reconciled with classical principles of mechanics and electrodynamics. Indeed, on Newtonian mechanics, no system of point charges admits of a stable static equilibrium, and any motion of the electrons around the nucleus would, according to Maxwell's electrodynamics, give rise to a dissipation of energy through radiation accompanied by a steady contraction of the system, resulting in the close combination of the nucleus and the electrons within a region of extension far smaller than atomic dimensions.

Still, this situation was not too surprising, since an essential limitation of classical physical theories had already been revealed by Planck's discovery in 1900 of the universal quantum of action which, especially in the hands of Einstein, had found such promising application in the account of specific heats and photochemical reactions. Quite independent of the new experimental evidence as regards the structure of the atom, there was therefore a widespread expectation that quantum concepts might have a decisive bearing on the whole problem of the atomic constitution of matter.

Thus, as I later learned, A. Haas had in 1910 attempted, on the basis of Thomson's atomic model, to fix dimensions and periods of electronic motions by means of Planck's relation between the energy and the frequency of a harmonic oscillator. Further, J. Nicholson had in 1912 made use of quantized angular momenta in his search for the origin of certain lines in the spectra of stellar nebulae and the solar corona. Above all, however, it deserves mention that, following early ideas of Nernst about quantized rotations of molecules, N. Bjerrum already in 1912 predicted the band structure of infra-red absorption lines in diatomic gases, and thereby made a first step towards the detailed analysis of molecular spectra eventually achieved on the basis of the subsequent interpretation, by quantum theory, of the general spectral combination law.

Early in my stay in Manchester in the spring of 1912 I became convinced that the electronic constitution of the Rutherford atom was governed throughout by the quantum of action. A support for this view was found not only in the fact that Planck's relation appeared approximately applicable to the more loosely bound electrons involved in the chemical and optical properties of the elements, but especially in the tracing of similar relationships as regards the most firmly bound electrons in the atom revealed by the characteristic penetrating radiation discovered by Barkla. Thus, measurements of the energy necessary to produce the Barkla radiation by electron bombardment of various elements, performed by Whiddington at the time when I was staying in Cambridge, exhibited simple regularities of the kind to be expected from an estimate of the firmest binding energy of an electron rotating in a Planck orbit round a nucleus with a charge given by the atomic number. From Lawrence Bragg's recently published Rutherford Lecture I have been very interested to learn that William Bragg, then in Leeds, in his first investigation of x-ray spectra, based on Laue's discovery in 1912, was fully aware of the bearing of Whiddington's results on the connection between the Barkla radiation and the ordering of the elements in Mendeleev's table, a problem which through Moseley's work in Manchester soon was to receive such complete elucidation.

During the last month of my stay in Manchester I was mainly occupied with a theoretical investigation of the stopping power of matter for α- and β-rays. This problem, which originally was discussed by J. J. Thomson from the point of view of his own atomic model, had just been re-examined by Darwin on the basis of the Rutherford model. In connection with the considerations mentioned above regarding the frequencies involved in the electron binding in the atom, it occurred to me that the transfer of energy from the particles to the electrons could be simply treated in analogy to the dispersion and absorption of radiation. In this way, it proved possible to interpret the results of the stopping power measurements as additional support for ascribing to hydrogen and helium the atomic numbers 1 and 2 in conformity with general chemical evidence, and in particular with Rutherford and Royds' demonstration of the formation of helium gas by the collection of α-particles escaping from thin-walled emanation tubes. Also for the more complex case of heavier substances, approximate agreement was ascertained with the expected atomic numbers and the estimated values for the binding energies of the electrons, but the theoretical methods were much too primitive to yield more accurate results. As is well known, an appropriate treatment of the problem by modern methods of quantum mechanics was first achieved in 1930 by H. Bethe.

Although Rutherford just at that time was concentrating on the preparation of his great book, *Radioactive Substances and Their Radiations*, he nevertheless followed my work with a constant interest, which gave me the opportunity to learn about the care which he always took in the publications of his pupils. After my return to Denmark I was married in mid-summer 1912 and, on our wedding trip in August to England and Scotland, my wife and I passed through Manchester to visit Rutherford and deliver the completed manuscript of my paper on the stopping problems. Both Rutherford and his wife received us with a cordiality which laid the foundation of the intimate friendship that through the many years connected the families.

II

After settling down in Copenhagen, I remained in close contact with Rutherford, to whom I regularly reported about the development of the work on general atomic problems, which I had started in Manchester. Common to Rutherford's answers, which were always very encouraging, was the spontaneity and joy with which he told about the work in his laboratory. It was indeed the beginning of a long correspondence which lasted over 25 years and which revives, every time I look into it, my memories of Rutherford's enthusiasm for the progress in the field he had opened up and the warm interest he took in the endeavours of every one trying to contribute to it.

My letters to Rutherford in the autumn of 1912 concerned the continued endeavours to trace the role of the quantum of action for the electronic constitution of the Rutherford atom, including problems of molecular bindings and radiative and magnetic effects. Still, the stability question presented in all such considerations intricate difficulties stimulating the search for a firmer hold. However, after various attempts to apply quantum ideas in a more consistent manner, it struck me in the early spring of 1913 that a clue to the problem of atomic stability directly applicable to the Rutherford atom was offered by the remarkably simple laws governing the optical spectra of the elements.

On the basis of the extremely accurate measurements of the wavelengths of spectral lines by Rowland and others, and after contributions by Balmer and by Schuster, Rutherford's predecessor in the Manchester Chair, the general spectral laws were most ingeniously clarified by Rydberg. The principal result of the thorough analysis of the conspicuous series in the line spectra and their mutual relationship was the recognition that the frequency ν of every line in the spectrum of a given element could be represented with unparalleled accuracy as $\nu = T' - T''$, where T' and T'' are two among a multitude of spectral terms T characteristic of the element.

This fundamental combination law obviously defied ordinary mechanical interpretation, and it is interesting to recall how in this connection Lord Rayleigh had pertinently stressed that any general relationship between the frequencies of the normal modes of vibration of a mechanical model would be quadratic and not linear in these frequencies. For the Rutherford atom we should not even expect a line spectrum since, according to ordinary electrodynamics, the frequencies of radiation accompanying the electronic motion would change continuously with the energy emitted. It was therefore natural to attempt to base the explanation of spectra directly on the combination law.

In fact, accepting Einstein's idea of light quanta or photons with energy $h\nu$, where h is Planck's constant, one was led to assume that any emission or absorption of radiation by the atom is an individual process accompanied by an energy transfer $h\ (T' - T'')$, and to interpret hT as the binding energy of the electrons in some stable, or so-called stationary, state of the atom. In particular, this assumption offered an immediate explanation of the apparently capricious appearance of emission and absorption lines in series spectra. Thus, in emission processes we witness the transition of the atom from a higher to a lower energy level, whereas in the absorption processes we have in general to do with a transfer of the atom from the ground state, with the lowest energy, to one of its excited states.

In the simplest case of the hydrogen spectrum, the terms are with great accuracy given by $T_n = R/n^2$, where n is an integer and R the Rydberg constant. Thus, the interpretation indicated led to a sequence of decreasing values for the binding energy of the electron in the hydrogen atom, pointing to a steplike process by which the electron, originally at a large distance from the nucleus, passes by radiative transitions to stationary states of firmer and firmer binding, characterized by lower and lower n-values, until the ground state, specified by $n = 1$, is reached. Moreover, a comparison of the binding energy in this state with that of an electron moving in a Keplerian orbit around the nucleus yielded orbital dimensions of the same order as the atomic sizes derived from the properties of gases.

On the basis of the Rutherford atomic model, this view also immediately suggested an explanation of the appearance of the Rydberg constant in the more complex spectra of other elements. Thus it was concluded that we were here faced with transition processes involving excited states of the atom, in which one of the electrons had been brought outside the region occupied by the other electrons bound to the nucleus, and therefore exposed to a field of force resembling that surrounding a unit charge.

The tracing of a closer relation between the Rutherford atomic model and the spectral evidence obviously presented intricate problems. On the one hand, the very definition of the charge and mass of the electron and the nucleus rested entirely on an analysis of physical phenomena in terms of the principles of classical mechanics and electromagnetism. On the other hand, the so-called quantum postulate, stating that any change of the intrinsic energy of the atom consists in a complete transition between two stationary states, excluded the possibility of accounting on classical principles for the radiative processes or any other reaction involving the stability of the atom.

As we know today, the solution of such problems demanded the development of a mathematical formalism, the proper interpretation of which implied a radical revision of the foundation for the unambiguous use of elementary physical concepts and the recognition of complementary relationships between phenomena observed under different experimental conditions. Still, at that time, some progress could be made by utilizing classical physical pictures for the classification of stationary states based on Planck's original assumptions on the energy states of a harmonic oscillator. In particular, a starting point was offered by the closer comparison between an oscillator of given frequency and the Keplerian motion of an electron around a nucleus, with a frequency of revolution depending on the binding energy.

In fact, just as in the case of a harmonic oscillator, a simple calculation showed that, for each of the stationary states of the hydrogen atom, the action integrated over an orbital period of the electron could be identified with nh, a condition which in the case of circular orbits is equivalent to a quantization of the angular momentum in units $h/2\pi$. Such identification involved a fixation of the Rydberg constant in terms of the charge e and mass m of the electron and Planck's constant, according to the formula

$$R = \frac{2\pi^2 me^4}{h^3}$$

which was found to agree with the empirical value within the accuracy of the available measurements of e, m and h.

Although this agreement offered an indication of the scope for the use of mechanical models in picturing stationary states, of course the difficulties involved in any combination of quantum ideas and the principles of ordinary mechanics remained. It was therefore most reassuring to find that the whole approach to the spectral problems fulfilled the obvious demand of embracing the classical physical description in the limit where the action involved is sufficiently large to permit the neglect of the individual quantum. Such considerations presented indeed the first indication of the so-called correspondence principle expressing the aim of representing the essentially statistical account of quantum physics as a rational generalization of the classical physical description.

Thus, in ordinary electrodynamics, the composition of the radiation emitted from an electron system should be determined by the frequencies and amplitudes of the harmonic oscillations into which the motion of the system can be resolved. Of course no such simple relation holds between the Keplerian motion of an electron around a heavy nucleus and the radiation emitted by transitions between the stationary states of the system. However, in the limiting case of transitions between states for which the values of the quantum number *n* are large compared with their difference, it could be shown that the frequencies of the components of the radiation, appearing as the result of the random individual transition processes, coincide asymptotically with those of the harmonic components of the electron motion. Moreover, the fact that in a Keplerian orbit, in contrast to a simple harmonic oscillation, there appears not only the frequency of revolution but also higher harmonics, offered the possibility of tracing a classical analogy as regards the unrestricted combination of the terms in the hydrogen spectrum.

Still, the unambiguous demonstration of the relation between the Rutherford atomic model and the spectral evidence was for a time hindered by a peculiar circumstance. Already twenty years before, Pickering had observed in the spectra of distant stars a series of lines with wavelengths exhibiting a close numerical relationship with the ordinary hydrogen spectrum. These lines were therefore generally ascribed to hydrogen and were even thought by Rydberg to remove the apparent contrast between the simplicity of the hydrogen spectrum and the complexity of the spectra of other elements including those of the alkalis, whose structure comes nearest to the hydrogen spectrum. This view was also upheld by the eminent spectroscopist A. Fowler, who just at that time in laboratory experiments with discharges through a mixture of hydrogen and helium gas had observed the Pickering lines and new related spectral series.

However, the Pickering and Fowler lines could not be included in the Rydberg formula for the hydrogen spectrum, unless the number *n* in the expression for the spectral terms were allowed to take half integrals as well as integral values; but this assumption would evidently destroy the asymptotic approach to the classical relationship between energy and spectral frequencies. On the other hand, such correspondence would hold for the spectrum of a system consisting of an electron bound to a nucleus of charge Ze, whose stationary states are determined by the same value nh of the action integral. Indeed, the spectral terms for such a system would be given by Z^2R/n^2, which for $Z=2$ yields the same result as the introduction of half-integral values of n in the Rydberg formula. Thus, it was natural to ascribe the Pickering and Fowler lines to helium ionized by the high thermal agitation in the stars and in the strong discharges used by Fowler. Indeed, if this conclusion were confirmed, a first step would have been made towards the establishment of quantitative relationships between the properties of different elements on the basis of the Rutherford model.

III

When in March 1913 I wrote to Rutherford, enclosing a draft of my first paper on the quantum theory of atomic constitution, I stressed the importance of settling the question of the origin of the Pickering lines and took the opportunity of asking whether experiments to that purpose could be performed in his laboratory, where from Schuster's days appropriate spectroscopic apparatus were available. I received a prompt answer, so characteristic of Rutherford's acute scientific judgment and helpful human attitude, that I shall quote it in full:

March 20, 1913.

Dear Dr. Bohr,

I have received your paper safely and read it with great interest, but I want to look over it again carefully when I have more leisure. Your ideas as to the mode of origin of spectrum and hydrogen are very ingenious and seem to work out well; but the mixture of Planck's ideas with the old mechanics make it very difficult to form a physical idea of what is the basis of it. There appears to me one grave difficulty in your hypothesis, which I have no doubt you fully realise, namely, how does an electron decide what frequency it is going to vibrate at when it passes from one stationary state to the other? It seems to me that you would have to assume that the electron knows beforehand where it is going to stop.

There is one criticism of minor character which I would make in the arrangement of the paper. I think in your endeavour to be clear you have a tendency to make your papers much too long, and a tendency to repeat your statements in different parts of the paper. I think that your paper really ought to be cut down, and I think this could be done without sacrificing anything to clearness. I do not know if you appreciate the fact that long papers have a way of frightening readers, who feel that they have not time to dip into them.

I will go over your paper very carefully and let you know what I think about the details. I shall be quite pleased to send it to the *Phil. Mag.* but I would be happier if its volume could be cut down to a fair amount. In any case I will make any corrections in English that are necessary.

I shall be very pleased to see your later papers, but please take to heart my advice, and try to make them as brief as possible consistent with clearness. I am glad to hear that you are coming over to England later and we shall be very glad to see you when you come to Manchester.

By the way, I was much interested in your speculations in regard to Fowler's spectrum. I mentioned the matter to Evans here, who told me that he was much interested in it, and I think it quite possible that he may try some experiments on the matter when he comes back next term. General work goes well, but I am held up momentarily by finding that the mass of the α-particle comes out rather bigger than it ought to be. If correct it is such an important conclusion that I cannot publish it until I am certain of my accuracy at every point. The experiments take a good deal of time and have to be done with great accuracy.

Yours very sincerely,
E. RUTHERFORD.

P.S. I suppose you have no objection to my using my judgment to cut out any matter I may consider unnecessary in your paper? Please reply.

Rutherford's first remark was certainly very pertinent, touching on a point which was to become a central issue in the subsequent prolonged discussions. My own views at that time, as expressed in a lecture at a meeting of the Danish Physical Society in October 1913, were that just the radical departure from the accustomed demands on physical explanation involved in the quantum postulate should of itself leave sufficient scope for the possibility of achieving in due course the incorporation of the new assumptions in a logically consistent scheme. In connection with Rutherford's remark, it is of special interest to recall that Einstein, in his famous paper of 1917 on the derivation of Planck's formula for temperature radiation, took the same starting point as regards the origin of spectra, and pointed to the analogy between the statistical laws governing the occurrence of spontaneous radiation processes and the fundamental law of radioactive decay, formulated by Rutherford and Soddy already in 1903. Indeed, this law, which allowed them at one stroke to disentangle the multifarious phenomena of natural radioactivity then known, also proved the clue to the understanding of the later observed peculiar branching in spontaneous decay processes.

The second point raised with such emphasis in Rutherford's letter brought me into a quite embarrassing situation. In fact, a few days before receiving his answer, I had sent Rutherford a considerably extended version of the earlier manuscript, the additions especially concerning the relation between emission and absorption spectra and the asymptotic correspondence with the classical physical theories. I therefore felt the only way to straighten matters was to go at once to Manchester and talk it all over with Rutherford himself. Although Rutherford was as busy as ever, he showed an almost angelic patience with me, and after discussions through several long evenings during which he declared he had never thought I should prove so obstinate, he consented to leave all the old and new points in the final paper. Surely, both style and language were essentially improved by Rutherford's help and advice, and I have often had occasion to think how right he was in objecting to the rather complicated presentation and especially to the many repetitions caused by reference to previous literature. This Rutherford Memorial Lecture has therefore offered a welcome opportunity to give a more concise account of the actual development of the arguments in those years.

During the following months, the discussion about the origin of the spectral lines ascribed to helium ions took a dramatic turn. In the first place, Evans was able to produce the Fowler lines in discharges through helium of extreme purity, not showing any trace of the ordinary hydrogen lines. Still, Fowler was not yet convinced and stressed the spurious manner in which spectra may appear in gas mixtures. Above all he noted that his accurate measurements of the wavelengths of the Pickering lines did not exactly coincide with those calculated from my formula with $Z=2$. An answer to the last point was, however, easily found, since it was evident that the mass m in the expression for the Rydberg constant had to be taken not as the mass of a free electron but as the so-called reduced mass $mM\,(m+M)^{-1}$, where M is the mass of the nucleus. Indeed, taking this correction into account, the predicted relationship between the spectra of hydrogen and ionized helium was in complete agreement with all the measurements. This result was at once welcomed by Fowler who took the opportunity of pointing out that also in the spectra of other elements series were observed in which the ordinary Rydberg constant had to be multiplied by a number close to four. Such series spectra, which are generally referred to as spark spectra, could now be recognized as originating from excited ions in contrast to the so-called arc spectra due to excited neutral atoms.

Continued spectroscopical investigations were in the following years to reveal many spectra of atoms, from which not only one but even several electrons were removed. In particular, the well-known investigations of Bowen led to the recognition that the origin of the nebular spectra discussed by Nicholson had to be sought not in new hypothetical elements, but in atoms of oxygen and nitrogen in a highly ionized state. Eventually, the prospect arose of arriving, by analysis of the processes by which the electrons one by one are bound to the nucleus, at a survey of the binding of every electron in the ground state of the Rutherford atom. In 1913, of course, the experimental evidence was still far too scarce, and the theoretical methods for classification of stationary states were not yet sufficiently developed to cope with so ambitious a task.

IV

In the meantime, the work on the electronic constitution of the atom gradually proceeded, and soon again I permitted myself to ask Rutherford for help and advice. Thus, in June 1913 I went to Manchester with a second paper which, besides a continued discussion of the radioactive displacement law and the origin of the Barkla radiation, dealt with the ground state of atoms containing several electrons. As regards this problem, I tried tentatively to arrange the electron orbits in closed rings resembling the shell structure originally introduced by J. J. Thomson in his early attempt to account by his atomic model for the periodicity features in Mendeleev's table of the elements.

In Rutherford's laboratory, I met on that occasion Hevesy and Paneth, who told me of the success of the first systematic investigations by the tracer method of the solubility of lead sulphide and chromate, which at the beginning of that year they had carried out together in Vienna. In every way, these repeated visits to Manchester were a great stimulation and gave me the welcome opportunity to keep abreast of the work in the laboratory . At that time, assisted by Robinson, Rutherford was busily engaged in the analysis of β-ray emission and in cooperation with Andrade studied γ-ray spectra. Moreover, Darwin and Moseley were then intensely occupied with refined theoretical and experimental investigations on the diffraction of x-rays in crystals.

A special opportunity to see Rutherford again soon arose in connection with the meeting of the British Association for the Advancement of Science in Birmingham in September 1913. At the meeting, attended by Madame Curie, there was in particular a general discussion about the problem of radiation with the participation of such authorities as Rayleigh, Larmor and Lorentz, and especially Jeans who gave an introductory survey of the application of quantum theory to the problem of atomic constitution. His lucid exposition was, in fact, the first public expression of serious interest in considerations which outside the Manchester group were generally received with much scepticism.

An incident which amused Rutherford and us all was the remark of Lord Rayleigh in response to a solemn request by Sir Joseph Larmor to express his opinion on the latest developments. The prompt reply from the great veteran, who in earlier years had contributed so decisively to the elucidation of radiation problems, was: " In my young days I took many views very strongly and among them that a man who has passed his sixtieth year ought not to express himself about modern ideas. Although I must confess that today I do not take this view quite so strongly, I keep it strongly enough not to take part in this discussion!"

On my visit to Manchester in June I had discussed with Darwin and Moseley the question of the proper sequence for the arrangement of the elements according to their atomic number, and learned then for the first time about Moseley's plans to settle this problem by systematic measurements of the high-frequency spectra of the elements by the Laue–Bragg method. With Moseley's extraordinary energy and gifts of purposeful experimentation, his work developed astonishingly quickly, and already in November 1913 I received a most interesting letter from him with an account of his important results and with some questions regarding their interpretation on the lines which had proved applicable to the optical spectra.

In modern history of physics and chemistry, few events have from the outset attracted such general interest as Moseley's discovery of the simple laws allowing an unambiguous assignment of the atomic number to any element from its high-frequency spectrum. Not only was the decisive support of the Rutherford atomic model immediately recognized, but also the intuition which had led Mendeleev at certain places in his table to depart from the sequence of increasing atomic weights was strikingly brought out. In particular, it was evident that Moseley's laws offered an unerring guide in the search for as yet undiscovered elements fitting into vacant places in the series of atomic numbers.

Also as regards the problem of the configuration of the electrons in the atom, Moseley's work was to initiate important progress. Certainly, the predominance, in the innermost part of the atom, of the attraction exerted by the nucleus on the individual electrons over their mutual repulsion afforded the basis for an understanding of the striking similarity between Moseley's spectra and those to be expected for a system consisting of a single electron bound to the bare nucleus. The closer comparison, however, brought new information pertaining to the shell structure of the electronic constitution of the atoms.

An important contribution to this problem was soon after given by Kossel who, as the origin of the K, L and M types of Barkla radiation, pointed to the removal of an electron from one of the sequence of rings or shells surrounding the nucleus. In particular he ascribed the $K\alpha$ and $K\beta$ components of Moseley's spectra to individual transition processes by which the electron lacking in the K-shell is replaced by one of the electrons in the L- and M-shells, respectively. Proceeding in this way, Kossel was able to trace further relationships between Moseley's measurements of the spectral frequencies which permitted him to represent the whole high-frequency spectrum of an element as a combination scheme in which the product of any of the terms and Planck's constant was to be identified with the energy required to remove an electron from a shell in the atom to a distance from the nucleus beyond all the shells.

In addition, Kossel's views offered an explanation of the fact that the absorption of penetrating radiation of increasing wavelength practically begins with an absorption edge representing the complete removal in one step of an electron of the respective shell. The absence of intermediate excited states was assumed to be due to the full occupation of all shells in the ground state of the atom. As is well known, this view eventually found its final expression through Pauli's formulation in 1924 of the general exclusion principle for electron binding states, inspired by Stoner's derivation of finer details of the shell structure of the Rutherford atom from an analysis of the regularities of the optical spectra.

V

In the autumn of 1913, another stir among physicists was created by Stark's discovery of the surprisingly large effect of electric fields on the structure of the lines in the hydrogen spectrum. With his vigilant attention to all progress in physical science, Rutherford, when he had received Stark's paper from the Prussian Academy, at once wrote to me: "I think it is rather up to you at the present time to write something on the Zeeman and electric effects, if it is possible to reconcile them with your theory." Responding to Rutherford's challenge, I tried to look into the matter, and it was soon clear to me that in the effects of electric and magnetic fields we had to do with two very different problems.

The essence of Lorentz' and Larmor's interpretations of Zeeman's famous discovery in 1896 was that it pointed directly to electron motions as the origin of line spectra in a way largely independent of special assumptions about the binding mechanism of the electrons in the atom. Even if the origin of the spectra is assigned to individual transitions between stationary states, the correspondence principle thus led one, in view of Larmor's general theorem, to expect a normal Zeeman effect for all spectral lines emitted by electrons bound in a field of central symmetry, as in the Rutherford atom. Rather did the appearance of so-called anomalous Zeeman effects present new puzzles which could only be overcome more than ten years later when the complex structure of the lines in series spectra was traced to an intrinsic electron spin. A most interesting historical account of this development, to which important contributions were given from various sides, can be found in the well-known volume recently published in memory of Pauli.

In the case of an electric field, however, no effect proportional to its intensity was to be expected for the radiation emitted by a harmonic oscillator, and Stark's discovery therefore definitely excluded the conventional idea of elastic vibrations of electrons as the origin of line spectra. Still, for a Keplerian motion of the electron around the nucleus even a comparatively weak external electric field will through secular perturbations produce considerable changes in the shape and orientation of the orbit. By the study of particular cases in which the orbit remains purely periodic in the external field it was possible, by arguments of the same type as those applied to the stationary states of the undisturbed hydrogen atom, to deduce the order of magnitude of the Stark effect and especially to explain its rapid rise from line to line within the hydrogen spectral series. Yet, these considerations clearly showed that, for an explanation of the finer details of the phenomenon, the methods for a classification of stationary states of atomic systems were not sufficiently developed.

In just this respect a great advance was achieved in the following years by the introduction of quantum numbers specifying components of angular momenta and other action integrals. Such methods were first suggested by W. Wilson in 1915 who applied them to electron orbits in the hydrogen atom. However, owing to the circumstance that on Newtonian mechanics every orbit in this case is simply periodic with a frequency of revolution depending only on the total energy of the system, no physical effects were disclosed. Still, the velocity dependence of the electron mass, predicted by the new mechanics of Einstein, removes the degeneracy of the motion and introduces a second period in its harmonic components through a continual slow progression of the aphelion of the Keplerian orbit. In fact, as was shown in Sommerfeld's famous paper of 1916, the separate quantization of the angular momentum and of the action in the radial motion permitted a detailed interpretation of the observed fine structure of the lines in the spectra of the hydrogen atom and helium ion.

Moreover, the effect of magnetic and electric fields on the hydrogen spectrum was treated by Sommerfeld and Epstein who by a masterly application of the methods for quantization of multiperiodic systems were able, in complete accordance with observations, to derive the spectral terms by the combination of which the resolution of the hydrogen lines appears. The compatibility of such methods with the principle of adiabatic invariance of stationary states, which Ehrenfest had formulated in 1914 in order to meet thermodynamical requirements, was secured by the circumstance that the action integrals to which the quantum numbers refer according to classical mechanics are not modified by a variation of the external field slow compared with the characteristic periods of the system.

Further evidence of the fruitfulness of the approach was derived from the application of the correspondence principle to the radiation emitted by multiperiodic systems, permitting qualitative conclusions regarding the relative probabilities for the different transition processes. These considerations were not least confirmed by Kramers' explanation of the apparently capricious variations in the intensities of the Stark effect components of the hydrogen lines. It was even found possible to account by the correspondence argument for the absence of certain types of transitions in other atoms, beyond those which, as pointed out by Rubinowicz, could be excluded by the conservation laws for energy and angular momentum applied to the reaction between the atom and the radiation.

With the help of the rapidly increasing experimental evidence about the structure of complicated optical spectra, as well as the methodical search for finer regularities in the high-frequency spectra by Siegbahn and his collaborators, the classification of the binding states in atoms containing several electrons continually advanced. In particular, the study of the way in which the ground states of the atoms could be built up by the successive bindings of the electrons to the nucleus led to a gradual elucidation of the shell structure of the electronic configuration in the atom. Thus, although such essential elements of the explanation as the electron spin were still unknown, it became in fact possible within about ten years of Rutherford's discovery of the atomic nucleus to achieve a summary interpretation of many of the most striking periodicity features of Mendeleev's table.

The whole approach, however, was still of largely semi-empirical character, and it was soon to become clear that, for an exhaustive account of the physical and chemical properties of the elements, a radically new departure from classical mechanics was needed in order to incorporate the quantum postulate in a logically consistent scheme. To this well-known development we shall have occasion to return, but I shall first proceed with the account of my reminiscences of Rutherford.

VI

The outbreak of the first world war brought about an almost complete dissolution of the Manchester group, but I was lucky to remain in close contact with Rutherford who in the spring of 1914 had invited me to succeed Darwin in the Schuster Readership of Mathematical Physics. On our arrival in Manchester in early autumn, after a stormy voyage round Scotland, my wife and I were most kindly received by the few of our old friends who remained in the laboratory after the departure of colleagues from abroad and the participation in military duties by most of the British. Rutherford and his wife were at that time still in America on their way back from a visit to their relatives in New Zealand, and it goes without saying that their safe return to Manchester some weeks later was greeted by all of us with great relief and joy.

Rutherford was himself soon drawn into military projects, especially concerning the development of methods of sound tracing of submarines, and teaching the students was almost entirely left to Evans, Makower and me. Still, Rutherford found time to continue his own pioneer work, which already before the end of the war was to give such great results, and showed the same warm interest as ever in the endeavours of his collaborators. As regards the problem of atomic constitution, a new impulse was given by the publication in 1914 of the famous experiments by Franck and Hertz on the excitation of atoms by electron impact.

On the one hand, these experiments, carried out with mercury vapour, gave most conspicuous evidence of the stepwise energy transfer in atomic processes; on the other hand, the value of the ionization energy of mercury atoms apparently indicated by the experiments was less than half of that to be expected from the interpretation of the mercury spectrum. One was therefore led to suspect that the ionization observed was not directly related to the electronic collisions but was due to an accompanying photoeffect on the electrodes, produced by the radiation emitted by the mercury atoms on their return from the first excited state to the ground state. Encouraged by Rutherford, Makower and I planned experiments to investigate this point, and an intricate quartz apparatus with various electrodes and grids was constructed with the help of the competent German glass blower in the laboratory, who in the earlier days had made the fine α-ray tubes for Rutherford's investigations on the formation of helium.

With his liberal human attitude, Rutherford had tried to obtain permission for the glass blower to continue his work in England in the war time, but the man's temper, not uncommon for artisans in his field, and releasing itself in violent super-patriotic utterances, eventually led to his internment by the British authorities. Thus when our fine apparatus was ruined by an accident in which its support caught fire, there was no help to reconstruct it, and when also Makower shortly afterwards volunteered for military service, the experiments were given up. I need hardly add that the problem was solved with the expected result quite independently by the brilliant investigations of Davis and Gauthier in New York in 1918, and I have only mentioned our fruitless attempts as an indication of the kind of difficulties with which work in the Manchester laboratory was faced in those days, and which were very similar to those the ladies had to cope with in their households.

Still, Rutherford's never failing optimism exerted a most encouraging influence on his surroundings, and I remember how at the time of a serious set-back in the war, Rutherford quoted the old utterance ascribed to Napoleon about the impossibility of fighting the British because they were too stupid to understand when they had lost. To me, it was also a most pleasant and enlightening experience to be admitted to the monthly discussions among a group of Rutherford's personal friends including Alexander, the philosopher, the historian Tout, the anthropologist Elliot Smith, and Chaim Weizmann, the chemist who thirty years later was to become the first president of Israel and for whose distinctive personality Rutherford had great esteem.

A terrible shock to us all was the tragic message in 1915 of Moseley's untimely death in the Gallipoli campaign, deplored so deeply by the community of physicists all over the world, and which not least Rutherford, who had endeavoured to get Moseley transferred from the front to less dangerous duties, took much to heart.

In the summer of 1916 my wife and I left Manchester and returned to Denmark where I had been appointed to the newly created professorship of theoretical physics in the University of Copenhagen. Notwithstanding the ever increasing difficulties of postal communication, a steady correspondence with Rutherford was kept up. From my side, I reported about the progress with the work on a more general representation of the quantum theory of atomic constitution which at that time was further stimulated by the development as regards the classification of stationary states, already referred to. In that connection, Rutherford took an interest in what news I could give from the continent and in particular of my first personal contact with Sommerfeld and Ehrenfest. In his own letters, Rutherford also gave a vivid description of how, in spite of the increasing difficulties and the pressure of other obligations, he strove to continue his investigations in various directions. Thus, in the autumn of 1916, Rutherford wrote about his intense interest in some surprising results regarding the absorption of hard γ-rays produced by high voltage tubes which had just then become available.

In the next years Rutherford was more and more occupied with the possibilities of producing nuclear disintegrations by means of fast α-rays and already in a letter on 9th December 1917 he writes: "I occasionally find an odd half day to try a few of my own experiments and have got I think results that will ultimately prove of great importance. I wish you were here to talk matters over with. I am detecting and counting the lighter atoms set in motion by α-particles, and the results, I think, throw a good deal of light on the character and distribution of forces near the nucleus. I am also trying to break up the atom by this method. In one case, the results look promising but a great deal of work will be required to make sure. Kay helps me and is now an expert counter." A year later, 17th November 1918, Rutherford in his characteristic manner announced further progress: "I wish I had you here to discuss the meaning of some of my results in collision of nuclei. I have got some rather startling results, I think, but it is a heavy and long business getting *certain* proofs of my deductions. Counting weak scintillations is hard on old eyes, but still with the aid of Kay I have got through a good deal of work at odd times the past four years."

In Rutherford's famous papers in the *Philosophical Magazine*, 1919, containing the account of his fundamental discovery of controlled nuclear disintegrations, he refers to the visit to Manchester, in November 1918, of his old collaborator Ernest Marsden who at the Armistice had got leave from military service in France. With his great experience of scintillation experiments from the old Manchester days when, in collaboration with Geiger, he performed the experiments which led Rutherford to his discovery of the atomic nucleus, Marsden helped him to clear up some apparent anomalies in the statistical distribution of the high-speed protons released by the bombardment of nitrogen with α-rays. From Manchester, Marsden returned to New Zealand to take up his own university duties, but kept in close contact with Rutherford through the years.

In July 1919, when after the Armistice travelling was again possible, I went to Manchester to see Rutherford and learned in more detail about his great new discovery of controlled, or so-called artificial, nuclear transmutations, by which he gave birth to what he liked to call 'modern Alchemy', and which in the course of time was to give rise to such tremendous consequences as regards man's mastery of the forces of nature. Rutherford was at that time almost alone in the laboratory, and as told in his letters, the only help in his fundamental researches, apart from Marsden's short visit, was his faithful assistant William Kay, who by his kindness and helpfulness through the years had endeared himself to everyone in the laboratory. During my visit Rutherford also spoke about the great decision he had had to make in response to the offer of the Cavendish professorship in Cambridge left vacant by the retirement of J. J. Thomson. Certainly, it had not been easy for Rutherford to decide to leave Manchester after the many rich years there, but of course he had to follow the call to succeed the unique series of Cavendish professors.

VII

From the beginning, Rutherford gathered around him in the Cavendish Laboratory a large and brilliant group of research workers. A most notable figure was Aston who through many years had worked with J. J. Thomson and already during the wartime had started the development of mass spectroscopic methods which was to lead to the demonstration of the existence of isotopes of almost every element. This discovery, which gave such a convincing confirmation of Rutherford's atomic model, was not entirely unexpected. Already in the early Manchester days, it was understood that the apparent irregularities in the sequence of the atomic weights of the elements when they were ordered according to their chemical properties suggested that, even for the stable elements, the nuclear charge could not be expected to have a unique relation to the nuclear mass. In letters to me in January and February 1920, Rutherford expressed his joy in Aston's work, particularly about the chlorine isotopes which so clearly illustrated the statistical character of the deviations of chemical atomic weights from integral values. He also commented humorously on the lively disputes in the Cavendish Laboratory about the relative merits of different atomic models to which Aston's discovery gave rise.

It was a great help in the continuation of Rutherford's own pioneering work on the constitution and disintegrations of atomic nuclei as well as in the management of the great laboratory, that from the very beginning he was joined by James Chadwick from the old Manchester group, who returned from a long detention in Germany where at the outbreak of the war he had been working in Berlin with Geiger. Among Rutherford's collaborators in the early Cambridge years were also Blackett and Ellis, both coming from a career in the defence services, Ellis having been initiated to physics by Chadwick during their comradeship under German imprisonment. A further asset to the group at the Cavendish was the arrival, a few years later, of Kapitza, who brought with him ingenious projects, in particular for the production of magnetic fields of hitherto unheard-of intensities. In this work he was from the start assisted by John Cockcroft, who with his singular combination of scientific and technological insight was to become such a prominent collaborator of Rutherford.

At the beginning, Charles Darwin, whose mathematical insight had been so helpful in the Manchester years, shared with Ralph Fowler responsibility for the theoretical part of the activities at the Cavendish. In collaboration, they made at that time important contributions to statistical thermodynamics and its application to astrophysical problems. After Darwin's departure for Edinburgh, the principal theoretical adviser and teacher in Cambridge right up to the second world war was Fowler, who had become Rutherford's son-in-law. Not only did Fowler with enthusiastic vigour participate in the work at the Cavendish, but he also soon found numerous gifted pupils who benefitted from his inspiration. Foremost among these were Lennard-Jones and Hartree who both contributed, each along his own line, to the development of atomic and molecular physics, and especially Dirac, who from his early youth distinguished himself by his unique logical power.

Ever since I left Manchester in 1916, I had of course tried to use the experience gained in Rutherford's laboratory and it is with gratitude that I recall how Rutherford from the very outset most kindly and effectively supported my endeavours in Copenhagen to create an institute to promote intimate collaboration between theoretical and experimental physicists. It was a special encouragement that already in the autumn of 1920, when the Institute building was nearing completion, Rutherford found time to visit us in Copenhagen. As a token of appreciation, the University conferred upon him an honorary degree, and on that occasion he gave a most stimulating and humorous address which was long remembered by all present.

For the work in the new Institute it was of great benefit that we were joined shortly after the war by my old friend from the Manchester days, George Hevesy, who during the more than twenty years he worked in Copenhagen carried out many of his famous physico-chemical and biological researches, based on the isotopic tracer method. A special event, in which Rutherford took great interest, was the application of Moseley's method by Coster and Hevesy in 1922 to the successful search for the missing element now called hafnium, the properties of which gave strong additional support to the interpretation of the periodic system of the elements. An auspicious start was given to the general experimental work by a visit, at the opening of the laboratory, of James Franck, who during the following months most kindly instructed the Danish collaborators in the refined technique of excitation of atomic spectra by electron bombardment which he had so ingeniously developed together with Gustav Hertz. The first among the many distinguished theoretical physicists who stayed with us for a longer period was Hans Kramers who as a quite young man came to Copenhagen during the war and proved to be such an invaluable asset to our group during the ten years he worked with us until, in 1926, he left his position as lecturer in the Institute to take over a professorship in Utrecht. Shortly after Kramers' arrival in Copenhagen came two promising young men, Oscar Klein from Sweden and Svein Rosseland from Norway, who already in 1920 made their names known by pointing to the so-called collisions of the second kind, in which atoms are transferred by electron bombardment from a higher to a lower stationary state with gain of velocity for the electron. Indeed, the occurrence of such processes is decisive for ensuring thermal equilibrium in a way analogous to the induced radiative transitions which played an essential role in Einstein's derivation of Planck's formula for temperature radiation. The consideration of collisions of the second kind proved particularly important for the elucidation of the radiative properties of stellar atmospheres, to which at that time Saha, working in Cambridge with Fowler, made such fundamental contributions.

The group at the Copenhagen Institute was joined in 1922 by Pauli, and two years later by Heisenberg, both pupils of Sommerfeld, and who, young as they were, had already accomplished most brilliant work. I had made their acquaintance and formed a deep impression of their extraordinary talent in the summer of 1922 during a lecturing visit to Göttingen, which initiated a long and fruitful cooperation between the group working there under the leadership of Born and Franck, and the Copenhagen group. From the early days our close connection with the great centre in Cambridge was maintained especially by longer visits to Copenhagen of Darwin, Dirac, Fowler, Hartree, Mott, and others.

VIII

Those years, when a unique cooperation of a whole generation of theoretical physicists from many countries created step by step a logically consistent generalization of classical mechanics and electromagnetism, have sometimes been described as the 'heroic' era in quantum physics. To everyone following this development, it was an unforgettable experience to witness how, through the combination of different lines of approach and the introduction of appropriate mathematical methods, a new outlook emerged regarding the comprehension of physical experience. Many obstacles had to be overcome before this goal was reached, and time and again decisive progress was achieved by some of the youngest among us.

The common starting point was the recognition that, notwithstanding the great help which the use of mechanical pictures had temporarily offered for the classification of stationary states of atoms in isolation or exposed to constant external forces, it was clear, as already mentioned, that a fundamentally new departure was needed. Not only was the difficulty of picturing the electronic constitution of chemical compounds on the basis of the Rutherford atomic model more and more evident, but insurmountable difficulties also arose in any attempts to account in detail for the complexity of atomic spectra, especially conspicuous in the peculiar duplex character of the arc spectrum of helium.

The first step to a more general formulation of the correspondence principle was offered by the problem of optical dispersion. Indeed, the close relation between the atomic dispersion and the selective absorption of spectral lines so beautifully illustrated by the ingenious experiments of R. W. Wood and P. V. Bevan on the absorption and dispersion in alkali vapours, suggested from the very beginning a correspondence approach. On the basis of Einstein's formulation of the statistical laws for the occurrence of radiation-induced transitions between stationary states of an atomic system, Kramers in 1924 succeeded in establishing a general dispersion formula, involving only the energies of these states and the probabilities of spontaneous transitions between them. This theory, further developed by Kramers and Heisenberg, included even new dispersion effects connected with the appearance, under the influence of the radiation, of possibilities for transitions not present in the unperturbed atom, and an analogue to which is the Raman effect in molecular spectra.

Shortly afterwards, an advance of fundamental significance was achieved by Heisenberg who in 1925 introduced a most ingenious formalism, in which all use of orbital pictures beyond the general asymptotic correspondence was avoided. In this bold conception, the canonical equations of mechanics are retained in their Hamiltonian form, but the conjugate variables are replaced by operators subject to a non-commutative algorism involving Planck's constant as well as the symbol $\sqrt{-1}$. In fact, by representing the mechanical quantities by hermitian matrices with elements referring to all possible transition processes between stationary states, it proved possible without any arbitrariness to deduce the energies of these states and the probabilities of the associated transition processes. This so-called quantum mechanics, to the elaboration of which Born and Jordan as well as Dirac from the outset made important contributions, opened the way to a consistent statistical treatment of many atomic problems which hitherto were only amenable to a semi-empirical approach.

For the completion of this great task the emphasis on the formal analogy between mechanics and optics, originally stressed by Hamilton, proved most helpful and instructive. Thus, pointing to the similar roles played by the quantum numbers in the classification of stationary states by means of mechanical pictures, and by the numbers of nodes in characterizing the possible standing waves in elastic media, L. de Broglie had already in 1924 been led to a comparison between the behaviour of free material particles and the properties of photons. Especially illuminating was his demonstration of the identity of the particle velocity with the group velocity of a wave-packet built up of components with wavelengths confined to a small interval, and each related to a value of the momentum by Einstein's equation between the momentum of a photon and the corresponding wavelength of radiation. As is well known, the pertinence of this comparison soon received a decisive confirmation with the discoveries by Davisson and Germer and by George Thomson of selective scattering of electrons in crystals.

The culminating event of this period was Schrödinger's establishment in 1926 of a more comprehensive wave mechanics in which the stationary states are conceived as proper solutions of a fundamental wave equation, obtained by regarding the Hamiltonian of a system of electric particles as a differential operator acting upon a function of the coordinates which define the configuration of the system. In the case of the hydrogen atom, not only did this method lead to a remarkably simple determination of the energies of the stationary states, but Schrödinger also showed that the superposition of any two proper solutions corresponded to a distribution of electric charge and current in the atom which on classical electrodynamics would give rise to the emission and resonance absorption of a monochromatic radiation of a frequency coinciding with some line of the hydrogen spectrum.

Similarly, Schrödinger was able to explain essential features of the dispersion of radiation by atoms by representing the charge and current distribution of the atom perturbed by the incident radiation as the effect of a superposition of the proper functions defining the manifold of possible stationary states of the unperturbed system. Particularly suggestive was the derivation on such lines of the laws of the Compton effect which, in spite of the striking support it gave to Einstein's original photon idea, at first presented obvious difficulties for a correspondence treatment, attempting to combine conservation of energy and momentum with a division of the process in two separate steps, consisting in an absorption and an emission of radiation resembling radiative transitions between the stationary states of an atomic system.

This recognition of the wide scope of arguments implying the use of a superposition principle similar to that of classical electromagnetic field theory, which was only implicitly contained in the matrix formulation of quantum mechanics, meant a great advance in the treatment of atomic problems. Still, it was from the beginning obvious that wave mechanics did not point to any less radical modification of the classical physical approach than the statistical description envisaged by the correspondence principle. Thus, I remember how, on a visit of Schrödinger to Copenhagen in 1926, when he gave us a most impressive account of his wonderful work, we argued with him that any procedure disregarding the individual character of the quantum processes would never account for Planck's fundamental formula of thermal radiation.

Notwithstanding the remarkable analogy between essential features of atomic processes and classical resonance problems, it must indeed be taken into account that in wave mechanics we are dealing with functions which do not generally take real values, but demand the essential use of the symbol $\sqrt{-1}$ just as the matrices of quantum mechanics. Moreover, when dealing with the constitution of atoms with more than one electron, or collisions between atoms and free electric particles, the state functions are not represented in ordinary space but in a configuration space of as many dimensions as there are degrees of freedom in the total system. The essentially statistical character of the physical deductions from wave mechanics was eventually clarified by Born's brilliant treatment of general collision problems.

The equivalence of the physical contents of the two different mathematical formalisms was completely elucidated by the transformation theory formulated independently by Dirac in Copenhagen and Jordan in Göttingen, which introduced in quantum physics possibilities for the change of variables similar to those offered by the symmetrical character of the equations of motion in classical dynamics in the canonical form given by Hamilton. An analogous situation is met with in the formulation of a quantum electrodynamics incorporating the photon concept. This aim was first achieved in Dirac's quantum theory of radiation treating phases and amplitudes of the harmonic components of the fields as non-commuting variables. After further ingenious contributions by Jordan, Klein and Wigner, this formalism found, as is well known, essential completion in the work of Heisenberg and Pauli.

A special illustration of the power and scope of the mathematical methods of quantum physics is presented by the peculiar quantum statistics pertaining to systems of identical particles where we have to do with a feature as foreign to classical physics as the quantum of action itself. Indeed, any problem which calls for relevant application of Bose–Einstein or Fermi–Dirac statistics in principle excludes pictorial illustration. In particular, this situation left room for the proper formulation of the Pauli exclusion principle, which not only gave the final elucidation of the periodicity relations in Mendeleev's table, but in the following years proved fertile for the understanding of most of the varied aspects of the atomic constitution of matter.

A fundamental contribution to the clarification of the principles of quantum statistics was afforded by Heisenberg's ingenious explanation in 1926 of the duplicity of the helium spectrum. In fact, as he showed, the set of stationary states of atoms with two electrons consists of two non-combining groups corresponding to symmetric and antisymmetric spatial wave functions, respectively associated with opposite and parallel orientations of the electron spins. Shortly afterwards, Heitler and London succeeded on the same lines in explaining the binding mechanism in the hydrogen molecule and thereby opened the way for the understanding of homopolar chemical bonds. Even Rutherford's famous formula for the scattering of charged particles by atomic nuclei had, as was shown by Mott, to be essentially modified when applied to collisions between identical particles like protons and hydrogen nuclei or α-rays and helium nuclei. However, in the actual experiments of large angle scattering of fast α-rays by heavy nuclei, from which Rutherford drew his fundamental conclusions, we are well within the range of validity of classical mechanics.

The increasing use of more and more refined mathematical abstractions to ensure consistency in the account of atomic phenomena found in 1928 a temporary climax in Dirac's relativistic quantum theory of the electron. Thus the concept of electron spin, to the treatment of which Darwin and Pauli had made important contributions, was harmoniously incorporated in Dirac's spinor analysis. Above all, however, in connection with the discovery of the positron by Anderson and Blackett, Dirac's theory prepared the recognition of the existence of antiparticles of equal mass but opposite electric charges and opposite orientations of the magnetic moment relative to the spin axis. As is well known, we have here to do with a development which in a novel manner has restored and enlarged that isotropy in space and reversibility in time which has been one of the basic ideas of the classical physical approach.

The wonderful progress of our knowledge of the atomic constitution of matter and of the methods by which such knowledge can be acquired and interrelated has indeed carried us far beyond the scope of the deterministic pictorial description brought to such perfection by Newton and Maxwell. Following this development at close hand, I have often had occasion to think of the dominating influence of Rutherford's original discovery of the atomic nucleus, which at every stage presented us with so forceful a challenge.

IX

In all the long and rich years during which Rutherford worked with untiring vigour in the Cavendish, I often came to Cambridge, where on Rutherford's invitation I gave several courses of lectures on theoretical problems including the epistemological implications of the development of quantum theory. On such occasions it was always a great encouragement to feel the open mind and intense interest with which Rutherford followed the progress in the field of research which he had himself so largely initiated and the growth of which should carry us so far beyond the horizon which limited the outlook at the early stages.

Indeed, the extensive use of abstract mathematical methods to cope with the rapidly increasing evidence about atomic phenomena brought the whole observational problem more and more to the foreground. In its roots this problem is as old as physical science itself. Thus the philosophers in ancient Greece, who based the explanation of the specific properties of substances on the limited divisibility of all matter, took it for granted that the coarseness of our sense organs would forever prevent the direct observation of individual atoms. In such respect, the situation has been radically changed in our days by the construction of amplification devices like cloud chambers and the counter mechanisms originally developed by Rutherford and Geiger in connection with their measurements of the numbers and charges of α-particles. Still, the exploration of the world of atoms was, as we have seen, to reveal inherent limitations in the mode of description embodied in common language developed for the orientation in our surroundings and the account of events of daily life.

In words conforming with Rutherford's whole attitude, one may say that the aim of experimentation is to put questions to nature, and of course Rutherford owed his success in this task to his intuition in shaping such questions so as to permit the most useful answers. In order that the enquiry may augment common knowledge it is an obvious demand that the recording of observations as well as the construction and handling of the apparatus, necessary for the definition of the experimental conditions, be described in plain language. In actual physical research, this demand is amply satisfied with the specification of the experimental arrangement through the use of bodies like diaphragms and photographic plates, so large and heavy that their manipulation can be accounted for in terms of classical physics, although of course the properties of the materials of which the instruments, as well as our own bodies, are built up depend essentially on the constitution and stability of the component atomic systems defying such account.

The description of ordinary experience presupposes the unrestricted divisibility of the course of the phenomena in space and time and the linking of all steps in an unbroken chain in terms of cause and effect. Ultimately, this viewpoint rests on the fineness of our senses which for perception demands an interaction with the objects under investigation so small that in ordinary circumstances it is without appreciable influence on the course of events. In the edifice of classical physics, this situation finds its idealized expression in the assumption that the interaction between the object and the tools of observation can be neglected or, at any rate, compensated for.

The element of wholeness, symbolized by the quantum of action and completely foreign to classical physical principles has, however, the consequence that in the study of quantum processes any experimental enquiry implies an interaction between the atomic object and the measuring tools which, although essential for the characterization of the phenomena, evades a separate account if the experiment is to serve its purpose of yielding unambiguous answers to our questions. It is indeed the recognition of this situation which makes the recourse to a statistical mode of description imperative as regards the expectations of the occurrence of individual quantum effects in one and the same experimental arrangement, and which removes any apparent contradiction between phenomena observed under mutually exclusive experimental conditions. However contrasting such phenomena may at first sight appear, it must be realized that they are complementary in the sense that taken together they exhaust all information about the atomic object, which can be expressed in common language without ambiguity.

The notion of complementarity does not imply any renunciation of detailed analysis limiting the scope of our enquiry, but simply stresses the character of objective description, independent of subjective judgment, in any field of experience where unambiguous communication essentially involves regard to the circumstances in which evidence is obtained. In logical respect, such a situation is well known from discussions about psychological and social problems where many words have been used in a complementary manner since the very origin of language. Of course we are here often dealing with qualities unsuited to the quantitative analysis characteristic of so-called exact sciences, whose task, according to the programme of Galileo, is to base all description on well-defined measurements.

Notwithstanding the help which mathematics has always offered for such a task, it must be realized that the very definition of mathematical symbols and operations rests on simple logical use of common language. Indeed, mathematics is not to be regarded as a special branch of knowledge based on the accumulation of experience, but rather as a refinement of general language, supplementing it with appropriate tools to represent relations for which ordinary verbal communication is imprecise or too cumbersome. Strictly speaking, the mathematical formalism of quantum mechanics and electrodynamics merely offers rules of calculation for the deduction of expectations about observations obtained under well-defined experimental conditions specified by classical physical concepts. The exhaustive character of this description depends not only on the freedom, offered by the formalism, of choosing these conditions in any conceivable manner, but equally on the fact that the very definition of the phenomena under consideration for their completion implies an element of irreversibility in the observational process emphasizing the fundamentally irreversible character of the concept of observation itself.

Of course all contradictions in the complementary account in quantum physics were beforehand excluded by the logical consistency of the mathematical scheme upholding every demand of correspondence. Still, the recognition of the reciprocal latitude for the fixation of any two canonically conjugate variables, expressed in the principle of indeterminacy formulated by Heisenberg in 1927, was a decisive step towards the elucidation of the measuring problem in quantum mechanics. Indeed it became evident that the formal representation of physical quantities by non-commuting operators directly reflects the relationship of mutual exclusion between the operations by which the respective physical quantities are defined and measured.

To gain familiarity with this situation, the detailed treatment of a great variety of examples of such arguments was needed. Notwithstanding the generalized significance of the superposition principle in quantum physics, an important guide for the closer study of observational problems was repeatedly found in Rayleigh's classic analysis of the inverse relation between the accuracy of image-forming by microscopes and the resolving power of spectroscopic instruments. In this connection not least Darwin's mastery of the methods of mathematical physics often proved helpful.

With all appreciation of Planck's happy choice of words when introducing the concept of a universal 'quantum of action', or the suggestive value of the idea of 'intrinsic spin', it must be realized that such notions merely refer to relationships between well-defined experimental evidence which cannot be comprehended by the classical mode of description. Indeed, the numbers expressing the values of the quantum or spin in ordinary physical units do not concern direct measurements of classically defined actions or angular momenta, but are logically interpretable only by consistent use of the mathematical formalism of quantum theory. In particular the much discussed impossibility of measuring the magnetic moment of a free electron by ordinary magnetometers is directly evident from the fact that in Dirac's theory the spin and magnetic moment do not result from any alteration in the basic Hamiltonian equation of motion, but appear as consequences of the peculiar non-commutative character of the operator calculus.

The question of the proper interpretation of the notions of complementarity and indeterminacy was not settled without lively disputes, in particular at the Solvay meetings of 1927 and 1930. On these occasions, Einstein challenged us with his subtle criticism which especially gave the inspiration to a closer analysis of the role of the instruments in the measuring process. A crucial point, irrevocably excluding the possibility of reverting to causal pictorial description, was the recognition that the scope of unambiguous application of the general conservation laws of momentum and energy is inherently limited by the circumstance that any experimental arrangement, allowing the location of atomic objects in space and time, implies a transfer, uncontrollable in principle, of momentum and energy to the fixed scales and regulated clocks indispensable for the definition of the reference frame. The physical interpretation of the relativistic formulation of quantum theory ultimately rests on the possibility of fulfilling all relativity exigencies in the account of the handling of the macroscopic measuring apparatus.

This circumstance was especially elucidated in the discussion of the measurability of electromagnetic field components raised by Landau and Peierls as a serious argument against the consistency of quantum field theory. Indeed, a detailed investigation in collaboration with Rosenfeld showed that all the predictions of the theory in this respect could be fulfilled when due regard was taken to the mutual exclusiveness of the fixation of the values of electric and magnetic intensities and the specification of the photon composition of the field. An analogous situation is met with in positron theory where any arrangement suited for measurements of the charge distribution in space necessarily implies uncontrollable creation of electron pairs.

The typical quantum features of electromagnetic fields do not depend on scale, since the two fundamental constants—the velocity of light c and the quantum of action h—do not allow of any fixation of quantities of dimensions of a length or time interval. Relativistic electron theory, however, involves the charge e and mass m of the electron, and essential characteristics of the phenomena are limited to spatial extensions of the order h/mc. The fact that this length is still large compared with the 'electron radius' e^2/mc^2, which limits the unambiguous application of the concepts of classical electromagnetic theory, suggests, however, that there is still a wide scope for the validity of quantum electrodynamics, even though many of its consequences cannot be tested by practical experimental arrangements involving measuring instruments sufficiently large to permit the neglect of the statistical element in their construction and handling. Such difficulties would of course also prevent any direct enquiry into the close interactions of the fundamental constituents of matter, whose number has been so largely increased by recent discoveries, and in the exploration of their relationships we must therefore be prepared for a new approach transcending the scope of present quantum theory.

It need hardly be stressed that such problems do not arise in the account of the ordinary physical and chemical properties of matter, based on the Rutherford atomic model, in the analysis of which use is only made of well-defined characteristics of the constituent particles. Here, the complementary description offers indeed the adequate approach to the problem of atomic stability with which we were faced from the very beginning. Thus, the interpretation of spectral regularities and chemical bonds refers to experimental conditions mutually exclusive of those which permit exact control of the position and displacement of the individual electrons in the atomic systems.

In this connection, it is of decisive importance to realize that the fruitful application of structural formulae in chemistry rests solely on the fact that the atomic nuclei are so much heavier than the electrons that, in comparison with molecular dimensions, the indeterminacy in the position of the nuclei can be largely neglected. When we look back on the whole development we recognize indeed that the discovery of the concentration of the mass of the atom within a region so small compared with its extension has been the clue to the understanding of an immense field of experience embracing the crystalline structure of solids as well as the complex molecular systems which carry the genetic characters of living organisms.

As is well known, the methods of quantum theory have also proved decisive for the clarification of many problems regarding the constitution and stability of the atomic nuclei themselves. To some early disclosed aspects of such problems I shall have occasion to refer in continuing the account of my reminiscences of Rutherford, but it would be beyond the scope of this Memorial Lecture to attempt a detailed account of the rapidly increasing insight in the intrinsic nuclear constitution, brought about by the work of the present generation of experimental and theoretical physicists. This development reminds indeed the elders among us of the gradual clarification of the electronic constitution of the atom in the first decades after Rutherford's fundamental discovery.

X

Every physicist is of course acquainted with the imposing series of brilliant investigations with which Rutherford to the very end of his life augmented our insight into the properties and constitution of atomic nuclei. I shall therefore here mention only a few of my remembrances from those years when I often had occasion to follow the work in the Cavendish Laboratory and learned in talks with Rutherford about the trend of his views and the problems occupying him and his collaborators.

With his penetrating intuition, Rutherford was early aware of the strange and novel problems presented by the existence and stability of composite nuclei. Indeed, already in the Manchester time he had pointed out that any approach to these problems demanded the assumption of forces of short range between the nuclear constitutents, of a kind essentially different from the electric forces acting between charged particles. With the intention of throwing more light on the specific nuclear forces, Rutherford and Chadwick, in the first years in Cambridge, performed thorough investigations of anomalous scattering of α-rays in close nuclear collisions.

Although much important new evidence was obtained in these investigations, it was more and more felt that, for a broader attack on nuclear problems, the natural α-ray sources were not sufficient and that it was desirable to have available intense beams of high-energy particles produced by artificial acceleration of ions. In spite of Chadwick's urge to start the construction of an appropriate accelerator, Rutherford was during several years reluctant to embark upon such a great and expensive enterprise in his laboratory. This attitude is quite understandable when one considers the wonderful progress which Rutherford hitherto had achieved with the help of very modest experimental equipment. The task of competing with natural, radioactive sources must also have appeared quite formidable at that time. The outlook, however, was changed by the development of quantum theory and its first application to nuclear problems.

Rutherford himself had as early as 1920 in his second Bakerian Lecture clearly pointed out the difficulties of interpreting α-ray emission from nuclei on the basis of the simple mechanical ideas, which had proved so helpful in explaining the scattering of α-particles by nuclei, since the velocity of the ejected particles was not large enough to allow them by reversal to re-enter the nuclei against the electric repulsion. However, the possibilities of penetration of particles through potential barriers was soon recognized as a consequence of wave mechanics, and in 1928 Gamow, working in Göttingen, as well as Condon and Gurney in Princeton, gave on this basis a general explanation of α-decay and even a detailed account of the relationship between the lifetime of the nucleus and the kinetic energy of the emitted α-particles, in conformity with the empirical regularities found by Geiger and Nuttall in the early Manchester days.

When, in the summer of 1928, Gamow joined us in Copenhagen, he was investigating the penetration of charged particles into nuclei by a reverse tunnel effect. He had started this work in Göttingen and discussed it with Houtermans and Atkinson, with the result that the latter were led to suggest that the source of solar energy might be traced to nuclear transmutations induced by impact of protons with the great thermal velocities which according to Eddington's ideas were to be expected in the interior of the sun.

During a brief visit to Cambridge in October 1928, Gamow discussed the experimental prospects arising from his theoretical considerations with Cockcroft, who by more detailed estimates convinced himself of the possibility of obtaining observable effects by bombardment of light nuclei with protons of an energy far smaller than that of α-particles from natural radioactive sources. As the result appeared promising, Rutherford accepted Cockcroft's proposal to build a high voltage accelerator for such experiments. Work on the construction of the apparatus was started by Cockcroft at the end of 1928 and was continued during the following year with the collaboration of Walton. The first experiments they made with accelerated protons in March 1930, in which they looked for gamma rays emitted as a result of the interaction of the protons with the target nuclei, gave no result. The apparatus then had to be rebuilt owing to a change of laboratory and, as is well known, production of high-speed α-particles by proton impact on lithium nuclei was obtained in March 1932.

These experiments initiated a new stage of most important progress, during which both our knowledge of nuclear reactions and the mastery of accelerator techniques rapidly increased from year to year. Already Cockcroft and Walton's first experiments gave results of great significance in several respects. Not only did they confirm in all details the predictions of quantum theory as regards the dependence of the reaction cross section on the energy of the protons, but it was also possible to connect the kinetic energy of the emitted α-rays with the masses of the reacting particles which were at that time known with sufficient accuracy thanks to Aston's ingenious development of mass spectroscopy. Indeed, this comparison offered the first experimental test of Einstein's famous relation between energy and mass, to which he had been led many years before by relativity arguments. It need hardly be recalled how fundamental this relation was to prove in the further development of nuclear research.

The story of Chadwick's discovery of the neutron presents similar dramatic features. It is characteristic of the broadness of Rutherford's views that he early anticipated the presence in nuclei of a heavy neutral constituent of a mass closely coinciding with that of the proton. As gradually became clear, this idea would indeed explain Aston's discoveries of isotopes of nearly all elements with atomic masses closely approximated by multiples of the atomic weight of hydrogen. In connection with their studies of many types of α-ray induced nuclear disintegrations Rutherford and Chadwick made an extensive search for evidence concerning the existence of such a particle. However, the problem came to a climax through the observation by Bothe and the Joliot–Curies of a penetrating radiation resulting from the bombardment of beryllium by α-particles. At first this radiation was assumed to be of γ-ray type, but with Chadwick's thorough familiarity with the multifarious aspects of radiative phenomena he clearly perceived that the experimental evidence was not compatible with this view.

Indeed, from a masterly investigation, in which a number of new features of the phenomenon were revealed, Chadwick was able to prove that one was faced with momentum and energy exchanges through a neutral particle, the mass of which he determined as differing from that of the proton by less than one part in a thousand. On account of the ease with which neutrons, compared with charged particles, can pass through matter without transfer of energy to the electrons and penetrate into atomic nuclei, Chadwick's discovery opened great possibilities of producing new types of nuclear transmutations. Some most interesting cases of such new effects were immediately demonstrated in the Cavendish by Feather, who obtained cloud chamber pictures showing nitrogen nuclei disintegrating under α-particle release by neutron bombardment. As is well known, continued studies in many laboratories along such lines were rapidly to increase our knowledge of nuclear constitution and transmutation processes.

In the spring of 1932, at one of our yearly conferences in the Copenhagen Institute, where as always we were happy to see many of our former collaborators, one of the main topics of discussion was of course the implications of the discovery of the neutron, and a special point raised was the apparently strange circumstance that in Dee's beautiful cloud chamber pictures no interaction whatever was observed between the neutrons and the electrons bound in the atoms. In relation to this point, it was argued that, owing to the dependence in quantum physics of the scattering cross section on the reduced mass of the colliding particles, this fact would not be inconsistent even with the assumption of short range interaction between the neutron and an electron of strength similar to that between the neutron and a proton. A few days later, I got a letter from Rutherford touching incidentally on this point, and which I cannot resist quoting in full:

April 21, 1932.

My dear Bohr,

I was very glad to hear about you all from Fowler when he returned to Cambridge and to know what an excellent meeting of old friends you had. I was interested to hear about your theory of the Neutron. I saw it described very nicely by the scientific correspondent of the Manchester Guardian, Crowther, who is quite intelligent in these matters. I am very pleased to hear that you regard the Neutron with favour. I think the evidence in its support, obtained by Chadwick and others, is now complete in the main essentials. It is still a moot point how much ionization is, or should be, produced to account for the absorption, disregarding the collisions with nuclei.

It never rains but it pours, and I have another interesting development to tell you about of which a short account should appear in *Nature* next week. You know that we have a High Tension Laboratory where steady D.C. voltages can be readily obtained up to 600,000 volts or more. They have recently been examining the effects of a bombardment of light elements by protons. The protons fall on a surface of the material inclined at 45° to the axis of the tube, and the effects produced were observed at the side by the scintillation method, the zinc sulphide screen being covered with sufficient mica to stop the protons. In the case of lithium brilliant scintillations are observed, beginning at about 125,000 volts and mounting up very rapidly with voltage when many hundreds per minute can be obtained with a protonic current of a few milliamperes. The α-particles apparently had a definite range, practically independent of voltage, of 8 cm in air. The simplest assumption to make is that the lithium 7 captures a proton breaking up with the emission of two ordinary α-particles. On this view the total energy liberated is about 16 million volts and this is of the right order for the changes in mass involved, assuming the Conservation of Energy.

Later special experiments will be made to test the nature of the particles but from the brightness of the scintillations and the trail in a Wilson chamber it seems probable they are α-particles. In experiments in the last few days similar effects have been observed in Boron and Fluorine but the ranges of the particles are smaller although they look like α-particles. It may be, Boron 11 captures a proton and breaks up into three alphas, while fluorine breaks up into oxygen and an alpha. The energy changes are in approximate accord with these conclusions. I am sure you will be much interested in these new results which we hope to extend in the near future.

It is clear that the α-particle, neutron and proton will probably give rise to different types of disintegration and it may be significant that so far results have only been observed in $4n+3$ elements. It looks as if the addition of the 4th proton leads at once to the formation of an α-particle and the consequent disintegration. I suppose, however, the whole question should be regarded as the result of one process rather than of steps.

I am very pleased that the energy and expense in getting high potentials has been rewarded by definite and interesting results. Actually they ought to have observed the effect a year or so ago but did not try it in the right way. You can easily appreciate that these results may open up a wide line of research in transmutation generally.

We are all very well at home and I start lectures tomorrow. With best wishes to you and Mrs. Bohr.

Yours ever

RUTHERFORD

Beryllium shows some queer effects—still to be made definite.
I shall possibly refer to these experiments in the Royal Society discussion on nuclei on Thursday April 25.

Of course, in reading this letter, it must be borne in mind that my previous visits to Cambridge had kept me acquainted with the work in progress in the Cavendish Laboratory, so that Rutherford had no need to specify the individual contributions of his collaborators. The letter is indeed a spontaneous expression of his exuberant joy in the great achievements of those years and his eagerness in pursuing their consequences.

XI

As a true pioneer, Rutherford never relied merely on intuition, however far it carried him, but was always on the look-out for new sources of knowledge which could possibly lead to unexpected progress. Thus, also in Cambridge, Rutherford and his collaborators continued with great vigour and steadily refined apparatus the investigations of the radioactive processes of α- and β-decay. The important work of Rutherford and Ellis on β-ray spectra revealed the possibility of a clear distinction between intranuclear effects and the interaction of the β-particle with the outer electron system and led to the clarification of the mechanism of internal conversion.

Moreover, Ellis' demonstration of the continuous spectral distribution of the electrons directly emitted from the nucleus raised a puzzling question about energy conservation, which was eventually answered by Pauli's bold hypothesis of the simultaneous emission of a neutrino, affording the basis for Fermi's ingenious theory of β-decay.

By the great improvement of accuracy in measurements of α-ray spectra by Rutherford, Wynn-Williams and others, much new light was thrown on the fine structure of these spectra and their relation to the energy levels of the residual nucleus resulting from the α-decay. A special adventure at an earlier stage was the discovery of the capture of electrons by α-rays which, after the first observation of the phenomenon in 1922 by Henderson, was explored by Rutherford in one of his most masterly researches. As is well known, this work, which brought so much information about the process of electron capture, was to attract new attention a few years after Rutherford's death when, with the discovery of the fission processes of heavy nuclei by neutron impact, the study of the penetration of highly charged nuclear fragments through matter, where electron capture is the dominating feature, came into the foreground.

Great progress both as regards general outlook and experimental technique was initiated in 1933 by the discovery by Frédéric Joliot and Irène Curie of so-called artificial β-radioactivity produced by nuclear transmutations initiated by α-ray bombardment. I need hardly here remind how, by Enrico Fermi's brilliant systematic investigations of neutron induced nuclear transmutations, radioactive isotopes of a great number of elements were discovered and much information gained about nuclear processes initiated by capture of slow neutrons. Especially the continued study of such processes revealed most remarkable resonance effects of a sharpness far surpassing that of the peaks in the cross section of α-ray induced reactions first observed by Pose and to Gurney's explanation of which, on the basis of the potential well model, Gamow at once drew Rutherford's attention.

Already Blackett's observations with his ingenious automatic cloud chamber technique had shown that, in the very process investigated in Rutherford's original experiments on artificial nuclear disintegrations, the incident α-particle remained incorporated in the residual nucleus left after proton escape. It now became clear that all types of nuclear transmutations within a large energy region take place in two well-separated steps. Of these the first is the formation of a relatively long-lived compound nucleus, while the second is the release of its excitation energy as a result of a competition between the various possible modes of disintegration and radiative processes. Such views, in which Rutherford took a vivid interest, were the theme for the last course of lectures which on Rutherford's invitation I gave in 1936 in the Cavendish Laboratory.

Less than two years after Rutherford's death in 1937, a new and dramatic development was initiated by the discovery of the fission processes of the heaviest elements by his old friend and collaborator in Montreal, Otto Hahn, working in Berlin with Fritz Strassmann. Immediately after this discovery, Lise Meitner and Otto Frisch, then working in Stockholm and Copenhagen, and now both in Cambridge, made an important contribution to the understanding of the phenomenon by pointing out that the critical decrease in stability of nuclei of high charge was a simple consequence of the balancing of cohesive forces between the nuclear constituents and the electrostatic repulsion. A closer investigation of the fission process in collaboration with Wheeler showed that many of its characteristic features could be accounted for in terms of the mechanism of nuclear reactions involving as a first step the formation of a compound nucleus.

In Rutherford's last years he found in Marcus Oliphant a collaborator and friend whose general attitude and working power reminds us so much of his own. At that time new possibilities of research were opened by Urey's discovery of the heavy hydrogen isotope ^{2}H or deuterium, and by the construction of the cyclotron by Lawrence, who in his first investigations on nuclear disintegrations by deuteron beams obtained a number of new striking effects. In the classical experiments of Rutherford and Oliphant, in which by bombardment of separated lithium isotopes with protons and deuterons they were led to the discovery of ^{3}H, or tritium, and ^{3}He, the foundation was indeed created for the vigorous modern attempt to apply thermonuclear reactions to the realization of the full promises of atomic energy sources.

From the very beginning of his radioactive researches, Rutherford was acutely aware of the wide perspectives they opened in several directions. In particular, he early took deep interest in the possibility of arriving at an estimate of the age of the earth and of understanding the thermal equilibrium in the crust of our planet. Even if the liberation of nuclear energy for technological purposes was still to come, it must have been a great satisfaction for Rutherford that the explanation of the hitherto completely unknown source of solar energy as a result of the development he had initiated had come within the horizon in his lifetime.

XII

When we look back on Rutherford's life we perceive it, of course, against the unique background of his epoch-making scientific achievements, but our memories will always remain irradiated by the enchantment of his personality. In earlier Memorial Lectures, several of Rutherford's closest co-workers have recalled the inspiration which emanated from his vigour and enthusiasm and the charm of his impulsive ways. Indeed, in spite of the large and rapidly expanding scope of Rutherford's scientific and administrative activities, the same spirit reigned in the Cavendish as we all had enjoyed so much in the early Manchester days.

A faithful account of Rutherford's eventful life from childhood till his last days has been written by his old friend from the Montreal period, A. S. Eve. Especially the many quotations in Eve's book from Rutherford's astonishingly large correspondence give a vivid impression of his relations with colleagues and pupils all over the world. Eve also does not fail to report some of the humorous stories which constantly grew around Rutherford, and to which I alluded in a speech, reproduced in his book, when Rutherford for the second and last time visited us in Copenhagen in 1932.

Characteristic of Rutherford's whole attitude was the warm interest he took in any one of the many young physicists with whom he came into contact for shorter or longer periods. Thus I vividly remember the circumstances of my first meeting in Rutherford's office in the Cavendish with the young Robert Oppenheimer, with whom I was later to come into such close friendship. Indeed, before Oppenheimer entered the office, Rutherford, with his keen appreciation of talents, had described the rich gifts of the young man, which in the course of time were to create for him his eminent position in scientific life in the United States.

As is well known, Oppenheimer, shortly after his visit to Cambridge, during his studies in Göttingen was among the first who called attention to the phenomenon of particle penetration through potential barriers, which should prove basic for the ingenious explanation of α-decay by Gamow and others. After his stay in Copenhagen, Gamow came in 1929 to Cambridge, where his steady contributions to the interpretation of nuclear phenomena were highly appreciated by Rutherford, who also greatly enjoyed the bizarre and subtle humour which Gamow unfolded in daily intercourse and to which he later gave so abundant expression in his well-known popular books.

Of the many young physicists from abroad working in the Cavendish Laboratory in those years, one of the most colourful personalities was Kapitza, whose power of imagination and talent as a physical engineer Rutherford greatly admired. The relationship between Rutherford and Kapitza was very characteristic of them both and was, notwithstanding inevitable emotional encounters, marked from first to last by a deep mutual affection. Such sentiments were also behind Rutherford's efforts to support Kapitza's work after his return to Russia in 1934, and were from Kapitza's side most movingly expressed in a letter which I received from him after Rutherford's death.

When, in the beginning of the nineteen thirties, as an extension to the Cavendish, the Mond Laboratory was created on Rutherford's initiative for the promotion of Kapitza's promising projects, Kapitza wanted in its decoration to give expression for his joy in Rutherford's friendship. Still, the carving of a crocodile on the outer wall caused comments which could only be appeased by reference to special Russian folklore about animal life. Above all, however, the relief of Rutherford, in Eric Gill's artistic interpretation, placed in the entrance hall, deeply shocked many of Rutherford's friends. On a visit to Cambridge I confessed that I could not share this indignation, and this remark was so welcomed that Kapitza and Dirac presented me with a replica of the relief; installed above the fireplace in my office at the Copenhagen Institute it has since given me daily enjoyment.

When, in recognition of his position in science Rutherford was given a British peerage, he took a keen interest in his new responsibilities as a member of the House of Lords, but there was certainly no change in the directness and simplicity of his behaviour. Thus I do not remember any more severe utterance of his to me than, when at a Royal Society Club dinner in a conversation with some of his friends I had referred to him in the third person as Lord Rutherford, he furiously turned on me with the words: "Do you lord me?".

In the nearly twenty years during which Rutherford, right up to his death, worked with undiminished energy in Cambridge, my wife and I kept in close touch with him and his family. Almost every year, we were hospitably received in their beautiful home in Newnham Cottage at the backs of the old colleges, with the lovely garden in which Rutherford found relaxation and the upkeep of which gave Mary Rutherford much enjoyable work. I remember many peaceful evening hours in Rutherford's study spent discussing not merely new prospects of physical science but also topics from many other fields of human interest. In such conversation one was never tempted to overrate the interest of one's own contributions since Rutherford after a long day's work was apt to fall asleep as soon as the discourse seemed pointless to him. One then just had to wait until he woke up and resumed the conversation with usual vigour as if nothing had happened.

On Sundays, Rutherford regularly played golf in the morning with some close friends and dined in the evening in Trinity College where he met many eminent scholars and enjoyed discussions on the most different subjects. With his insatiable curiosity for all aspects of life, Rutherford had great esteem for his learned colleagues; however, I remember how he once remarked, on our way back from Trinity, that to his mind so-called humanists went a bit too far when expressing pride in their complete ignorance of what happened in between the pressing of a button at their front door and the sounding of a bell in the kitchen.

Some of Rutherford's utterances have led to the misunderstanding that he did not fully appreciate the value of mathematical formalisms for the progress of physical science. On the contrary, as the whole branch of physics, created so largely by himself, rapidly developed, Rutherford often expressed admiration for the new theoretical methods, and even took interest in questions of the philosophical implications of quantum theory. I remember especially how, at my last stay with him a few weeks before his death, he was fascinated by the complementary approach to biological and social problems and how eagerly he discussed the possibility of obtaining experimental evidence on the origin of national traditions and prejudices by such unconventional procedures as the interchange of newborn children between nations.

A few weeks later, at the Centenary Celebrations for Galvani in Bologna, we learned with sorrow and consternation of Rutherford's death, and I went at once to England to attend his funeral. Having been with them both so shortly before and found Rutherford in full vigour and in the same high spirits as always, it was under tragic circumstances, indeed, that I met Mary Rutherford again. We talked about Ernest's great life in which from their early youth she had been so faithful a companion, and how to me he had almost been as a second father. On one of the following days, Rutherford was buried in Westminster Abbey, close to the sarcophagus of Newton.

Rutherford did not live to see the great technological revolution which was to ensue from his discovery of the atomic nucleus and his subsequent fundamental researches. However, he was always aware of the responsibility connected with any increase in our knowledge and abilities. We are now confronted with a most serious challenge to our whole civilization, to see to it that disastrous use of the formidable powers which have come into the hands of man be prevented, and that the great progress be turned into promoting the welfare of all humanity. Some of us, who were called to take part in the war projects, often thought of Rutherford and modestly strove to act in the way which we imagined he himself would have taken.

The memory which Rutherford has left us remains to everyone who had the good fortune to know and come close to him a rich source of encouragement and fortitude. The generations who in coming years pursue the exploration of the world of atoms will continue to draw inspiration from the work and life of the great pioneer.

C. V. BOYS LECTURE

Counter Techniques in High Energy Nuclear Physics: Rare Decays of π- and μ-mesons

By A. W. MERRISON

Lecture delivered before the Institute of Physics and the Physical Society at the Conference on Nuclear Physics, Birmingham, on 17th April 1961

Abstract. It is shown, with particular reference to the decay $\mu^+ \rightarrow e^+ + \gamma$, how the study of rare decays of pions and muons, by means of counter techniques, has contributed to our understanding of the weak interactions.

In this talk I want to discuss some of the experiments that have been done, principally by counter techniques, on the unusual modes of decay of π- and μ-mesons. Counter experiments, because of selection criteria which can be built into them, have contributed very largely to this field and I shall in this talk show how the study of these decays has contributed to our knowledge of the weak interactions. I have listed in Table 1 all the known and presently conjectured decay modes of π- and μ-mesons along with their observed or predicted branching ratios and whether any particular mode of decay has any special interest. This last is, to some extent, a personal judgment, but I think there would not be too much divergence of views of high-energy physicists over this. I should point out there exist π^--decays corresponding to all the π^+-decays listed here and I have not distinguished neutrinos from anti-neutrinos.

Table 1. Decays of π- and μ-mesons

Decay	Observed	Branching ratio	Interest
$\pi^0 \rightarrow \gamma + \gamma$			
$\gamma + e^+ + e^-$	Yes	$1{\cdot}2 \times 10^{-2}$	No
$e^+ + e^- + e^+ + e^-$	Yes	4×10^{-5}	Yes
$\pi^+ \rightarrow \mu^+ + \nu$			
$\mu^+ + \nu + \gamma$	Yes		No
$e^+ + \nu$	Yes	$1{\cdot}2 \times 10^{-4}$	Yes
$e^+ + \nu + \gamma$	No	5×10^{-6}	No
$e^+ + \pi^0 + \nu$	No	10^{-8}	Yes
$\mu^+ \rightarrow e^+ + \nu + \nu$			
$e^+ + \nu + \nu + \gamma$	Yes	5×10^{-2}	No
$e^+ + \gamma$	No	?	Yes
$e^+ + e^+ + e^-$	No	?	Yes

Some comments on this table are appropriate. The so-called 'double Dalitz' decay of the neutral pion into 2 electron pairs is of interest in that it makes possible an experiment suggested some years ago by Yang (1950). He pointed out that if the neutral pion is pseudoscalar, then when it decays into two photons their planes of polarization will be perpendicular, and similarly there will be a correlation between the planes of the two electron pairs. Preliminary results (Plano *et al.* 1959) indicate clearly that the neutral pion is in fact pseudoscalar.

The electron decay mode of the pion is still of interest in that if one looks on the decay of the pion as going through a virtual nucleon–antinucleon state, then the branching ratio $(\pi \rightarrow e + \nu)/(\pi \rightarrow \mu + \nu)$ gives a direct comparison of the axial vector coupling of muons and electrons to nucleons. The most accurate measurements so far (Anderson *et al.* 1960) show that the strengths of the electron and muon couplings to nucleons are identical.

Having declared the field of interest, I shall illustrate what I have to say about counter techniques by discussing in some detail one particular rare, and perhaps non-existent, decay (namely $\mu \rightarrow e + \gamma$) and a particular counter experiment which was made to search for it by a CERN group about two years ago.

DECAYS OF THE μ-MESON

The normal decay mode of the μ-meson is now well established as $\mu \rightarrow e + \nu + \nu$, but it is worth looking at the experiments which established this, as they form an interesting background to more recent experiments which establish the existence of other decay modes.

It had been known ever since the first ‘ mesons ’ were discovered in the cosmic rays that they normally decayed into a single charged particle of small mass, and without inventing more new particles it seemed reasonable to suppose that this particle was an electron. But it was not until the decisive experiment of Leighton, Anderson and Seriff (1949) (Fig. 1) that it was established that the electron had a spectrum of energies, so that at least two neutral particles accompanied the emission of an electron. Again, using only *known* light neutral particles one could speculate that the decay was through $\mu \rightarrow e + \nu + \nu$, $\mu \rightarrow e + \nu + \gamma$, or $\mu \rightarrow e + \gamma + \gamma$. As it happened, an experiment by Hincks and Pontecorvo (1948) in the previous year had ruled out the possibility that μ-meson decays were accompanied by any substantial fraction of γ-rays. I will spend a little time describing this experiment as it is interesting to compare it with a more recent and, in detail, more complicated experiment which had the same end in view. Cosmic-ray μ-mesons were brought to rest in the block of graphite surrounded by the banks of Geiger counters C and B (Fig. 2). The arrival of a μ-meson was registered by a coincidence AB, and BC coincidences delayed by 0·6 to 5·3 μsec with respect to AB were looked for. (Note

one counter in B must be dead as it has recorded arrival of a μ-meson.) The idea was that the electron from $\mu \rightarrow e+\gamma$ would be detected by either A or B, and the γ-ray by conversion in the lead sheets in front of A and B and by the detection of the resulting pair in A or B.

Fig. 3. Schematic diagram of the apparatus.

A modern version of the same experiment is shown in Fig. 3, which shows an experiment carried out by CERN (by Ashkin, Fazzini, Fidecaro, Lipman, Merrison and Paul 1959) specifically to search for the decay $\mu \rightarrow e + \gamma$. This became fashionable at the end of 1958 for the following reasons. The weak interactions can be summed up in the archetypes

$$\mu \rightarrow e + \nu + \nu$$
$$n \rightarrow p + e + \nu$$
$$\mu + p \rightarrow n + \nu$$

leading to the well-known Puppi triangle (Fig. 4), which sums up the selection rules for the allowed weak interactions, and it is now well-established that one coupling constant is sufficient to account for the rates of all three interactions. An attractive way to account for these facts is to assume that the weak interactions are mediated by a charged vector boson; but this immediately runs into the difficulty that if this boson exists then $\mu \rightarrow e + \gamma$ will have an appreciable decay rate through a diagram of the form shown in Fig. 5. One simple calculation (by Feinberg 1958) gives a branching ratio for $(\mu \rightarrow e + \gamma)/(\mu \rightarrow e + \nu + \nu) \simeq 10^{-3}$. There are, of course, many ways of reducing or even completely suppressing this mode of decay, and one way, which is receiving a tremendous amount of experimental attention at the moment, is by supposing that the neutrinos associated with electrons and those associated with muons are different. An experiment to test this idea is now in an advanced state of preparation at the CERN laboratories in Geneva. It is a neutrino capture experiment similar to the experiment performed by Reines and Cowan with β-decay neutrinos. A difficulty which seemed to preclude such experiments with muon neutrinos (i.e. neutrinos from $\pi \rightarrow \mu + \nu$) was simply that the available fluxes of such neutrinos are so small. But it was pointed out by a number of people (see Rochester Conference 1960, p. 585) that one could overcome the scarcity of muon neutrinos by making use of the rise of cross section with momentum, which could lead to cross sections of the order of 10^{-38} cm^2 for 1 GeV neutrinos, and counting rates of the order of 1 per ton of detector per day with the fluxes currently available at the CERN proton synchrotron. The experiment would then be to look for the production of *electrons* with these muon neutrinos.

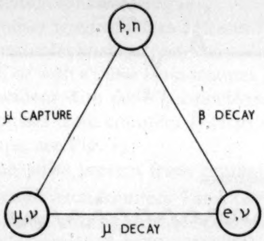

Fig. 4.

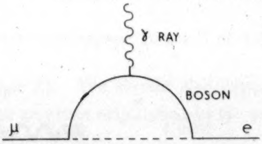

Fig. 5.

One can take a more simple-minded attitude to the problem, and if a reaction which obeys all the well-established conservation laws does not appear, one can ask experimentally what is its degree of forbiddenness. The search for $\mu \rightarrow e + \gamma$ is made difficult, as has been recently realized, by the existence of the decay $\mu \rightarrow e + \nu + \nu + \gamma$ which provides a background of (e, γ) pairs. The branching ratio of this process compared with the normal decay mode of the muon has been calculated by Fronsdal and Uberall (1959) and Kinoshita and Sirlin (1959). The $\mu \rightarrow e + \gamma$ mode, however, can be distinguished because, firstly, the *whole* rest energy of the muon goes into the electron and the γ-ray so that one should observe, as it is a two-body decay, a mono-energetic electron and a mono-energetic γ-ray each of about 53 MeV. Secondly, the electron and γ-ray will be emitted at 180° to each other. The bremsstrahlung process, on the other hand, gives continuous spectra for both the electron and γ-ray which are heavily weighted towards low energies, and the angular correlation does not favour 180° emission. So, by searching for high energy electrons and γ-rays at 180° we discriminate strongly against this process.

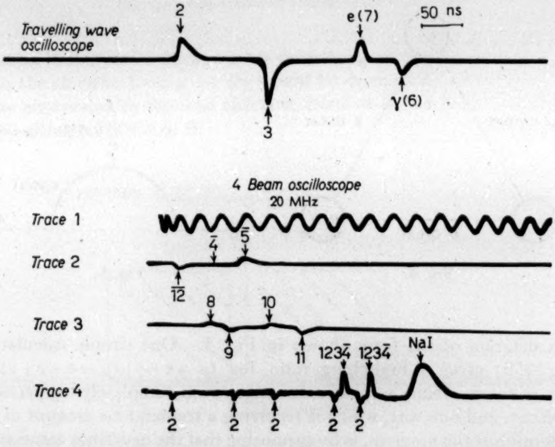

Fig. 6. Examples of traces from the travelling wave and four-beam oscilloscopes.

Of course, the principal difficulty in searching for rare decay modes is to be sure that nothing has been introduced into the design of the apparatus which would obscure the effect one is looking for. For this reason the apparatus was not designed with the idea of rejecting electronically as many unwanted events as possible. We preferred to record during the run also events to be re-examined later, which would show that the apparatus was working properly.

In the CERN experiment the muons were generated by allowing a beam of pions from the 600 MeV cyclotron to come to rest and decay in counter 3. So a stopping pion was first identified by a 123$\bar{4}$ coincidence. Counter 3 was surrounded on three sides by anticoincidence counters $\overline{12}$, $\bar{5}$, $\bar{4}$. On the fourth side was a coincidence counter telescope 7, 8, 9, 10, 11, with a certain amount of graphite absorber between the counters, and this served to detect the expected ~50 MeV electrons. On the opposite side to the electron telescope was a γ-ray telescope formed of the anticoincidence counter $\bar{5}$, the coincidence counter 6 and a lead converter between them, the whole backed by a very large NaI counter which analysed the energy spectrum of γ-rays detected in the electron telescope. Whenever a fast coincidence was recorded in counters 6, 7, 8 and $\bar{5}$ and $\overline{13}$ in anticoincidence† then the pulses from counters 2, 3, 6 and 7 were recorded on a fast oscilloscope.

A typical trace from this oscilloscope with pulses from all four counters present is shown in the top trace of Fig. 6. At the same time we displayed (as shown also in Fig. 6) on a four-beam oscilloscope pulses from counters 4, 5, 12 (on trace 2); from counters 8, 9, 10 and 11 (on trace 3); from counter 2, the NaI counter, and the coincidence pulse $123\bar{4}$ (on trace 4). On trace 1 we displayed a 20 Mc/s calibration signal. Traces 1, 2 and 3 were all run from the same time base. Trace 4 was run from an independent time base having a speed of 2 μsec cm^{-1}.

The event we searched for was a high-energy electron coming from counter 3, in time coincidence with a high energy γ-ray. This would be characterized by a pair of photographs showing:

(i) pulses from counters 3, 6 and 7 on the fast oscilloscope, present with the proper time relationship for a coincident event, but with either no pulse from counter 2, or with a pulse from counter 2 not in the right position for an incoming pion coincident with the e–γ coincidence;

(ii) pulses from counters 7–11 in the electron telescope (trace 3 of 4-beam oscilloscope, see Fig. 1);

(iii) no pulse present from counter $\bar{5}$ (trace 2). We should also expect no pulses present from counters $\bar{4}$ and $\overline{12}$, because an event originating in the source counter should not trigger these (trace 2);

(iv) a large pulse from the NaI(Tl) counter (trace 4).

For example, the event in Fig. 1 would be accepted as an e–γ event if the time relationship of the pulses in the fast and slow oscilloscopes were correct and if there were no pulses present in counters $\bar{5}$ and $\overline{12}$. Because of the high input rate of pions, many counter 2 and 1, 2, 3, $\bar{4}$ pulses were present on trace 4 of the slow oscilloscopes.

We ran the experiment in its final version for about 50 hours and in this time stopped $7{\cdot}35 \times 10^8$ pions in counter 3, taking a total of 5394 pairs of photographs on the oscilloscopes. We scanned the films first for events with a high energy electron (i.e. pulses from counters 8, 9, 10, 11 present on trace 3 of the slow oscilloscope). Examining the fast oscilloscope, the events which were left could be classified into the following categories:

(*a*) *Prompts.* These are events with pulses from counters 2, 6 and 7 in prompt coincidence. Such an event could arise from the decay of a neutral pion produced by a charge exchange interaction of an incoming positive pion. Of the resulting two γ-rays, one is converted and triggers the electron telescope, and the other triggers the γ-ray telescope. In most of the prompt events a pulse from counter 12 was present on trace 2 of the 4-beam oscilloscope.

(*b*) '*e*(7) γ(6)' *events.* Pulses from counters 6 and 7 are present but not from counter 3. This could be a muon decaying with emission of a γ-ray in some place other than counter 3. Some of these events are random; for example, the electron from one muon triggers the electron telescope in random coincidence with a γ-ray from another muon.

---

† Counter 13 protected the apparatus from showers generated in the lead collimator.

(*c*) '3*e*(7) γ(6)' *events.* These are the same as (*b*) but with a pulse from counter 3. They are essentially the events we are searching for and will be analysed in detail. They will, of course, include random events similar to these described in (*b*).

(*d*) '3*e*(7)3 γ(6)' *events.* These are a class of random events which contain two separate pulses from counter 3, one in coincidence with a pulse in counter 6 and the other with a pulse in counter 7.

(*e*) *Random events.* Triggered by a random coincidence circuit and clearly recognizable. We recorded these for the purpose of comparison. These also could be classified into the categories (*b*), (*c*), (*d*) and a few into category (*a*).

After this analysis we were left with 184 events of the first four categories (associated with a high-energy electron) as shown in Table 2.

Table 2

Prompt	e(7) γ(6)	3e(7) γ(6)	3e(7)3γ(6)
65	26	72	21

On examination of trace 2 of the slow oscilloscope it was necessary to reject a further 50 of the 72 events 3e(7)γ(6) because of the presence of $\overline{4}$, $\overline{5}$ or $\overline{12}$ pulses.

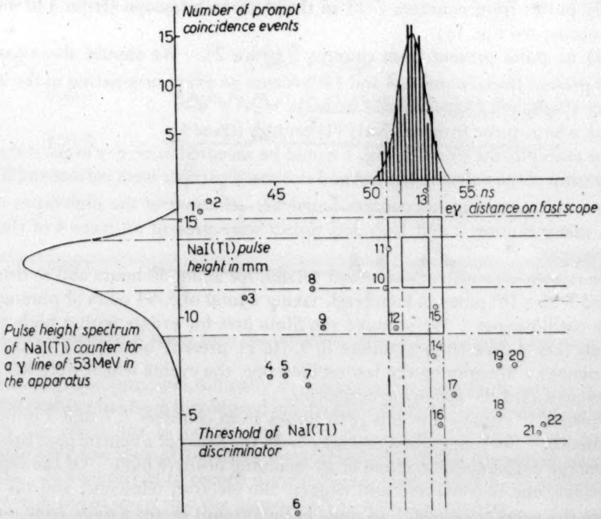

Fig. 7. Time delay and pulse height analysis of the twenty-two observed e–γ events. Abscissa gives the time delay between the e(7) and γ(6) pulses; comparison is made with the measured resolution curve for 'prompt' events. The ordinate gives the NaI(Tl) pulse height; comparison is made with a computed curve of the expected pulse height distribution for 53 MeV γ-rays incident on the Pb converter.

31 of the rejections were due to a $\bar{5}$ pulse being present. We did not expect the apparatus to record any such events, and in fact it was verified that these were random events which could be recorded only because the time interval for which the anticoincidence counter $\bar{5}$ was rejecting events was not wide enough to cover the whole acceptance time interval of the coincidence circuit.

The remaining 22 events were then subjected to a careful time analysis, and the associated NaI pulse heights were measured in order to select those events which had the correct e(7)γ(6) time delay, defined to the closest possible limits, and a γ-ray energy lying within the small range defined by the apparatus.

The total time resolution of the system was determined by measuring 133 prompt events (for which one knows that particles went through counters 6 and 7 in exact coincidence). The result obtained is shown in the top part of Fig. 7. The best-fit Gaussian to the histogram has a standard deviation of 0·70 nsec. This has been used as the defining time resolution curve in the analysis of the 3e(7)γ(6) events.

Plotted also in Fig. 7 is the expected pulse height distribution from the NaI(Tl) counter for 53 MeV γ-rays emitted from counter 3, and converted with the 3 mm Pb converter. The energy distribution of the electron–positron pair in the Pb converter and counter 6 has been taken into account, together with the experimentally determined NaI(Tl) resolution curve for mono-energetic particles.

The final analysis of the 22 events which had an energetic electron, in terms of the time resolution between electron and γ-ray events and in terms of γ-ray energy, is shown in Fig. 7. We have drawn in this figure the threshold for the NaI discrimination and we would expect to see no events below this. One event (6) has, however, been recorded, and this could be due perhaps to 'pile up' in the slow coincidence circuit or discriminator.

We have drawn on Fig. 7 'boxes' which correspond to 68% of the area under each of the resolution curves and 95% of the area under each curve. It can be seen that no events survive the first criteria and 3 events (11, 12, 15) the second. It is clear from the number of events falling outside the time-resolution curve that we can attribute a certain number of events in the 'boxes' to random events, and this we evaluated to be one event for the larger box. Using the results in the larger box we obtained a final branching ratio

$$\frac{\mu \rightarrow e + \gamma}{\mu \rightarrow e + \nu + \nu} = (1{\cdot}2 \pm 1{\cdot}5) \times 10^{-6}.$$

THE DECAY $\pi^+ \rightarrow \pi^0 + e^+ + \nu$

One final word about a reaction in Table 1, so far unobserved, which again looks most interesting: this is the decay $\pi^\pm \rightarrow \pi^0 + e^\pm + \nu$ which looks very much like a nuclear β-decay with the nuclei replaced by pions. The interest in this decay is that a universal coupling scheme, of the sort proposed by Feynman and Gell-Mann (1958), predicts very straightforwardly the rate of this decay. Unfortunately, because of the small momentum-space available (the charged pion is only 4 MeV heavier than the neutral pion) the branching ratio is about 10^{-8}. There is no doubt that technically this is not an impossible thing to look for because the decay of the π^0 into two high energy γ-rays provides a very characteristic 'signature', but with existing pion fluxes the rate of gathering events would be discouragingly small.

The Nuclear Scattering of High Energy Photons

By W. S. C. WILLIAMS†, H. S. CAPLAN‡ and D. T. STEWART
Department of Natural Philosophy, The University, Glasgow

MS. received 23rd February 1961

Abstract. The scattering from carbon nuclei of photons in the energy range 50–130 Mev has been measured by the use of a total absorption Čerenkov spectrometer in conjunction with a counter telescope. The angular range investigated was 90° to 135°. The results have been analysed by means of a simple model of nuclear charge distribution with nucleon polarizability and indicate the presence of some magnetic dipole scattering. A dispersion relation is applied to check the validity of this simple model.

§ 1. Introduction

There are many ways of exploring the structure of atomic nuclei, and each method reveals certain aspects of this structure. Important among these methods are the measurements of differential cross section for the scattering of electrons and of photons by nuclei. The former technique has been extensively used by Hofstadter and his co-workers (Hofstadter 1956) and it yields what is essentially the charge density distribution for the nucleus under study. The scattering of photons can, in principle, yield the same information but it is more influenced by the anomalous structure of the nucleon in the nucleus than is the electron scattering. Thus the existence of the resonant isobar nucleon state will affect the photon scattering whereas it may have no effect on the electron scattering. One of the objectives of the present study is to detect such anomalous effects in the scattering of high energy photons from carbon nuclei.

It is worth noting the main features of the nuclear photon scattering cross section. At energies close to zero (<1 Mev) the cross section is given by the Thomson cross section $\frac{1}{2}(1+\cos^2\theta)\,(Z^2e^2/AMc^2)^2$. M is the mass of a single nucleon and other symbols have their usual meaning. As the energy increases in the range 15–40 Mev the scattering increases with the giant resonance in the photodisintegration cross section and the scattering total cross section can reach a value of $\sigma_a{}^2/6\pi\lambda^2$, where σ_a is the photon nuclear absorption cross section. Beyond the giant resonance the elastic cross section will fall to a value expected for Z free protons scattering coherently, multiplied by a nuclear form factor f^2,

$$\frac{d\sigma}{d\Omega}=Z^2f^2\tfrac{1}{2}(1+\cos^2\theta)\left(\frac{e^2}{Mc^2}\right)^2. \qquad \ldots\ldots(1)$$

There will also be a small amount of inelastic scattering. At higher energies the elastic scattering will become negligible except for scattering in the forward direction. The work described in this paper has been done at energies well above the giant resonance but below meson production threshold. Eqn (1) is expected to hold at these energies.

§ 2. Experimental Method

2.1. *The Experimental Arrangement*

This experiment was conducted using the bremsstrahlung beam of the Glasgow University Synchrotron. Fig. 1 shows the experimental arrangement to observe photon scattering at 90° from the beam. The peak of the bremsstrahlung spectrum was set at 132 Mev in order to exclude the background from γ-rays from π^0 photoproduction. The total scattered γ-ray spectrum was measured and both elastic and inelastic events were accepted. However, in the energy range of interest, from 50 to 130 Mev, it is almost certain that the contribution of the inelastic scattering is small.

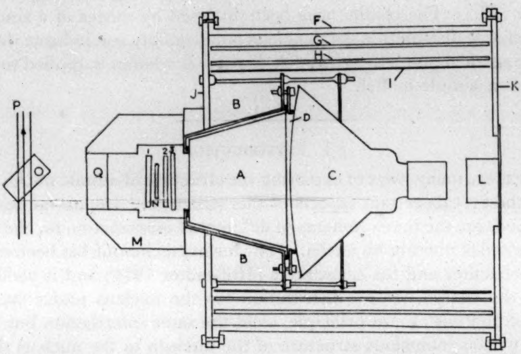

Fig. 1. A horizontal section through the equipment when arranged to measure scattering at 90°. A, lead glass truncated cone; B, magnesium oxide powder; C, DuMont K1258 photomultiplier; D, Perspex light guide; F–H, mild steel screening; I, mu-metal screening; J–K, steel end plates; L, White cathode follower; M, lead shielding; N, lead converter; O, target; P, bremsstrahlung beam; 1, 2 and 3, scintillation counters.

The electrons circulating in the synchrotron were allowed to spiral into a tungsten radiator during a period of approximately 500 μsec at peak magnetic field, giving a variation of less than 1% in the bremsstrahlung peak energy during the beam pulse. The beam was collimated and 'scrubbed' by a magnetic field so as to have a diameter of 5 cm at the target. The target, formed of 6 g cm^{-2} of graphite, was set to intercept the entire beam.

2.2. *The Detector and Electronics*

The photon detector must be highly efficient and must also measure the energy of the scattered photon. These requirements were satisfied by a γ-ray telescope followed by a total absorption Čerenkov counter (see Fig. 1). The Čerenkov counter consists of a truncated cone of lead glass (A), 22·5 cm high, 19 cm diameter expanding to 30 cm. This cone was mounted in MgO powder (B) to enhance the light collection, and viewed at its 30 cm diameter face by a 40 cm diameter photomultiplier (C) (DuMont K 1258). The counter was magnetically shielded by a cylinder of mu-metal (I) and three layers (F, G, H) of mild steel. Radiation screening was provided by packing lead shot between the cone and magnetic shield and by an external lead brick wall (not shown in Fig. 1). The counter telescope was contained in a lead block (M) which has a circular aperture, 7 cm in diameter, plugged with 3·5 gm cm^{-1} of graphite (Q) to filter out low energy scattered radiation and heavy charged particles.

In order to register a true count, a photon scattered from the target (O) had to pass through the graphite filter, through counter 1 and convert in the lead plate (N). The resulting electron pair then had to pass through counters 2 and 3 and generate a shower in the Čerenkov counter. A block diagram of the associated electronics is shown in Fig. 2. A 6BN6 coincidence unit with a resolving time of 6×10^{-8} sec was operated by positive pulses from the last dynodes of the R.C.A. 6810 photomultipliers of counters 2 and 3. The bias levels of this unit were set to respond only to events corresponding to an electron pair passing through the counters. This, together with the anti-coincidence counter 1, screens out scattered electrons from the target. The output from this circuit and negative pulses from the counters C1, C2, C3 were presented to two fast coincidence units (resolving times $2{\cdot}5 \times 10^{-8}$ sec). One of these detects a 'real' event, a [2, 3] coincidence, and the other detects [1, 2, 3] coincidences ('veto' events).

Fig. 2. Block diagram of electronics.

The pulse from the last dynode of the spectrometer photomultiplier was amplified and discriminated. The discriminator level corresponds to a γ-ray depositing 20 MEV in the spectrometer. The slow coincidence unit detected coincidences between (*a*) the discriminated output from the spectrometer, (*b*) a gate pulse which surrounded the beam pulse, and (*c*) the real coincidence circuit output, in the absence of an output from the veto coincidence circuit. Thus the slow coincidence unit detected the required [$\bar{1}$, 2, 3 + spectrometer] coincidences occurring during the beam pulse. (This method of specifying a real event was determined by the very high counting rate in counter 1 and reduced the loss of real events due to random anticoincidence to a reasonable level.) The clipped and amplified photomultiplier anode pulse from the spectrometer was examined by a kicksorter gated by the slow coincidence unit. Some early runs employed a camera-oscilloscope combination for pulse height analysis. This arrangement gave information on ‘pile-up’ and random background pulses and showed that the experiment could be performed with the present system.

The stability of the spectrometer electronics was checked by injecting standard pulses of various heights into the anode of the spectrometer multiplier. The gain did not change by more than 2% during the 12-hour runs.

2.3. *The Calibration of the Spectrometer*

The pulse height response of the Čerenkov counter was determined by utilizing a beam of mono-energetic electrons. Electron–positron pairs were produced in a 60 mg cm^{-2} Cu foil placed in the bremsstrahlung beam. The electrons were magnetically analysed and an electron beam with a narrow momentum range was selected by a counter telescope and presented to the Čerenkov counter. That part of the electron orbit which lay within the magnet was enclosed in hydrogen atmosphere in order to minimize the effects of multiple scattering on the momentum definition. This arrangement restricted the momentum spread of the selected electrons to approximately 1%. Pulse height distributions were recorded for electron energies of 50, 100, 150 and 200 MeV. Figs 3 and 4 show respectively the mean pulse height and the standard deviation of the distribution, as a function of incident energy. The results correspond to a full width at half height resolution of about 33% at 100 MeV and 27% at 200 MeV.

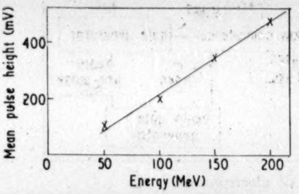

Fig. 3. Čerenkov counter mean output pulse height against incident electron energy.

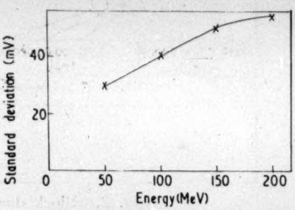

Fig. 4. Standard deviation of Čerenkov output pulse height distribution against incident electron energy.

2.4. *The Efficiency of the System*

The efficiency of the system for detection of photons was calculated and the result confirmed by measurement. The calculation involved an analysis of the converter efficiency in conjunction with the counters of the telescope and yielded the curve shown in Fig. 5 showing the detection efficiency against photon energy for a 3·3 gm cm^{-2} converter.

The measurement depends on the fact that the Čerenkov spectrometer alone is very nearly 100% efficient as a detector of photons. The complete system was placed in the bremsstrahlung beam, which was reduced by a factor of 10^7 from its normal intensity, and the number of incident photons recorded by counting the output pulses from the discriminator. At the same time the number of photons giving rise to electron pairs in the converter was measured by counting the gate pulses from the slow coincidence unit. The ratio of these two counts gives the efficiency of the system averaged over the bremsstrahlung beam. The discriminator was set to detect pulse heights corresponding to photons of energy greater than

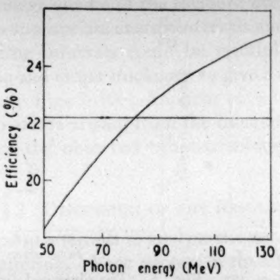

Fig. 5. Calculated photon detection efficiency versus photon energy for 3·3 g cm^{-2} lead converter.

50 Mev giving an energy range of 50–130 Mev. The measured efficiency was 22·2% and as the calculated efficiency, averaged over the same energy interval, was 22%, this result confirms the analysis of the data by the use of the calculated efficiency curve.

2.5. *Experimental Procedure*

The first part of the experiment was to measure the relative scattering cross sections at angles of 90°, 112° and 135° with a converter of 6·6 gm cm^{-2}. A measurement at a given angle consisted of recording the scattered photon spectrum for a certain value of the integrated beam intensity, followed by a similar run, for the same value of integrated beam with the converter removed. The spectrum due to scattered photons which convert in the lead plate could then be determined. The beam intensity was measured and integrated by the use of Wilson quantameter (Wilson 1957).

The second part of the experiment was the measurement of the absolute cross section at 90°. A number of runs were made with a 3·3 gm cm^{-1} converter in order to reduce the effects of multiple scattering of the electron pairs in the converter. The random anticoincidence rate was found by measuring the ratio of [1, 2, 3] coincidences to real [2, 3] coincidences when the signal from counter 1 was delayed by 5 × 10^{-8} sec. This measurement was made several times at each angle and the necessary corrections were found to be always less than 10%.

2.6. *Analysis of Data*

In order to check the operation of the apparatus a comparison was made between the pulse height spectrum generated by the scattered photons with that generated by the incident bremsstrahlung beam when the complete detection system lay in the beam. The expected pulse height spectrum generated by 1000 equivalent quanta of 132 Mev bremsstrahlen was calculated using the calculated detection efficiency and the known resolution and response of the spectrometer. This comparison is shown in Fig. 6 where the predicted spectrum (solid curve) is superimposed upon the observed spectrum (histogram), the two spectra being normalized to the same total number of pulses above 100 millivolts. Next the pulse height spectrum generated by scattered photons at a certain angle for a known number of incident equivalent quanta is compared with the spectrum

generated by 1000 equivalent quanta of the incident bremsstrahlen. These two spectra were divided into appropriate energy intervals and the ratio of the number of pulses in corresponding intervals could be multiplied by a known factor, containing the solid angle and target thickness, to give a differential cross section. These results are shown in Figs 7–10. An error of ±10% must be assigned to the vertical scales due to errors arising from the calculation of counter efficiency and the normalization of the observed bremsstrahlung pulse spectrum to the calculated spectrum.

§ 3. DISCUSSION OF THE RESULTS

The following discussion attempts to analyse the results in terms of a classical model of the photon scattering. Each proton in the nucleus gives rise to three scattering amplitudes: the first is due to the pure Thomson scattering, the second due to an induced magnetic dipole, and the third due to an induced electric dipole. Each neutron contributes only to the last two amplitudes and it is assumed that charge independence will cause the proton and neutron polarizability to be equal. The nucleons are assumed to be free but spread out uniformly throughout a sphere of radius $R=1\cdot 2A^{1/3}\times 10^{-13}$ cm, where $A=12$.

This model cannot be expected to hold below about 70 MeV because the giant resonance effects, which are due to nuclear structure, will be reflected by an increase in the scattering at the corresponding energies (Penfold and Garwin 1959). At very low energies it is known that the nuclear scattering is pure Thomson scattering from the entire nucleus (Alvarez, Crawford and Stevenson 1958).

Using the methods developed for the atomic scattering of X-rays (Compton and Allison 1935) it is found that this model leads to the following expression for the differential scattering cross section:

$$\begin{aligned}\frac{2}{r^2}\frac{d\sigma}{d\Omega} = {} & f^2[\{(Z-A\alpha)^2+A^2\beta^2\}(1+\cos^2\theta)-4A\beta(Z-A\alpha)\cos\theta] \\ & +(1-f^2)[Z\{(1-\alpha)^2+\beta^2\}(1+\cos^2\theta)-4Z(1-\alpha)\beta\cos\theta \\ & +N\{\alpha^2+\beta^2\}(1+\cos^2\theta)+4N\alpha\beta\cos\theta]. \qquad \ldots\ldots(2)\end{aligned}$$

A, Z and N have the usual meaning, r is the classical electric radius of the proton, f^2 is the nuclear form factor given by

$$f=\frac{3}{K^3R^3}\{\sin KR-KR\cos KR\}, \qquad \ldots\ldots(3)$$

K being the momentum transfer in units of reciprocal length,

$$K=\frac{2\sin\theta/2}{\lambda}. \qquad \ldots\ldots(4)$$

The symbols α and β stand for the amplitudes (relative to the Thomson amplitude) due to the electric and magnetic polarizability of a nucleon. If $\gamma=E/Mc^2$, E being the photon energy, then α/γ^2 and β/γ^2 are the nuclear polarizabilities in units of $(e^2/\hbar c)(\hbar/Mc)^3=6\cdot 8\times 10^{-44}\,\mathrm{cm}^3$ (Baldin 1960).

The differential cross section receives contributions from two parts: the first, proportional to f^2, is the coherent scattering from the nucleus; the second, proportional to $1-f^2$, is the contribution due to incoherent scattering, i.e. inelastic scattering. The Pauli exclusion principle and other effects due to nuclear binding reduce this inelastic scattering by an unknown factor and so we shall consider two cases, the first in which it is present and the second in which it is absent.

The solid lines on Fig. 10 are plots of $d\sigma/d\Omega$ against $\cos\theta$ at 100 MeV, for different values of α and β. Superimposed on the curves are the observed cross sections which are the average of the observations in the range 80–120 MeV. The presence of α decreases the scattering at all angles as the electric dipole amplitude interferes destructively with the Thomson amplitude at all angles. On the other hand, β decreases the scattering in forward directions and enhances the scattering in the backward direction. It is evident that the data are not sufficiently accurate to determine α and β with any confidence. However, Figs 11 and 12 show the two sets of contours of equal total square deviation on an α–β plane, the deviation being that between the observed and the predicted cross section. One set is for the coherent plus incoherent scattering (Fig. 11), the other for the coherent alone (Fig. 12). If $\alpha=0$, the curves suggest $\beta=0{\cdot}2$ or $0{\cdot}1$ for the cases of coherent or coherent and incoherent scattering respectively. An increase in α requires a corresponding increase in β. The two values mentioned correspond to a polarizability of $1{\cdot}2$ or $0{\cdot}6\times10^{-42}\,\text{cm}^3$. The solid lines of Figs 8–10 show $d\sigma/d\Omega$ given by Eqn (1) for coherent scattering alone and $\beta=0{\cdot}2$, $\alpha=0$. The agreement is as good as can be expected at higher energies. At the lower energies the experimental points lie above the line, presumably due to the effect of the tail of the giant resonance. The line for $\alpha=0$, $\beta=0{\cdot}1$ and coherent plus incoherent scattering would be very close to that for the conditions stated above.

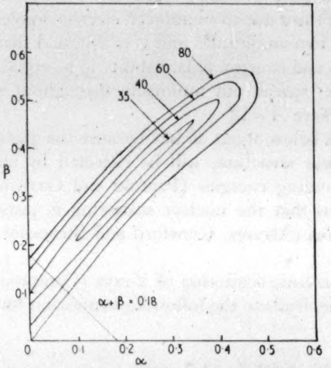

Fig. 11. Contours of equal total square deviations of cross section on α–β plane for coherent plus incoherent scattering. Units of square deviation are $1{\cdot}38\times10^{-64}\,\text{cm}^4$.

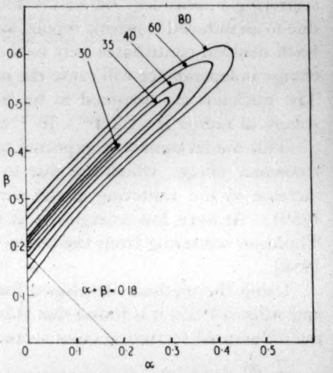

Fig. 12. Contours of equal total square deviations of cross section on α–β plane for coherent scattering alone. Units of square deviations are $1{\cdot}38\times10^{-64}\,\text{cm}^4$.

Dispersion relations can also be applied to photon scattering but, in general, only at a scattering angle of 0°. Fuller and Hayward (1956) give a dispersion relation which gives the total scattering cross section at low energies, assuming dipole scattering alone. At our energies it cannot be applied other than at 0°

and the relevant expression is

$$\frac{d\sigma}{d\Omega}(\theta=0^\circ)=[D(\omega)]^2+[A(\omega)]^2=\left[\frac{\omega^2}{2\pi^2}P\int_0^\infty\frac{\sigma_a(\omega')}{\omega'^2-\omega^2}\,d\omega'+D(0)\right]^2+\left[\frac{\omega\sigma_a(\omega)}{4\pi}\right]^2. \qquad \ldots\ldots(5)$$

$D(0)$ is the nuclear scattering amplitude at 0° and zero energy: this is just the Thomson amplitude $=-Z^2e^2/AMc^2=-(3\sigma_T/8\pi)^{1/2}$. $D(\omega)$ and $A(\omega)$ are the real and imaginary parts of the 0° scattering amplitude, ω is the photon energy in units of reciprocal length and $\sigma_a(\omega)$ is the total cross section for all processes at the energy ω.

The data used to evaluate the dispersion integral were as follows. The total cross section for photons undergoing nuclear effects in carbon in the energy range 15 to 60 MEV was obtained from the measurements of Wyckoff and Koch (1960). Above these energies the total cross section is assumed to be due to quasi-deuteron photodisintegration. The cross section for the absorption of a photon which leads to this process is $\sigma\simeq\sigma_D(3NZ/A)$ (Stein *et al.* 1960), where σ_D is the total deuteron photodisintegration cross section. (An escape factor has been dropped from their quasi-deuteron formula as it is irrelevant to the absorption of the incident photon.) The data for the deuteron photodisintegration cross section σ_D were obtained from the work of Galey (1960). Meson photoproduction also contributes to the total cross section and from the data given by Marshak (1952) was assumed to be constant at 0·8 mbn between 200 and 400 MEV. The results are

$$A(\omega)\simeq\ \ 2{\cdot}4\times10^{-16}\,\text{cm},$$
$$D(\omega)\simeq-1{\cdot}5\times10^{-15}\,\text{cm},$$

at $\omega=100$ MEV.

Hence

$$\frac{d\sigma}{d\Omega}(\theta=0^\circ)=2{\cdot}3\times10^{-30}\,\text{cm}^2\ \text{sterad}^{-1}.$$

The uncertainties in the evaluation of $D(\omega)$ and $A(\omega)$ are considerable due to the uncertainties in the total cross section. The real part of the dispersion calculated forward scattering amplitude $D(\omega)$, calculated from the dispersion formula, is expected to be larger (in magnitude) than the value calculated from our model. This latter amplitude is real and for $\alpha=0$, $\beta=0{\cdot}2$ has the value $-4{\cdot}7\times10^{-16}$ cm. It is $-7{\cdot}2\times10^{-16}$ for $\alpha=0$, $\beta=0{\cdot}1$, and $-1{\cdot}3\times10^{-15}$ for $\alpha=\beta=0$. Any increase in α increases (in a positive sense) the amplitude from these values. The difference between $D(\omega)$ and the amplitude of our model is least when $\alpha\simeq\beta\simeq0$ and thus the dispersion theory suggests that there is is no magnetic scattering. This could be because the meson photoproduction contribution to the dispersion integral has been underestimated whereas the giant resonance contribution has been overestimated. It is the former which should be the source of expected magnetic contribution because the magnetic polarizability is mesonic in origin. However, the forward scattering amplitude, calculated from dispersion theory, is greater in magnitude than that calculated from our model and that is all that was required.

Dispersion relations can also be applied to give an estimate of the upper limit of nucleon electric plus magnetic polarizability (Goldansky *et al.* 1960).

This value is $11 \times 10^{-43}\,\text{cm}^3$ and corresponds to the straight line drawn on Figs 11 and 12, $\alpha+\beta=0{\cdot}18$.

The conclusions are that the observed scattering is consistent with Thomson scattering from nucleons possessing a degree of magnetic polarizability in nuclear matter spread over a radius of $1{\cdot}2\,A^{1/3} \times 10^{-13}$ cm. This result is not in agreement with the measurements of Goldansky *et al.* (1960) who find for the free proton at 70 MeV that the magnetic polarizability is $2 \pm 2 \times 10^{-43}\,\text{cm}^3$ and the electric polarizability is $9 \pm 3 \times 10^{-43}\,\text{cm}^3$. However, it is not obvious that the free proton polarizabilities will be observed in nuclei. Our results are in general agreement with the results of Pugh *et al.* (1957).

Acknowledgments

The authors are indebted to Professor P. I. Dee for his interest and encouragement, and to Dr. W. McFarlane and the synchrotron crew for providing the photon beam.

Differential Energy Loss and Ranges of Ne, N and He Ions

By D. I. PORAT† and K. RAMAVATARAM‡
The Physical Laboratories, The University, Manchester

MS. received 27th April 1961

Abstract. The rate of energy loss for ^{20}Ne and ^{14}N ions in the energy region of 0·4 to about 6 Mev has been measured in C, Al, Ni, Ag and Au. The ranges of the ions in the above elements were calculated by integrating the differential energy loss taking into account scattering and energy losses due to nuclear collisions. The rate of energy loss for ^{4}He ions up to 2 Mev kinetic energy is reported and range curves in Al, Ni, Ag and Au up to 3 Mev are presented. Results on the energy loss of deuterons in Ag are used to extend the data at present available for protons to lower energies. The relative accuracy of the stopping power data is to about 1% and the absolute accuracy to better than 5%.

§ 1. INTRODUCTION

SOME low-energy nuclear physics experiments require information on the state of a heavy, slow ion which had traversed a target material. The differential energy loss, the range or the charge state may be of interest. These were subject to detailed investigations (Livingston and Bethe 1937, Bohr 1948, Bohr and Lindhard 1954) and the results are generally applicable to ion velocities $v \gg v_0$, where $v_0 = e^2/\hbar$ is the classical velocity of an electron in a hydrogen atom. Bohr has also shown the complementarity of the classical and quantum mechanical treatments of the subject.

At low ion velocities, where $v \sim v_0$, the problem of energy loss for heavy ions is complicated by charge exchange phenomena and by nuclear collisions in screened fields. The continual capture and loss of electrons not only modifies the interaction because of a changing effective charge of the ion, but also constitutes in itself one mode of energy loss.

Data on energy losses of He, C, N and O ions were reported earlier (Porat and Ramavataram 1959, 1960). The present paper reports results obtained with Ne ions and additional data with N and He ions. Several values on the $(dE/dx, E)$ curve for deuterons in Ag were also measured.

§ 2. EXPERIMENTAL

A detailed description of the method of measurement as well as an error analysis was given in an earlier paper (Porat and Ramavataram 1959). In brief, ions are accelerated by a 6 MV Van de Graaff generator and are selected in velocity to 1 part in 10^4, with the help of a magnetic analyser. A 90° cylindrical electrostatic analyser is used to measure the kinetic energy E_1 of the ion beam. A thin foil Δx is then interposed in the path of the ions at the object point of the electrostatic analyser and the reduced ion energy E_2 is measured. In the limit

$$\frac{E_1 - E_2}{\Delta x} = dE/dx \quad \Delta x \rightarrow 0.$$

The foils were obtained by evaporation and their surface density was measured by absorption of alpha particles. The measuring techniques were described in detail elsewhere (Ramavataram and Porat 1959), while the calibration of the instrument for measuring surface densities of the foils also yielded air equivalents for Al, Ni, Ag and Au at 3.72 and 4·33 MEV alpha-particle energy. The surface densities of the foils used in the present experiments were in the region of 20 to 500 μg cm^{-2}, depending on the ion, its energy and the stopping element in a particular measurement. Up to twelve different foils were used to establish a curve of (dE/dx, E) for any one combination of ion and stopping element. The comparatively large amount of foils used, together with frequent calibrations of the electrostatic analyser using the ^{19}F(p, $\alpha\gamma$)^{16}O resonance reactions at 874·5 and 935·1 kev (Hunt and Firth 1955) ensured relative values of dE/dx and E with an accuracy to 1% and absolute values with an accuracy to 5% or better.

§ 3 RESULTS

The experimental points for Ne ions are plotted in Fig. 1 and are based on 148 independent measurements. The values in Table 1 were taken from free-hand curves of Fig. 1 representing a best fit to the experimental points. In the lower energy region one has to take into account energy losses from nuclear collisions $(dE/dx)_n$ in addition to the electronic stopping $(dE/dx)_e$. The measured energy losses include $(dE/dx)_e$ and only part of $(dE/dx)_n$, since instrument geometry

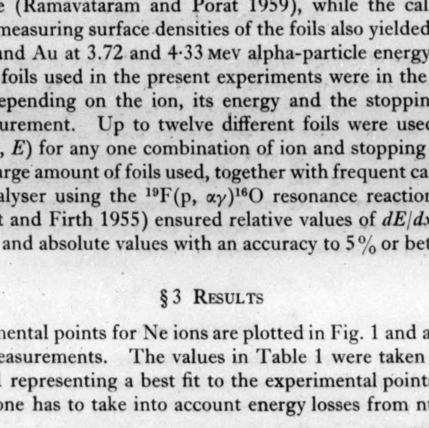

Fig. 1. Stopping power for neon ions. ——— present experiment - - - - Weyl (1953).

excludes detection of those particles which suffered large energy losses and large angular deflections as a result of close, nuclear collisions. An estimate of the contribution of such collisions to the total stopping power was made using the same arguments as in an earlier paper (Porat and Ramavataram 1959). The values under columns (a) in Table 1 refer to electronic stopping power and include a small correction based on the arguments above concerning nuclear large angle scattering. Columns (b) list the nuclear energy loss $(dE/dx)_n$ which was calculated on the basis of Bohr's (1948) theory of nuclear collisions in screened fields. As $(dE/dx)_n$ is only a small fraction of $(dE/dx)_e$, any correction to $(dE/dx)_{\text{exptl}}$ should introduce negligible errors in the final value of $(dE/dx)_e$, even though these corrections are based on an approximate theory. No previous measurements of the differential energy loss for neon ions in solids are available for comparison. The broken lines in Fig. 1 refer to measurements by Weyl (1953), using gases as absorbers. On plotting dE/dx in units of ev cm² per atom one would expect a monotonic increase in dE/dx with the atomic number of the stopping element. This is true for solid absorbers as a group as well as for the gaseous stopping media. However, the curves for gaseous absorbers are as a group displaced towards the lower rates of energy loss suggesting that the time between collisions in a gas of low pressure is sufficient for atomic de-excitation of the moving ion to take place, which in turn causes a low effective charge and hence lower rates of energy loss in gases than in solids of comparable atomic number.

(a) Electronic stopping power $(dE/dx)_e$ in kev cm² μg^{-1}.
(b) Nuclear stopping power $(dE/dx)_n$ in kev cm² μg^{-1}.

The ranges of neon ions in the five stopping elements were calculated by numerical integration of the differential energy loss and are shown in Fig. 2. Thus

$$\text{Range, } \bar{R} = \int_{E_{\text{final}}}^{E_{\text{initial}}} \{(dE/dx)_{\text{e}} + (dE/dx)_{\text{n}}\}^{-1}\, dE. \qquad \ldots\ldots(1)$$

The trapezium rule was used for integration at intervals of 100 kev and an extrapolated value of $(dE/dx)_{\text{e}}$ was used in the lower energy region. No accuracy is therefore claimed for ranges below about 400 kev. Powers (1960) measured ranges of N, Ne, A and Kr ions of 500 kev kinetic energy and below in the following targets: Be, B, C and Al. It is of interest to compare his results with the semi-empirical ranges of the present work, where these data are in overlapping energy regions. The comparsion is drawn in Table 2 and provides an indication of the accuracy of the results for Ne and N ions in the extrapolated (low energy) region.

The measurements on the stopping power for nitrogen ions, reported earlier (Porat and Ramavataram 1959), were extended to higher energies and an additional stopping element, namely carbon, has been included. The experimental points presented in Fig. 3 are based on 108 independent measurements. Table 3 lists the electronic and nuclear stopping powers under columns (a) and (b) respectively. Corrections due to large-angle scattering were applied as in the case of neon ions, above.

(a) Electronic stopping power $(dE/dx)_e$ in kev cm² μg⁻¹.
(b) Nuclear stopping power $(dE/dx)_n$ in kev cm² μg⁻¹.

Reynolds, Scott and Zucker (1954) measured the range of 8 to 29 Mev nitrogen ions in nickel from which one can deduce $dE/dx = 3{\cdot}7$ kev cm^2 μg^{-1}, nearly constant over this energy range. Their results as well as Weyl's (1953) results for nitrogen ions in gases up to 400 kev are indicated in Fig. 3. The values deduced from the range measurements of Reynolds *et al.* appear to be some 12% lower than an extrapolation of the present curves would indicate. However, a differentiation of a range curve cannot yield great accuracy especially at the low-energy end. Also, the value of $dE/dx = 3{\cdot}7$ kev cm^2 μg^{-1} is an average over an energy interval in which the $(dE/dx, E)$ curve reaches its maximum and from then on assumes a negative slope. The remarks concerning the differences of differential energy

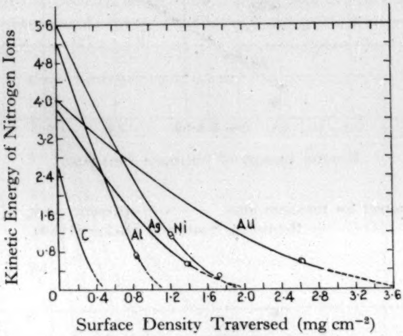

Fig. 4. Ranges of nitrogen ions.

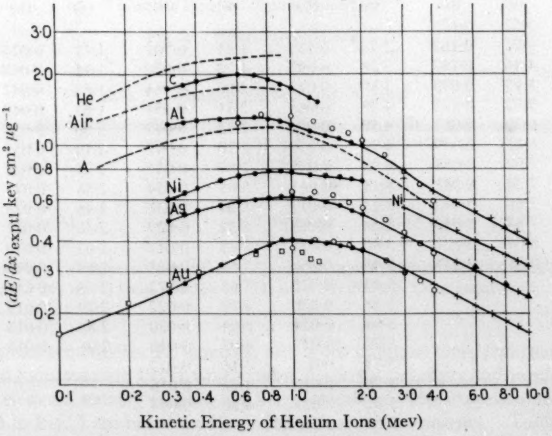

Fig. 5. Stopping power for helium ions. —— present work; – – Weyl and Burgy (1957, private communication); o Whaling (1958) calculated from Gobeli's (1956) work; + Rosenblum (1928); ▲ Aron *et al.* (1949); ☐ Wilcox (1948).

loss in gases as compared with solids made in connection with neon ions are equally applicable here.

The ranges of nitrogen ions in the five absorbers are presented in Fig. 4. The curves are seen to start at different energy values according to the highest energy for which dE/dx has been obtained in a particular stopping element (see Fig. 3). The circles indicate experimental values of ranges obtained with 'thick' absorbers.

Former measurements of dE/dx for helium ions (Porat and Ramavataram 1959) have now been extended to 2 MEV and are shown in Table 4 and in Fig. 5 together with the results obtained by others (Aron, Hoffman and Williams 1949, Gobeli 1956, Rosenblum 1928, Weyl and Burgy 1957 (private communication from S. K. Allison), Wilcox 1948). Whaling (1958) calculated dE/dx for helium ions from Gobeli's measurements of air equivalents for alpha particles in various foils. These values seem several per cent higher than the present dE/dx in Al and Ag absorbers.

Table 4. Stopping Power for Helium Ions

Energy (kev)	Velocity v/v_0	Stopping Power dE/dx (kev cm^2 μg^{-1}) Carbon	Aluminium	Nickel	Silver	Gold
300	1·73	1·73	1·23	0·60	0·49	0·243

2000	4·49		1·00	0·715	0·52	0·369

† at 1300 kev.

One could use Whaling's summary of stopping power for comparison with the present results since

$$\left(\frac{dE}{dx}\right)_{\mathrm{He}} = \left(\frac{Z_{\mathrm{He}}}{Z_{\mathrm{H}}}\right)^2 \left(\frac{dE}{dx}\right)_{\mathrm{H}} \qquad \ldots\ldots(2)$$

at equal ion velocities. However, the helium ion in the energy region of 0·4 to 2 MEV has an effective charge lower than 2 (Rutherford 1924, Dissanaike 1953) which results in a lower rate of energy loss than expected from Eqn (2). Conversely, one may calculate the effective charge of the helium ion as a function of velocity. The calculation is possible where dE/dx data for protons of the same velocities are available. As the cross sections for capture and loss of electrons are only weak functions of the atomic number of the stopping material one can use dE/dx data for He and protons in different materials to obtain an average value of Z_{eff} of the helium ion. The results are presented in Fig. 6 and should be useful in estimating the stopping power for slow helium ions in various media if the stopping powers for protons in these materials have been measured.

Ranges of helium ions have been obtained by integration of the differential energy loss and are shown in Fig. 7. It should be noted that here the abcissa now represents the range of a particle of given energy rather than the thickness of target traversed as in Figs 2 and 4. This representation was possible because the constant of integration is known from experimental range measurements of alpha particles. The curves of Fig. 7 are thus extensions into the low energy region of the information on alpha-particle ranges compiled by Whaling (1958). The cross-over of the range curves for Ag and Au at the low energy end is of interest and can also be observed in the case of heavy ions if one plots the atomic stopping power (dE/dx in units of ev cm^2/atom) against energy. At low velocities of C, N, O and Ne ions one finds the atomic stopping power in gold to be lower than in silver. At higher ion velocities dE/dx increases monotonically with the atomic number of the stopping element, a fact which is also observed in protons and which is in accordance with theory, where applicable. The 'anomaly' of lower atomic stopping power in Au as compared with Ag is interpreted as being due to the lower effective charge of the ion in the heavier stopping element. This lower effective charge of the ion in materials of high Z is expected from Bohr's (1948) theory and

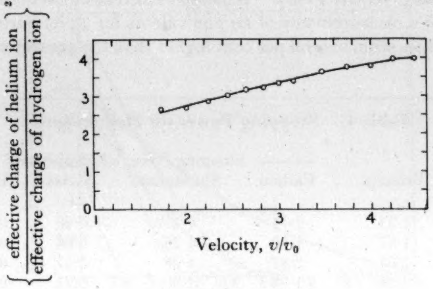

Fig. 6

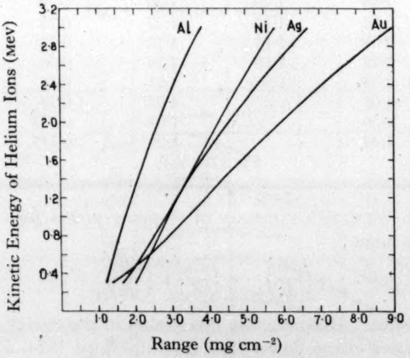

Fig. 7. Ranges of helium ions.

was substantiated in the case of light and heavy fission fragments (Lassen 1955) as well as with protons (Phillips 1955).

The differential energy loss for deuterons in silver in the energy range of 400 to 1000 kev has been measured. The data are useful to extend the curves at present available for dE/dx of protons in Ag to lower energies. The assumption is made that isotopes of equal velocities suffer the same energy loss in a given stopping medium. Table 5 summarizes the results which are presented in terms of deuteron energy losses. Green *et al.* (1955) measured dE/dx for protons in silver in the energy interval of 0·4 to 1·0 Mev by means of the apparent shift in energy of lithium and fluorine (p, γ) resonances. Thus a comparison of their results with the present work is possible in the energy interval of 0·4 to 0·5 Mev. Such a comparison shows dE/dx for protons in silver as obtained by Green *et al.* to be about 4% lower than in the present work. This discrepancy is well within the experimental errors of both measurements.

Table 5. Stopping Power for Deuterons in Silver

Energy (kev)	400	500	600	700	800	900	1000
dE/dx (kev cm^2 μg^{-1})	0·185	0·172	0·162	0·154	0·146	0·138	0·130

The Depolarization of Negative Muons in Light Elements

By A. ASTBURY[†], P. M. HATTERSLEY, M. HUSSAIN[‡], M. A. R. KEMP[§], H. MUIRHEAD and T. WOODHEAD
Nuclear Physics Research Laboratory, University of Liverpool

MS. received 8*th May* 1961

Abstract. A measurement of the polarization retained by negative muons in light elements is described. For elements with spin 0 the muon is found to retain about 17% of its initial polarization.

§ 1. INTRODUCTION

MEASUREMENTS of the angular distribution of the decay electrons, appearing when polarized muons are brought to rest in matter, have shown that the asymmetry coefficient α is much smaller for negatively charged muons than for their positive counterparts (see for example Garwin, Lederman and Weinrich 1957).

The distribution of the decay electrons is of the form $1+\alpha\cos\theta$ where θ represents the angle between the direction of the muon entering the target assembly and that of the outgoing decay electron. The difference in the magnitude of α for the two types of charge may be attributed to the difference in the degree of polarization of the muons when brought to rest. The term α may be written as

$$\alpha^+=P^+a^+ \quad \alpha^-=P^-a^- \qquad \ldots\ldots(1)$$

where P^+ and P^- represent the polarization of the positive and negative muons respectively. If the neutrino appearing in μ-decay is massless, then current theories predict that

$$a^-=a^+=-0{\cdot}33.$$

The measurement of the term α is of interest for two reasons. Firstly, there is the intrinsic interest of a contribution to the understanding of the mechanism of the capture of muons by atoms; secondly, an evaluation of the polarization factor P^- is necessary for certain experiments involving the nuclear capture of muons (Astbury *et al.* 1959) and for experiments which attempt to measure the helicity of muons by detecting the circular polarization of the μ-mesic X-rays.

In the present paper an account is given of the measurement of the parameter α of a number of elements between carbon and sulphur in the periodic table.

§ 2. EXPERIMENTAL METHOD

The apparatus used in the experiment is shown in Fig. 1. Muons in the negative meson beam of the University of Liverpool synchrocyclotron were slowed by a polythene absorber, and brought to rest in the target material. The polythene absorber also filtered out negative pions from the muons in the beam. The electron contamination in the beam was removed by the use of a lead radiator, in the manner indicated in a previous communication from this laboratory (Astbury *et al.* 1958).

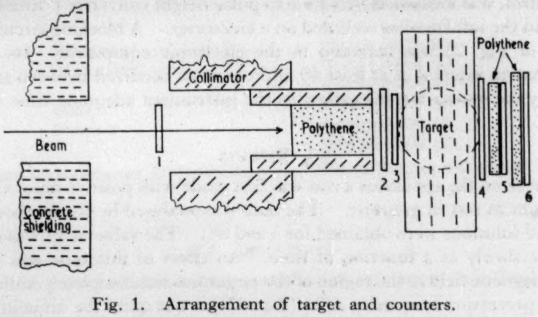

Fig. 1. Arrangement of target and counters.

The principle used in the determination of the asymmetry parameter has already been described by Cassels *et al.* (1957). If polarized muons are brought to rest in matter, and if a magnetic field H is applied at right angles to the plane defined by the muon and electron telescopes, then the number of decay electrons observed at an angle θ is given by the expression

$$\begin{aligned} N(t) &= e^{-\lambda t}(1+\alpha\cos\theta) \\ &= e^{-\lambda t}\{1+\alpha\cos(\omega t+\delta)\} \qquad \ldots\ldots (2) \end{aligned}$$

where

$$\omega = g\,\frac{e}{2mc}\,H$$

and t represents the time between the arrival of the muon in the target and the appearance of the decay electron. The other symbols have the usual significance. In the present experiment $\delta = 0$, and a magnetic field of 200 gauss was used.

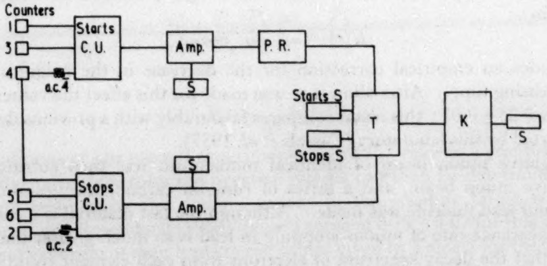

Fig. 2. Block diagram of electronics: C.U., coincidence unit; Amp., amplifier; S, scaler; P.R., pulse rationer; T, timesorter; K, kicksorter.

The arrival of the muons in the target was indicated by a coincidence between counters 1 and 3 and an anti-coincidence from counter 4 (134 in the normal notation). Decay electrons were detected by the sequence $\bar{2}456$. Two slabs of polythene of total thickness 1 inch were inserted between counters 4, 5 and 6.

The polythene was present to eliminate Compton electrons arising from γ-rays; the latter can appear during the muon capture process.

The time interval between the arrival of the muon and the appearance of the decay electron was measured by a time to pulse height converter ('timesorter' of Fig. 2), and the information recorded on a kicksorter. A blocking circuit ('pulse rationer' of Fig. 2) was included in the electronic equipment. Its presence ensured that an interval of at least 40 microseconds occurred between successive analyses by the timesorter, thus allowing the instrument adequate time in which to recover.

§ 3. RESULTS

As a check on the apparatus a run was first made with positive muons. These were brought to rest in graphite. The data was analysed by the method of least squares and solutions were obtained for λ and α^+. The value of α^+ was observed to decrease slowly as a function of time. An effect of this type was expected since the magnetic field in the region of the target was not completely uniform, and hence the precession frequency $\omega/2\pi$ (Eqn (2)) is not quite the same in all parts of the target. This effect vanishes at zero time, i.e. when the time interval between the muon and electron pulses is zero.

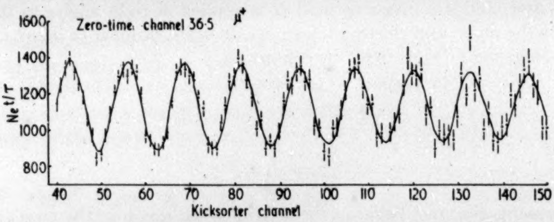

Fig. 3. Asymmetry in electrons from μ^+ on a carbon target.

The results for positive muons are shown in Fig. 3; the data have been plotted in the form

$$N(t)\,e^{\lambda t} = 1 + \alpha^+ \cos \omega t$$

and includes an empirical correction for the decrease in the magnitude of α^+ with increasing time. After allowance was made for this effect the value obtained for α^+ was $0{\cdot}23 \pm 0{\cdot}01$; this result compares favourably with a previous determination reported by this laboratory (Cassels *et al.* 1957).

A negative muon beam of identical momentum was then substituted for the positive muon beam, and a series of runs on carbon, magnesium, silicon, sulphur and lead fluoride was made. Although the last material is a compound, the disappearance rate of muons stopping in lead is so much greater than that in fluorine, that the decay spectrum of electrons from each element could easily be separated.

The results are shown in Table 1. The data include corrections for the solid angle subtended by the counters, and for the variation of α with electron energy (the apparatus would not detect electrons of low energy owing to the thickness of the absorbers). Both corrections are small and tend to cancel. No attempt was made to observe an asymmetry coefficient in lead.

---

§ 4. Discussion

The results given in Table 1 show a satisfactory agreement with the data of the Dubna group.

The measured asymmetry coefficients may be used to determine the amount of depolarization of negative muons in different elements. This depolarization occurs during the process of de-excitation from a high mesic orbit to a K shell (the period for this transition is negligible compared with the muon lifetime, hence virtually all the muons reach the atomic K shell). The observed asymmetry coefficient may be written as

$$\alpha^- = P^-a^- = P_1{}^-P_2{}^-a^-$$

where $P_1{}^-$ is the polarization of the negative muons arriving at the target and $P_2{}^-$ is the polarization retained by the muons in the target, i.e. $1 - P_2{}^-$ represents the depolarization produced in the target. Similarly, we may write

$$\alpha^+ = P_1{}^+P_2{}^+a^+$$

for positive muons.

Since the conditions for production of positive and negative muons are identical, it would seem reasonable to write $P_1{}^+ = P_1{}^-$ so that

$$\frac{\alpha^+}{\alpha^-} = \frac{P_1{}^+P_2{}^+a^+}{P_1{}^-P_2{}^-a^-} = \frac{P_2{}^+}{P_2{}^-}$$

or

$$P_2{}^- = \frac{\alpha^-}{\alpha^+}P_2{}^+. \qquad \ldots\ldots(3)$$

In the conditions of our present experiment α^+ and $P_2{}^+$ refer to a graphite target. The polarization retained by the negative muons can then be determined if the polarization retained by the positive muons in the graphite target is known. Lynch, Orear and Rosendorff (1960) quote a value of $0{\cdot}79 \pm 0{\cdot}07$ for this quantity. The present experiment then leads to the values given in Table 2 for the polarization retained by the negative muon for various elements.

Calculations of the magnitude of $P_2{}^-$ have been made by Shmushkevich (1959), Dzhrbashyan (1959) and Mann and Rose (1961). Briefly the following physical processes can occur. Firstly, the muons are captured into states with high values for the quantum numbers n and l. In the initial capture, the calculations indicate that the muon retains about $\frac{1}{3}$ of its polarization. The mu-mesic atom then

Table 2

Element	P_2^-	
Carbon	24 ± 4%	14 ± 4% (a)
Magnesium	18 ± 4%	20 ± 5% (a)
Silicon	16 ± 4%	
Sulphur	14 ± 3%	15 ± 4% (a)
Fluorine	4 ± 4%	

(a) Ignatenko *et al.* (1959).

reaches states with $n \sim 3$ or 4 by a series of Auger transitions. Radiative transitions then follow the Auger transitions, and on the average the muon loses 50% of its residual polarization, by the radiative process, before reaching the K shell. Thus the residual polarization is approximately $\frac{1}{3} \times \frac{1}{2} \sim 17\%$ of its initial value.

It can be seen that the figure of 17% is in good accord with the data of Table 2, with the exception of fluorine. A result of this nature was expected for fluorine, however, since it possesses a nuclear spin of $\frac{1}{2}$, whereas all the other elements in Table 2 have spin 0.

If a nucleus possesses non-zero spin then a spin–spin interaction can take place whilst the muon is in the K shell leading to further depolarization. A number of workers (Uberall 1959, Lubkin 1960) have shown that in a nucleus of spin I the polarization is reduced by a factor $\frac{1}{3}[1+2/(2I+1)^2]$; for a nucleus of spin $\frac{1}{2}$ the polarization retained by the muon would be expected, therefore, to be of the order of 8%. The result for fluorine is compatible with this figure.

ACKNOWLEDGMENTS

We should like to thank B. Halliday and the cyclotron crew for their cooperation during the course of this experiment.

Capture Rates for Negative Muons in Light Elements

By A. ASTBURY†, I. M. BLAIR, M. HUSSAIN‡, M. A. R. KEMP§ AND H. MUIRHEAD

Nuclear Physics Research Laboratory, University of Liverpool

MS. received 8th May 1961

Abstract. Measurements are reported on the capture rates of negative muons in certain light elements. Agreement with other experimental data is found, but a discrepancy between the calculated and experimental values of the capture rate in fluorine is noted.

§ 1. INTRODUCTION

THE results obtained with the apparatus described in the previous paper (Astbury *et al.* 1961) may be used to evaluate the capture rates for negative muons in various light elements.

After background was removed the data recorded on the screen of the kicksorter were of the form

$$N(t) = e^{-\lambda t}(1 + \alpha \cos \omega t).$$

The symbol λ represents the disappearance rate of negative muons in the target material; its magnitude was found by integrating the data over an even number of complete cycles of the term $\cos \omega t$, starting at $t = \pi/2\omega$. The data were then split into two equal time intervals of length T. The total number of counts in the first and second intervals, n_1 and n_2 respectively, were related by the expression

$$n_1/n_2 = e^{\lambda T}$$

and hence λ can be determined.

The term λ represents the sum of the rates for decay λ_d and capture λ_c:

$$\lambda = \lambda_d + \lambda_c.$$

The value of λ_d was taken to be equal to that of the free muon, since Coulomb effects have a negligible influence on the decay rate of negative muons stopped in light nuclei (Astbury *et al.* 1959, Yovanovitch 1960). Hence λ_c can be calculated.

§ 2. RESULTS

The results of the experiment are shown in the Table.

It can be seen that the experimental data from different laboratories are in agreement. The theory of Primakoff (based on a Universal Fermi Interaction) appears to fit the data with the exception of fluorine. The nuclear part of the muon capture process was calculated by Primakoff using a closure approximation. A similar approach was made by Burkhardt and Caine (1960), who used more detailed shell model wave functions than Primakoff.

Element	Capture rates × 10^5 (sec^{-1})				
	Present experiment	Other results		Theoretical	
Carbon	0·3 ± 0·1	0·44 ± 0·1	(a)	0·43	(f)
		0·36 ± 0·04	(b)		
		0·373 ± 0·011	(c)		
Fluorine	2·5 ± 0·4	2·54 ± 0·22	(a)	1·51	(f)
		2·72 ± 0·20	(d)	2·02	(g)
		3·70 ± 0·54	(e)		
Magnesium	5·0 ± 0·2	5·07 ± 0·20	(a)	5·2	(f)
Sulphur	13·5 ± 0·5	13·9 ± 0·9	(a)	14·0	(f)

(a) Sens (1959), (b) Stannard (1960), (c) Reiter *et al.* (1960), (d) Astbury *et al.* (1958), (e) Bertram (1960), (f) based on work of Primakoff (1959) and data of Sens (1959), (g) Burkhardt and Caine (1960).

In view of the excellent agreement of the theory of Primakoff with experimental data (Astbury *et al.* 1958, Sens 1959) for a large number of nuclei between beryllium and lead, the discrepancy noted in the Table for fluorine probably can be attributed to nuclear effects specific to this element.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Halliday and the crew of the cylotron for its steady operation, and Mr. P. M. Hattersley for assistance with the computations.

A Measurement of the Total Cross Section for the Production of Neutral Pions in Proton–Proton Collisions at 383 MeV

By A. ASTBURY†, M. A. R. KEMP‡, H. MUIRHEAD, R. G. P. VOSS§ and T. WOODHEAD

Nuclear Physics Research Laboratory, University of Liverpool

MS. received 8*th May* 1961

Abstract. A value of $(59 \pm 9)\,\mu$bn has been obtained for the total cross section for the production of π°-mesons in proton–proton collisions at 383 MeV.

§ 1. Introduction

The total cross section for the reaction $p+p \rightarrow p+p+\pi^0$, which we shall denote by the symbol $\sigma^0{}_{pp}$, is characterized by its comparatively small size near threshold, and the rapid rise in its value as the energy of the incoming proton is increased. In nucleon–nucleon collisions at energies not too far from threshold, the most important transition in the production of pions is that which leaves the final nucleons in an S state relative to each other, and the meson in a p state with respect to the centre of mass of the system (an Sp transition in the notation of Rosenfeld (1954)). This transition is enhanced by the $(\frac{3}{2}, \frac{3}{2})$ resonance in the pion–nucleon interaction. This transition is allowed for the production of charged mesons in proton–proton collisions, but is forbidden for π^0 mesons for the following reason.

The two final protons in the π^0 production process exist predominantly in the S state at low energies. This state has $J=0$ because of the Pauli principle, and even parity. If the meson is emitted in a p state, the final state of the meson and protons has $J=1$ and even parity. The initial state of the two protons must have zero spin in states of even parity because of the Pauli principle, so that J must equal L and hence be an even integer. There is no initial state of two protons which has $J=1$ and even parity, and hence the Sp transition cannot occur in the production of π^0 mesons in proton–proton collisions. The absence of this transition amplitude explains the smallness of the π^0 production cross section just above the threshold.

Mather and Martinelli (1953) have pointed out that, in addition to the type of transition described above, there can also exist ‘displaced transitions’. Let us consider the Ss transition. In this case one of the final nucleons and the pion can be partly in the $(\frac{3}{2}, \frac{3}{2})$ resonance state whilst the complete system has zero overall angular momentum. This is termed a ‘displaced S state transition’ Similarly for production into a Sd state there could be a ‘displaced D state transition '. In Table 1 the variation of the cross section $\sigma^0{}_{\rm pp}$ with η is given for the different transitions, where η is the maximum momentum of the pion, in the centre-of-mass system, in units of μc, where μ is the pion mass.

Table 1

Transition	Ss	Sp	Ps	Pp	Displaced-S	Displaced-D
$\sigma^0{}_{\rm pp}$	η^2	Forbidden	η^6	η^8	η^6	η^6

Mandelstam (1958) has developed a semi-phenomenological theory for the production of a single pion in nucleon–nucleon collisions. In this theory he assumes that all pion production takes place in such a manner that the outgoing pion is in a $(\frac{3}{2}, \frac{3}{2})$ resonant state with one of the nucleons. A theory of this type cannot be very accurate immediately above threshold, but should give good agreement with experiment in the energy ranges where kinematic conditions favour the $(\frac{3}{2}, \frac{3}{2})$ resonance. The form of the cross section $\sigma^0{}_{\rm pp}$ predicted by Mandelstam is

$$\sigma^0{}_{\rm pp} = (0{\cdot}040\,\eta^6 + 0{\cdot}047\,\eta^8) \times 10^{-27}\ {\rm cm}^2. \qquad \ldots\ldots (1)$$

The most recent experimental results (Dunaitzev and Prokoshkin 1959) have been analysed in conjunction with the Mandelstam resonance model. These authors conclude that a term $(0{\cdot}032 \pm 0{\cdot}007)\,\eta^2 \times 10^{-27}$ cm^2 must be added to (1) in order to fit the experimental points below 400 MeV. This term gives the contribution to the cross section from the non-resonant Ss transition. The final form of the excitation function suggested by Dunaitzev and Prokoshkin is

$$\sigma^0{}_{\rm pp} = (0{\cdot}032 \pm 0{\cdot}007)\,\eta^2 + 0{\cdot}040\,\eta^6 + 0{\cdot}047\,\eta^8) \times 10^{-27}\ {\rm cm}^2. \qquad \ldots\ldots (2)$$

The present experiment is a measurement of the total cross section in the 383 MeV proton beam of the Liverpool synchrocyclotron. The result at this energy serves as a further check on whether a non-resonant term must be added to the Mandelstam formula (1).

§ 2. EXPERIMENTAL METHOD

The experimental arrangement is shown in Fig. 1. The external proton beam of the synchrocyclotron is focused on to a target of liquid hydrogen. The protons travel to the target in a vacuum pipe, and enter and leave the liquid hydrogen container through thin mylar windows. The π^0 mesons are registered by the detection of one of their decay photons. These pass through the anticoincidence counter 1 and materialize in the lead radiator. The electron or positron then gives a triple coincidence in counters 2, 3, 4. The ion chamber was used as a monitor to measure beam intensity. The proton flux which could be used in the experiment was limited by the high counting rate in counter 1, due to protons scattered into it from proton–proton collisions in the liquid hydrogen.

In order to determine the number of γ-rays incident on the counter telescope due to the decay of the π^0 mesons produced in the liquid hydrogen, four runs were made. These were as follows: one with liquid hydrogen and a lead radiator (H_2 Pb), one with liquid hydrogen but no radiator (H_2 [Pb]), one with an empty target, but with the radiator ([H_2] Pb), and finally a run with no liquid hydrogen

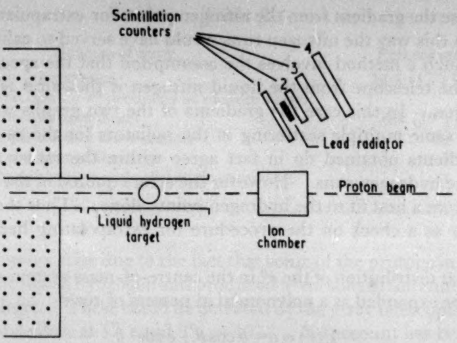

Fig. 1. Experimental arrangement.

and no radiator ([H_2] [Pb]). By the following subtraction:

$$(H_2\,Pb - H_2\,[Pb]) - ([H_2]\,Pb - [H_2]\,[Pb]) = N_{H_2} \qquad \ldots\ldots(3)$$

we obtain the counts from the liquid hydrogen per monitor count from the ion chamber. N_{H_2} was measured for different thicknesses t of lead radiator. It was necessary to take account of electrons multiply scattered in the lead and hence not detected in the telescope. This was done by extrapolating the $(N_{H_2}/t,\ t)$ plot to $t=0$ as shown in Fig. 2. We obtain from this intercept and the value of the pair production cross section in lead, the number of γ-rays produced per monitor count.

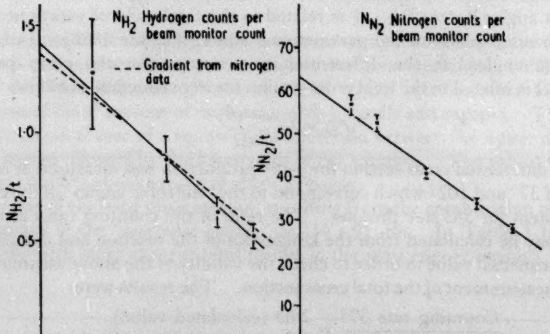

Fig. 2. Comparison of data from nitrogen and hydrogen.

A preliminary experiment was performed with liquid nitrogen in the target. In this case the counting rate due to γ-rays from π^0 decay is increased by a factor of the order of 40, because of the increased production cross section for π^0 mesons in nitrogen. The results of these runs are also plotted in Fig. 2. It was originally intended to use the gradient from the nitrogen points for extrapolating the hydrogen data. In this way the nitrogen runs would have served to calibrate the γ-ray telescope. Such a method involves the assumption that the spectrum of γ-rays incident on the telescope from the liquid nitrogen is the same as that from the liquid hydrogen. In this case the gradients of the two graphs would be equal, implying the same multiple scattering in the radiators for the two experiments. The two gradients obtained do in fact agree within the rather poor counting statistics of the hydrogen runs. However the errors quoted in the final result are those found from a best fit to the hydrogen points alone. Thus the nitrogen data was used only as a check on the procedure for extrapolating back to zero lead thickness.

The angular distribution of the π^0 in the centre-of-mass system of the colliding protons may be expanded as a polynomial in powers of cos θ

$$\mathrm{F}(\theta)=a+b\cos\theta+c\cos^2\theta \qquad \ldots\ldots(4)$$

where θ is the angle of emission of the π^0 with respect to the direction of the incoming proton. At an incident proton energy of 383 MeV the highest power expected in the polynomial is $\cos^2\theta$, since transitions involving final states with an orbital angular momentum quantum number $l>1$ are unlikely at this energy. Since the reaction is symmetric with respect to the two colliding protons it is apparent that $b=0$. Thus Eqn (4) becomes

$$\mathrm{F}(\theta)=a+c\cos^2\theta.$$

It may then be shown (Tiapkin 1956) that the corresponding angular distribution of the γ-rays takes the form

$$\mathrm{F}(\theta)=A+C\cos^2\theta.$$

This distribution possesses the convenient property that the intensity of the γ-rays at angles $\bar{\theta}=\cos^{-1}\pm\sqrt{\tfrac{1}{3}}$ is related to the total yield of γ-rays in a manner which is independent of the parameters a and c (Tiapkin 1956). In fact at the 'isotropic angles' $\bar{\theta}$, the differential cross section for the γ-ray production $d\sigma^{\gamma}(\bar{\theta})/d\Omega$ is related to the total cross section for π^0 production as follows

$$\sigma^0{}_{\mathrm{pp}}=2\pi\,\frac{d\sigma^{\gamma}(\bar{\theta})}{d\Omega}. \qquad \ldots\ldots(5)$$

The differential cross section for γ-ray production was measured at laboratory angles of 37° and 102° which correspond to the 'isotropic angles' in the centre-of-mass system for 383 MeV protons. The ratio of the counting rates at these two angles may be calculated from the kinematics of the reaction and compared with the experimental value in order to check the validity of the above assumption used for the measurement of the total cross section. The results were

$$\frac{\text{Counting rate }37^\circ}{\text{Counting rate }102^\circ}=\begin{array}{l}2{\cdot}63\ \text{(calculated value).}\\ 2{\cdot}8\pm0{\cdot}6\ \text{(experimental value).}\end{array}$$

In view of this result the two measurements of the γ-ray differential cross section were used to give independent determinations of the total cross section for π^0 production.

§ 3. RESULTS

The values of the total cross section $\sigma^0{}_{\mathrm{pp}}$ from the measurements at 37° and 102° respectively are $(62\pm12)\,\mu$bn and $(58\pm10)\,\mu$bn. The sources of error in the experiment are given in Table 2.

Table 2

	Sources of error	Percentage error
(*a*)	Counting statistics	14·5 (37°) 9 (102°)
(*b*)	Correction for π^0 produced in vacuum vessel of hydrogen target	6·5 (37°) 3 (102°)
(*c*)	Pair production cross section	10
(*d*)	Ion chamber calibration	5
(*e*)	Target thickness and solid angle correction	3

In (*b*) the errors arise due to the fact that some of the protons in the beam were scattered by the liquid hydrogen and produced π^0 mesons in the aluminium vacuum vessel of the target. These could be detected by the γ-ray telescope and comprised 22% of the total effect at 37°, and 9% at 102°. No account has been taken of the γ-ray background due to protons scattered from the empty target. It has been estimated that this gives a correction of the order of 0·5%, which was neglected in the face of larger errors.

The pair production cross sections were taken from the theory of Bethe and Heitler, and the empirical correction derived by Davies, Bethe and Maximon (1954) applied. This correction is based on experimental results which are accurate to about 2%. The remainder of the error in (*c*) is due to integrating the cross sections over the spectrum of γ-rays incident on the radiator. The shape of this spectrum, and hence the final pair production cross section used in the calculation, depends on the angular distribution and energy distribution of the π^0. The assumptions made were those of an angular distribution of the form $(\frac{1}{3}+\cos^2\theta)$ and the energy distribution derived by Gell-Mann and Watson (1954) for a Pp transition.

The magnitude of the pair production cross section resulting from these calculations is not very sensitive to the shape of the γ-ray spectrum. Values were obtained for four different spectra, three of which corresponded to angular distribution of the π^0 mesons of the form $\cos^2\theta$, $\frac{1}{3}+\cos^2\theta$ and istropic. The fourth was a non-physical case of a square γ-ray spectrum between the upper and lower limits of energy allowed by the kinematics of the reaction. The values showed a spread of about 6% about a mean of about 30 barns.

The value of the total cross section, resulting from the combination of the two measurements at the 'isotropic angles', is $(59 \pm 9)\,\mu$bn. In Table 3 this value is compared with other experimental results in the same energy region.

Table 3

Incident proton energy (MeV)	σ^0_{pp} (μbn)	Measured cross sections
408	81 ± 22	Stallwood *et al.* (1958)
383	33 ± 17	
367	25 ± 12	
360	30 ± 8	Dunaitzev & Prokoshkin (1959)
374	40 ± 10	
400	90 ± 20	
383	59 ± 9	Present experiment

If the appropriate value of η (0·863 for incident protons of 383 Mev) is substituted into Eqn (2), then the experiment gives a further check on the excitation function of Mandelstam, with the addition of the empirical correction of Dunaitsev and Prokoshkin. The results are shown in Table 4.

Table 4

Expected contributions to the cross section		Experiment
$(0{\cdot}047\eta^6 + 0{\cdot}047\eta^8) \times 10^{-27}$ cm^2 (theory of Mandelstam)	31 μbn	
Empirical correction for non-resonant Ss transition (Dunaitsev & Prokoshkin) $0{\cdot}032\eta^2 \times 10^{-27}$ cm^2	24 μbn	
Total	55 μbn	(59 ± 9) μbn

It is clear that at the rather low proton energy of 383 Mev the Mandelstam resonance theory cannot account for all the production of π^0 mesons, and a non-resonant Ss transition, introduced through the empirical correction term, can account for the discrepancy.

Low Energy Elastic Scattering of Neutrons by Deuterons

By J. W. HUMBERSTON
Department of Physics, University College, London

Communicated by Sir Harrie Massey; *MS. received* 1st *June* 1961

Abstract. Neutron–deuteron scattering phases are evaluated at five energies below 8 MeV for two ranges of a central Yukawa interaction. The dependence of the phases on the range is found to be very slight. Considerable differences are found between these results and those given by Haas and Robertson in 1959 who used the same form of interaction with the shorter of the two ranges considered here. The results and subsequent discussion resolve some previously inexplicable differences between the scattering lengths obtained with various potential shapes.

---

§ 1. Introduction

A theoretical investigation of low energy neutron–deuteron scattering has been performed by Haas and Robertson (1959, to be referred to as HR) assuming a central two-body internucleonic interaction with symmetric exchange and Yukawa shape,

$$V(r) = V_0 \frac{\exp(-r/\lambda)}{r/\lambda}. \qquad \ldots\ldots(1)$$

They ignored any distortion of the deuteron by the incident neutron and represented the deuteron ground state by the Hulthén wave function

$$\chi(r) = \frac{\exp(-\alpha r) - \exp(-\beta r)}{\eta r}, \qquad \ldots\ldots(2)$$

where η is the normalization constant. Their results agree quite well with those of Christian and Gammel (1953), who also used a Yukawa potential, but differ significantly from those of Buckingham, Hubbard and Massey (1952) and Burke and Robertson (1957) who assumed exponential and Gaussian shapes respectively. However, as mentioned by Massey (1960), exponential and Yukawa shapes would be expected to give similar results and there is no *a priori* reason why they should be very different from those obtained using a Gaussian shape. In view of these discrepancies, the S phase shifts are calculated for five neutron energies in the range 0–8 MeV using two different values of the range λ in the interaction (1). Of the two ranges considered, the shorter, used by HR, is consistent with all two-body data whilst the longer range is appropriate in binding energy calculations for light nuclei. The values assumed by the parameters for the two interactions have been determined by Burke (1956) and are given in Table 1.

Table 1. Values of the Parameters occurring in Eqns (1) and (2)

	Interaction A	Interaction B
V_0 (Mev)	$-68{\cdot}01$	$-33{\cdot}8$
λ (10^{-13} cm)	1·18	1·78
α (10^{13} cm^{-1})	0·22315	0·22302
β (10^{13} cm^{-1})	1·615	1·170

In the notation used by HR, the integro-differential equation describing the scattering in a state of orbital angular momentum $l\hbar$ is

$$\frac{d^2 f_l(r)}{dr^2} + \left(k^2 - \frac{l(l+1)}{r^2} - \alpha U(r)\right) f_l(r)$$

$$= \int_0^\infty \left(\beta q_l(r, r') + \gamma\left[p_l(r, r') + \left(1 + \frac{E_{\mathrm{n}}}{E_{\mathrm{d}}}\right) n_l(r, r')\right]\right) f_l(r')\,dr', \quad \ldots\ldots (3)$$

where the potential function $U(r)$, the kernels $q_l(r, r')$, $p_l(r, r')$ and $n_l(r, r')$, and the values of α, β and γ for the two spin states are as defined by HR. The solution of this equation satisfies the boundary conditions $f_l(0) = 0$, $f_l(r) \sim \sin(kr - \frac{1}{2}l\pi + \delta_l)$ where δ_l is the phase shift.

§ 2. METHOD OF SOLUTION

Equation (3) was solved numerically on the University of London's Ferranti MERCURY computer for the case of $l = 0$ using a method due to Robertson (1956). It involves calculating the kernels for values of r and r' ranging from 0 to 21 fermis at a constant interval of 0·3 fermi, and tabulating the results in the form of square matrices so that the element p_{nm} of the kernel matrix $p(r, r')$ is equal to $p(r = 0{\cdot}3n, r' = 0{\cdot}3m)$ etc., r and r' being measured in units of 10^{-13} cm. All integrands in the kernel functions are singular at the lower limit of angular integration when $r = 2r'$ and $r' = 2r$, the integrands in $q_0(r, r')$ also being singular at the upper limit when $r = r'$. Removal of these singularities by means of appropriate substitutions enables the kernels to be evaluated accurately for all values of r and r'.

The contour diagrams of the kernels $q_0(r, r')$ and $n_0(r, r')$ obtained using the A interaction agree well with those of HR but that of $p_0(r, r')$ differs from theirs in the vicinity of the lines $r = 2r'$ and $r' = 2r$. This, however, is probably due to errors in drawing the contours and the fact that, owing to the rapid variations of the kernel in these regions, their interpolation method of calculating the elements on these lines is not accurate. Similar diagrams are obtained for the B interaction but, because of its longer range and the smaller value of the deuteron wave function parameter β, the kernels die away more slowly.

§ 3. RESULTS

Values of the phases for both interactions are given in Table 2 and the corresponding Blatt–Jackson curves are plotted in the Figure. From the zero energy intercepts on the $k\cot\delta$ axis the following two sets of scattering lengths are obtained

$$\left.\begin{aligned} a_4 &= 5{\cdot}6 \times 10^{-13}\,\mathrm{cm} \\ a_2 &= 4{\cdot}0 \times 10^{-13}\,\mathrm{cm} \end{aligned}\right\} \text{ for the A interaction,}$$

$$\left.\begin{aligned} a_4 &= 5{\cdot}9 \times 10^{-13}\,\mathrm{cm} \\ a_2 &= 3{\cdot}9 \times 10^{-13}\,\mathrm{cm} \end{aligned}\right\} \text{ for the B interaction.}$$

These are to be compared with HR's values

$$a_4 = 6{\cdot}9 \times 10^{-13}\,\text{cm}, \qquad a_2 = 1{\cdot}4 \times 10^{-13}\,\text{cm},$$

and the two experimentally permissible sets,

$$a_4 = 2{\cdot}4 \times 10^{-13}\,\text{cm}, \qquad a_2 = 8{\cdot}3 \times 10^{-13}\,\text{cm}, \tag{i}$$

$$a_4 = 6{\cdot}2 \times 10^{-13}\,\text{cm}, \qquad a_2 = 0{\cdot}8 \times 10^{-13}\,\text{cm}. \tag{ii}$$

Table 2. S Phases

	Quartet			Doublet		
$k \times 10^{13}$ (cm^{-1})	A	B	HR(0·8)	A	B	HR(0·8)

S phases are given in degrees. Columns A and B contain the phases using interactions A and B respectively. Haas and Robertson's final results are given in columns headed HR(0·8).

The results seem to favour set (ii) rather than (i) although good agreement exists only for the quartet scattering lengths.

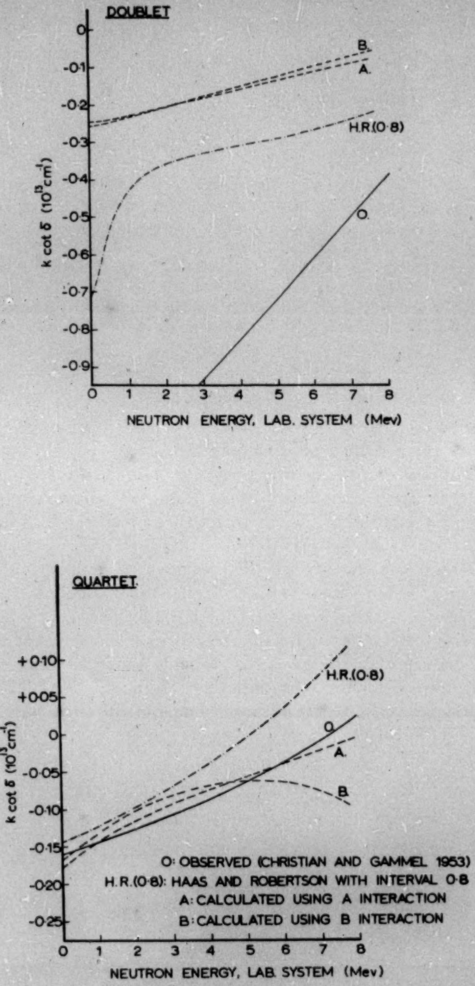
It would appear that the quartet phases are more sensitive to the range of the interaction than are the doublet phases. But, as mentioned previously, the longer range of the B interaction increases the tails of the long range kernels so that they are no longer negligibly small at 21 fermis. This is particularly important for quartet states since the coefficient γ multiplying the long range kernels in Eqn (3) then has the value $+1$ whereas it is only $-\frac{1}{2}$ for the doublet states. Consequently the error introduced by neglecting the kernels beyond 21 fermis has a greater effect on the quartet phases. In fact most of the difference between the two sets of quartet phases is probably due to this error, which may also be partly responsible for the slight difference in the doublet phases.

It is therefore concluded that the dependence of both quartet and doublet phases on the range of the interaction is very slight.

Table 3. S Phases

	Quartet		Doublet	
$k \times 10^{13}$ (cm^{-1})	(11·4)	HR(0·4)	(11·4)	HR(0·4)
0·4	+83·017	+87·953	−74·773	−75·591
0·3	−72·616		−62·007	
0·2	−45·159	−38·371	−47·055	−47·250
0·12	−24·857	−19·220	−30·727	−30·341
0·075	−14·832	−10·741	−19·813	−19·427

S phases are given in degrees. The columns (11·4) contain the phases using the A interaction with neglect of the kernels beyond r, $r' = 11{\cdot}4$ fermis. The columns HR(0·4) contain the results of Haas and Robertson using a constant interval of 0·4 fermi and neglecting the kernels beyond r, $r' = 11{\cdot}6$ fermis.



Comparison of ' observed ' and calculated zero-order phase shifts.

In order to explain the considerable differences between the results of HR and the present ones, the A interaction phases have been recalculated using exactly the same method as before but neglecting the kernels beyond 11·4 fermis. Since HR performed very similar calculations using a constant interval of 0·4 fermi with the kernels extending to 11·6 fermis, agreement between the two sets of phases would be expected. They are contained in Table 3 and are seen to agree as well as can be expected in view of the slight differences in the interval and extent of the kernels and the possible errors in $p_0(r, r')$, mentioned previously,

§ 4. DISCUSSION

Comparison of the results in columns (11·4) of Table 3 and the A interaction phases of Table 2 indicates that, contrary to the conclusions of HR, neglect of the tails of the long range kernels does not affect the doublet phases to any great extent although it has a serious influence on the quartet phases. The doublet phases, however, are more sensitive to the interval of integration, making it essential to use as small an interval as possible.

Buckingham, Hubbard and Massey, using a symmetric exchange interaction of exponential shape, obtained similar results to the present ones, the agreement being particularly good in doublet states. Although the calculations of Burke and Robertson, who used a Gaussian shape with various ranges, are not in such good agreement, evidence exists in their paper to suggest that, had they used smaller intervals of integration and extended the kernels further, they would have obtained results closer to the present ones with less dependence on the range. This similarity of the results using three different shapes and a variety of ranges suggests that for central interactions with Serber and symmetric exchange, the phases are almost independent of the form of the interaction provided that, for a given range, the depth is chosen so as to give the correct deuteron binding energy. It is therefore unlikely that any purely central interaction will provide doublet phases in better agreement with experiment without an explicit inclusion of deuteron polarization.

Recently, variational techniques have been used to investigate the effect of polarization on the phases, but the results are not altogether satisfactory. Thus Burke and Haas (1959) and Sartori and Rubinow (1958), using the Kohn and Rubinow methods respectively, concluded that the effect was small for quartet and doublet phases, whereas Efimov (1959), who also used the Rubinow method but considered a more complicated trial function, obtained results contrary to this. He obtained the scattering lengths

$$a_4 = 6{\cdot}3 \times 10^{-13}\,\mathrm{cm}, \quad a_2 = 1{\cdot}1 \times 10^{-13}\,\mathrm{cm},$$

both of which are in good agreement with experiment.

A disadvantage of both variational methods discussed above is that they fail to give either an upper or lower bound on the scattering lengths. Therefore, it is not possible to infer that, because Efimov obtains results close to set (ii), this set is necessarily correct. Only if one of the two possible experimental values were larger than the result of a calculation of the upper bound on the scattering length could the experimental set containing the larger value be definitely rejected. A variational method which does lead to an upper bound on the scattering lengths has been devised by Spruch and Rosenberg (1960) but no numerical results have yet been obtained using it. The authors claim, however, that the conversion of Efimov's calculations to the form used in their method reduces the value of the scattering lengths so that Efimov's results are in fact upper bounds. As the doublet scattering length of set (i) is larger than the value of the upper bound it follows that the correct set is (ii).

This conclusion is only justified if the equivalent central potential is an accurate approximation to the true potential, but there is very little evidence that this is so. A more realistic approximation is a mixture of central and tensor potentials, and the neutron–deuteron scattering problem with such an interaction has been formulated by Bransden, Smith and Tate (1958). Using this formulation, a recent determination at University College London of the doublet scattering length yielded the result $a_2 = 8{\cdot}3$ fermis which agrees with set (i). A Gaussian shape was assumed for the central and tensor components and the exchange mixtures were taken to be Serber for the central part and, in the notation of Bransden, Smith and Tate, $w' = \frac{1}{3}$, $m' = \frac{2}{3}$ for the tensor part. The numerical values of all other parameters are given by Massey (1960). A more detailed report of this work will be published later.

Despite the good agreement with set (i), no firm conclusions can be reached until the quartet scattering length has also been calculated. Furthermore, no allowance has been made for distortion of the deuteron which is expected to be a predominantly doublet effect. It is therefore intended to apply the method of Spruch and Rosenberg to the tensor force problem.

ACKNOWLEDGMENTS

I am indebted to Professor Sir Harrie Massey for suggesting the investigation, to the Department of Scientific and Industrial Research for a Research Studentship and to the University of London Computer Unit for the extensive use of its facilities.

I would also like to thank Mr. B. Pardoe for communicating the results of the tensor force calculations prior to publication.

The Transfer and Exchange Transfer of Nucleons between ^{16}O and ^{27}Al

BY R. F. COLEMAN AND J. L. PERKIN
Atomic Weapons Research Establishment, Aldermaston, Berks.

MS. received 17*th May* 1961

Abstract. Cross sections for the following reactions with 36 MeV ^{16}O ions have been measured:

Neutron transfer	$^{27}Al(^{16}O, {}^{15}O)^{28}Al$	$\leqslant 7\,\mu bn$
Proton transfer	$^{27}Al(^{16}O, {}^{17}F)^{26}Mg$	$210 \pm 50\,\mu bn$
Neutron–proton exchange transfer	$^{27}Al(^{16}O, {}^{16}F)^{27}Mg$	$0{\cdot}7 \pm 0{\cdot}4\,\mu bn$

The mechanism of the exchange transfer reactions is discussed in terms of the single transfer reactions. There is some evidence to suggest that an exchange reaction is not composed of two single transfer reactions.

---

§ 1. INTRODUCTION

THE only work on neutron–proton exchange transfer reactions previously reported is that of Pinajian (1960) who found that the cross section of the $^{27}Al(^{14}N, {}^{14}O)^{27}Mg$ reaction is $2{\cdot}2 \pm 1\,\mu bn$ for nitrogen ions of 27·6 MeV. This result is consistent with the prediction by Goldansky (1958) that the magnitude of neutron–neutron exchange transfer reactions are of the order of 1 to 10 μbn. Goldansky obtained this value by calculating the relative probabilities for neutron transfer and neutron–neutron exchange transfer for the 'tunnelling' model of these reactions and comparing these with the geometrical cross section and experimentally determined neutron transfer reaction cross sections (see also Breit 1959).

The aim of the present experiments was to examine a neutron–proton exchange transfer reaction where it was possible to measure the cross sections of the two single transfer reactions of which it was composed. The $^{27}Al(^{16}O, {}^{16}F)^{27}Mg$ reaction was chosen for this purpose. An activation method involving the chemical separation of the reaction products was used to measure the cross sections. The products measured for the neutron, proton and exchange transfer reactions were ^{15}O(2 min) ^{17}F(1·1 min) and ^{27}Mg(9·5 min) respectively.

As the activities measured in this work were so small, it was essential to ensure a very good chemical separation of these products from the products of other reactions. It was also important to show either experimentally or by inference from other work on transfer reactions that the transfer products observed could not have been produced in any other way. These points are discussed in the following sections.

§ 2. EXPERIMENTAL DETAILS

2.1. *Irradiation of the Aluminium Targets*

Currents of the order of 0·1 μA of magnetically analysed ^{16}O 5^+ and 6^+ ion beams with energies up to 38 MeV were obtained with the Atomic Weapons Research Establishment Tandem Van de Graaff (Allen *et al.* 1959). Thick

($9\,\text{mg cm}^{-2}$) targets of aluminium foil were irradiated by placing them across the end of a Faraday cup. Irradiation times were of the order of the half-life of the particular reaction product examined.

2.2. *Separation of Magnesium from Aluminium*

It was found that after irradiation most of the activity in the aluminium foils consisted of some 10^5 disintegrations per second of ^{38}K (7·7 min). In order to ensure that no trace of this activity was counted with any ^{27}Mg activity present the following procedure was adopted.

The irradiated aluminium was dissolved in 6N sodium hydroxide containing $300\,\mu$g of magnesium carrier. The magnesium hydroxide was centrifuged off and washed. This precipitate was dissolved in dilute acid, about 1 mg of iron carrier was added and then precipitated with ammonia. Ammonium phosphate was added to the supernate and the solution made strongly ammoniacal to precipitate magnesium phosphate which was then redissolved and re-precipitated as a further purification step. The efficiency of the scheme for eliminating potassium was measured in a separate experiment by adding ^{42}K tracer to unirradiated aluminium. The fraction of potassium remaining was found to be less than 3×10^{-7}. This was sufficient to ensure that the observed magnesium activity was uncontaminated.

The final precipitate was slurried on to a plastic foil for counting in a 4π gas flow proportional counter. Activities of the order of a few counts per second decaying with the half-life of ^{27}Mg were observed. An anticoincidence ring of Geiger counters was used to reduce the background of this counter to 0·3 c/s.

After counting, the source was dissolved in dilute acid and the yield of magnesium was determined by a micro-titration using ethylene-diamine-tetra-acetic acid.

2.3. *Separation of Fluorine from Aluminium*

In this separation special care was taken to remove ^{30}P (2·5 min) found in the irradiated aluminium foils which, because of its mode of decay (positron) and its half-life, was likely to cause errors in the measurements of the ^{17}F activity produced.

The foil was dissolved in 1 ml of sodium hydroxide solution containing 15 mg of fluorine carrier. The solution was scavenged twice with $200\,\mu$g of zirconium and then 2 ml of saturated barium hydroxide solution was added. The resulting barium fluoride was washed and then the tube and precipitate were placed in a counter to measure the positron activity from ^{17}F. Counting commenced about three minutes after the end of the irradiation. The chemical yield of the separation scheme was measured by titrating the fluoride with a standard thorium nitrate solution.

Positrons were detected by means of two cylindrical (5·7 cm × 5·7 cm) sodium iodide scintillation counters on opposite sides of the source. Pulses from the positron annihilation photo-peaks in the two counters were counted when in coincidence in order to discriminate against any γ-ray background from traces of other reaction products remaining after the chemical separation. The overall efficiency of this counting arrangement ($\sim 10\%$) was found by calibration with a solution containing ^{18}F which has been standardized by counting weighed amounts in a 4π proportional counter.

2.4. *The Separation of Oxygen from Aluminium*

The irradiated aluminium was dissolved in 1 ml of 6N sodium hydroxide and then transferred to a small still. The water was rapidly boiled off under reduced pressure and then condensed in a tube surrounded by liquid air. The distillate was melted and the decay of the positron activity from ^{15}O was measured in the same counter used for the ^{17}F determinations. The yield was measured by weighing the water. About three minutes elapsed between the end of the irradiations and the commencement of the counting. No activity was detected in any of these experiments.

§ 3. PRODUCTION OF TRANSFER REACTION PRODUCTS BY OTHER REACTIONS

3.1. *Magnesium* 27 *from Reactions with Impurities*

The possibility that the ^{27}Mg activity observed was produced by compound nucleus or transfer reactions between ^{16}O ions and impurities in the aluminium targets was investigated. Thick targets of carbon, nitrogen, oxygen, sodium, magnesium, silicon, phosphorus and sulphur, in a suitable form, were irradiated with 38 MEV ^{16}O ions and the yields of ^{27}Mg were determined. By means of a procedure described in a previous paper (Coleman *et al.* 1961) these results were used to calculate the yield which would be obtained from one part per million of each of these elements in an aluminium target.

This yield was found to be not more than 7×10^{-16} per ^{16}O ion for all the elements examined with the exception of carbon. As the total amount of impurity in the aluminium was not more than 0·1% the total yield of ^{27}Mg from impurities other than carbon in the aluminium must be not more than 7×10^{-13} per ^{16}O ion which is negligible compared with that observed (Table 1).

The yield for one part per million of carbon impurity in aluminium was 56×10^{-16} per ^{16}O ion and this fell to 36×10^{-16} per ^{16}O ion when measured at 30 MEV. In contrast the observed yield from the aluminium targets was reduced by a factor of at least 50 over this energy range (Table 1). Thus the amount of carbon either present in the aluminium target or deposited on the surface of the target (from traces of oil vapour in the accelerator vacuum system) was too small to cause any significant error in the determination of the yield of ^{27}Mg in these experiments.

3.2. *Magnesium* 27 *from the* $^{27}Al(n, p)^{27}Mg$ *Reaction*

When two identical aluminium foils were placed in close contact and irradiated together it was found that the foil that was shielded from the ^{16}O beam contained about half the ^{27}Mg activity contained in the foil in which the beam was stopped (Table 1). The activity in the shielded foil was due to the ^{27}Al(n, p)^{27}Mg reaction caused by neutrons from ^{27}Al(^{16}O, xn) reactions in the target. The flux in this foil was calculated to be 77% of that in the foil in the beam. An isotropic distribution of neutrons was assumed as it was found that the correction for any anisotropy due to the centre-of-mass motion could be neglected. The yield from the shielded foil can be used therefore to correct the yield of the foil in the ^{16}O beam for the effect of the neutron background. A similar correction was made by Pinajian (1960) in his determination of the ^{27}Al(^{14}N, ^{14}O)^{27}Mg exchange transfer reaction cross section.

3.3. *Fluorine* 17 *from Reactions with Impurities*

The possibility that the observed yield of ^{17}F in the aluminium targets (see § 4) could be due to reactions between ^{16}O and any impurities in targets was considered. It is energetically possible in these experiments to produce ^{17}F from compound nucleus reactions with light elements up to and including boron. The cross section for the production of ^{17}F is some fraction of the total cross section for the formation of the compound nucleus, which is of the order of 1 barn (Thomas 1959). An analysis of the aluminium targets showed however that there was less than 0·01% of each of these elements present. Therefore no significant contribution to the ^{17}F activity observed could come from this source.

This conclusion also applies to transfer reactions with any impurities as the largest section observed for this type of reaction (Zucker 1960) is of the order of 50 mbn.

§ 4. NUCLEAR EMISSION FROM TRANSFER PRODUCTS

There is a possibility that the ^{27}Mg activity observed is derived from the proton decay of ^{28}Al produced in an excited state from the ^{27}Al(^{16}O, ^{15}O)^{28}Al reaction. The possibility also exists that some of the single transfer products ^{15}O and ^{17}F are formed with sufficient excitation energy to emit nucleons (most probably protons in these cases) and escape detection in these experiments. Excitation energies of about 13, 10 and 6 MEV for ^{28}Al, ^{15}O and ^{17}F respectively were required before proton emission was possible. An estimate can be made of the cross sections of transfer reactions which result in products with these excitation energies. This can be done by reference to the general trend of transfer cross sections with the energy 'available' at the moment of transfer, 'available' energy being defined as: the incident energy in centre-of-mass coordinates – the barrier height + $Q/2$. It has been found that when (^{14}N, ^{13}N) neutron transfer reaction cross sections are plotted in this way (Halbert *et al.* 1957) the curves, although differing in magnitude of cross section, all have a similar shape. Cross section measurements for other transfer reactions show a similar dependence on 'available' energy ((^{14}N, ^{15}O) Reynolds and Zucker 1956 and Reynolds *et al.* 1956; (^{19}F, ^{18}F) recent unpublished work by the present authors).

The excitation energies required for proton emission from the various transfer products in the present work reduce the effective 'available' energy. The corresponding reduced cross sections for reactions involving proton emission can be inferred from the curves already described. In this way it is found that only about 1% of the neutron transfer product ^{15}O formed will escape detection by proton emission and that less than about 1% of the neutron–proton exchange transfer product ^{27}Mg could have been produced by proton emission from ^{28}Al from the ^{27}Al(^{16}O, ^{15}O)^{28}Al reaction. The correction for the loss of the proton transfer product ^{17}F due to proton emission is about 20%, which is about the experimental error of the measured cross section (see § 5).

§ 5. RESULTS

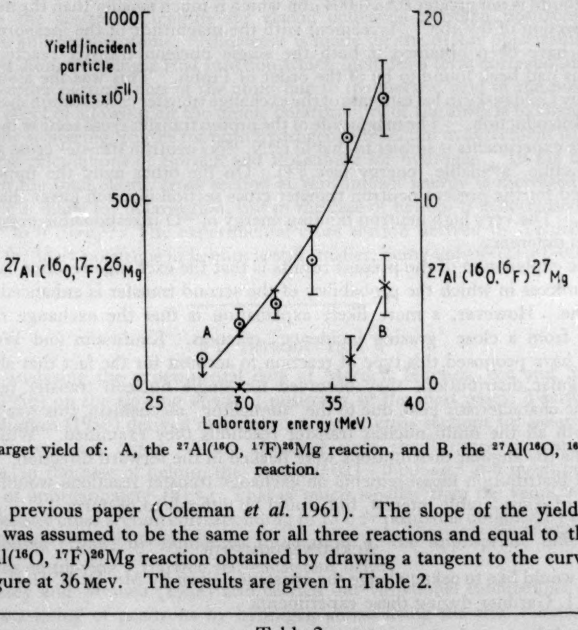
Since ^{15}O activity from the reaction ^{27}Al(^{16}O, ^{15}O)^{28}Al was not detected it was possible to estimate an upper limit of 2×10^{-10} per ^{16}O ion for the yield of this reaction at 36 MEV. The results for the ^{27}Al(^{16}O, ^{17}F)^{26}Mg reaction are shown in the Figure; those for the ^{27}Al(^{16}O, ^{16}F)^{27}Mg reaction are given in the Figure and Table 1.

Table 1. Thick Target Yield of ^{27}Mg per ^{16}O Ion (units 10^{-11})

Energy of ^{16}O ion (MeV)	30	36	38
Thick target yield in aluminium Y_1	$\leqslant 0{\cdot}15$	$8{\cdot}7 \pm 0{\cdot}9$	$12{\cdot}5 \pm 1$
Yield in neutron background foil Y_2†	—	$7{\cdot}1 \pm 0{\cdot}8$	$7{\cdot}0 \pm 1{\cdot}3$
Yield from the ^{27}Al(^{16}O, ^{16}F)^{26}Mg reaction			
$Y_1 - Y_2$	$\leqslant 0{\cdot}15$	$1{\cdot}6 \pm 1{\cdot}2$	$5{\cdot}5 \pm 1{\cdot}6$

† Normalized to the neutron flux in the foil in the oxygen beam.

The cross sections of these reactions at 36 MeV were calculated using the expression $\sigma = \epsilon dY/dE$ where ϵ is the atomic stopping power of ^{27}Al for ^{16}O ions at this energy. A value of $2{\cdot}2 \times 10^{-13}$ ev cm^2 for this stopping power was taken from a previous paper (Coleman *et al.* 1961). The slope of the yield curve dY/dE was assumed to be the same for all three reactions and equal to that for the ^{27}Al(^{16}O, ^{17}F)^{26}Mg reaction obtained by drawing a tangent to the curve A in the Figure at 36 MeV. The results are given in Table 2.



Thick target yield of: A, the ^{27}Al(^{16}O, ^{17}F)^{26}Mg reaction, and B, the ^{27}Al(^{16}O, ^{16}F)^{27}Mg reaction.

Table 2

Neutron transfer cross section	^{27}Al(^{16}O, ^{15}O)^{28}Al	$\leqslant 7\mu$bn
Proton transfer cross section	^{27}Al(^{16}O, ^{17}F)^{26}Mg	$210 \pm 50\,\mu$bn
Neutron–proton exchange transfer cross section	^{27}Al(^{16}O, ^{16}F)^{27}Mg	$0{\cdot}7 \pm 0$[illegible]μbn

The estimated errors are almost entirely due to the poor counting statistics. Uncertainties associated with the identification of these reactions have been discussed in §§ 3 and 4.

§ 6. DISCUSSION

The transfer of single nucleons has been found to take place between nuclei in Rutherford orbits where the closest distance of approach is about the sum of their respective radii (Zucker 1960). The cross section of this process can be considered simply as the product of the average Rutherford scattering cross section σ_R, over the small angular region in which products from these reactions have been found to be emitted, and the probability P that a neutron n, or proton p, will transfer from one nucleus to the other. Thus provided that P_n and $P_p \ll 1$, the neutron transfer cross section is given by $\sigma_n \sim \sigma_R P_n$ and similarly $\sigma_p \sim \sigma_R P_p$.

If the neutron–proton exchange transfer reaction is considered as two independent single transfers then $\sigma_{np} \sim \sigma_R P_n P_p \sim \sigma_n \sigma_p / \sigma_R$. The calculated value of σ_R for 36 MeV ^{16}O ions on ^{27}Al is about 400 mbn. This value together with the measured cross sections for σ_n and σ_p in Table 2 enables σ_{np} to be evaluated. The value found is not greater than 0·004 μbn which is much smaller than the measured cross section of 0·7 μbn. Agreement with the magnitude of the measured value would have been obtained if both the single nucleon transfer reaction cross sections had been found to be of the order of 1 mbn. This was the assumption made by Goldansky in his estimate of the exchange transfer cross section mentioned in the Introduction. The magnitude of the proton transfer cross section measured in these experiments is similar to that of (^{14}N, ^{13}N) neutron transfer cross sections at the same 'available' energy (see §4). On the other hand the upper limit obtained for the present neutron transfer cross section is much lower than these values. The very high neutron binding energy of ^{16}O is responsible presumably for this difference.

One explanation of the present results is that the exchange reaction is a two-stage process in which the probability of the second transfer is enhanced by the first one. However, a more likely explanation is that the exchange reaction results from a close 'grazing incidence' reaction. Kaufmann and Wolfgang (1961) have proposed this type of reaction to account for the fact that although the angular distributions they observed for single nucleon transfer reactions have the characteristic peak due to the 'tunnelling' mechanism, this was not the case with all the multi-nuclear transfer reactions they examined. With these reactions the angular distributions were peaked in the forward direction. Some angular distribution measurements on exchange transfer reactions would therefore be of considerable interest, but would be difficult to perform.

ACKNOWLEDGMENTS

We would like to acknowledge the assistance given by Mr. D. N. Herbert and Mr. B. J. Gardner during these experiments.

The Elastic Scattering of Positrons by Atomic Hydrogen and Helium

By D. C. S. ALLISON, H. A. J. McINTYRE and
B. L. MOISEIWITSCH

Department of Applied Mathematics, The Queen's University of Belfast

MS. received 15th June 1961

Abstract. The variational methods of Kohn and Hulthén are employed to calculate the scattering lengths for elastic collisions between positrons and hydrogen and helium atoms. Allowance is made for the dipole polarizability of the target atom by using a trial function which includes a term corresponding to the first-order perturbation of the atom due to the electric field of the positron.

The effect of allowing for the dipole polarizability of the atom is to change the sign of the scattering lengths for both hydrogen and helium in agreement with the variational calculations of Spruch and Rosenberg for hydrogen. In the case of hydrogen the total elastic cross section at zero impact energy is increased when allowance is made for polarization, but in the case of helium it is decreased from $0{\cdot}72\pi a_0^2$ to $0{\cdot}10\pi a_0^2$. The experimental cross section derived by Teutsch and Hughes for 18 ev positrons in helium is still smaller, being only $0{\cdot}023 \pm 0{\cdot}006\pi a_0^2$.

---

§ 1. Introduction

By analysing the experimental data of Marder, Hughes, Wu and Bennett (1956) on the slowing down of positrons in the inert gases, Teutsch and Hughes (1956) derived momentum transfer cross sections for positrons in helium, neon and argon. They obtained very small cross sections. For example, in the case of helium they found $0{\cdot}023 \pm 0{\cdot}006\pi a_0^2$ at a mean positron energy of approximately 18 ev. This is much smaller than the value $0{\cdot}53\pi a_0^2$ for the elastic cross section corresponding to 13·6 ev positrons obtained by Massey and Moussa (1958) by numerical integration of the appropriate differential equations employing a Hartree self-consistent field.

Massey and Moussa (1958) also carried out variational calculations on the elastic scattering of positrons by hydrogen atoms using the trial function that Massey and Moiseiwitsch (1951) found to be satisfactory in the case of the elastic scattering of electrons by hydrogen atoms. They obtained the values $0{\cdot}512a_0$ and $0{\cdot}582a_0$ for the scattering length with and without allowance for polarization. Subsequently Moussa (1959) used a trial function allowing for the polarization due to the virtual formation of positronium. Again, only a small effect was found, the zero-order phase shift being increased as a result of polarization from $-0{\cdot}264$ radian to $-0{\cdot}211$ radian for positrons having 3·4 ev energy. This decreased the elastic cross section from $1{\cdot}09\pi a_0^2$ to $0{\cdot}70\pi a_0^2$.

Recently Spruch and Rosenberg (1960) have carried out variational calculations on the elastic scattering of positrons by hydrogen atoms employing a similar trial function to that used by Moussa (1959) with allowance for virtual positronium formation. They obtained an upper bound $-1{\cdot}397a_0$ to the scattering length and a lower bound $7{\cdot}80\pi a_0^2$ to the elastic cross section for positrons of zero energy. Their value for the scattering length is rather larger in absolute magnitude and opposite in sign to that found by Moussa demonstrating that the effect of polarization is in fact considerable and results in an increased elastic cross section for the case of atomic hydrogen.

The surprisingly small value for the elastic cross section obtained by Teutsch and Hughes (1956) for the scattering of positrons by helium atoms therefore still remains unexplained. It is the purpose of the present paper to investigate this case further.

§ 2. THEORY

We first consider the elastic scattering of positrons by hydrogen atoms. The wave function $\Psi(\mathbf{r}_1, \mathbf{r}_2)$ of the total system satisfies the Schrödinger equation

$$[H-E]\Psi=0 \qquad \ldots\ldots(1)$$

where E is the total energy and the Hamiltonian is given by

$$H=-\frac{\hbar^2}{2m}(\nabla_1^2+\nabla_2^2)+\frac{e^2}{r_1}-\frac{e^2}{r_2}-\frac{e^2}{r_{12}}, \qquad \ldots\ldots(2)$$

$\mathbf{r}_1$ and $\mathbf{r}_2$ being respectively the position vectors of the incident positron and the atomic electron relative to the proton, and r_{12} being the distance between the positron and the electron. In the case of the elastic scattering of positrons with zero energy and zero angular momentum by hydrogen atoms in the ground state, the wave function has the asymptotic form for large r_1

$$\Psi(\mathbf{r}_1, \mathbf{r}_2) \sim \psi_0(r_2) r_1^{-1}(a-r_1) \qquad \ldots\ldots(3)$$

where a is the scattering length and $\psi_0(r)$ is the wave function of the 1s state of atomic hydrogen.

It can be shown by using perturbation theory (Dalgarno and Lewis 1955) that the wave function of a hydrogen atom in the Coulomb field of a positron is given to first order by

$$\psi_0(r_2)\left[1+\sum_{m=1}^{\infty}\frac{1}{r_1^{m+1}}\left\{\frac{r_2^{m+1}}{m+1}+\frac{a_0 r_2^m}{m}\right\}\mathrm{P}_m(\cos\Theta_{12})\right] \qquad \ldots\ldots(4)$$

where $\hat{\mathbf{r}}_1 . \hat{\mathbf{r}}_2=\cos\Theta_{12}$. The $m=1$ term of this expression arises from the dipole polarizability of the hydrogen atom. Hence allowance may be made for the dipole polarizability of the atom by choosing the trial function

$$\Psi_t(\mathbf{r}_1, \mathbf{r}_2)=\psi_0(r_2)\{1+\gamma f(\mathbf{r}_1, \mathbf{r}_2)\}F(r_1) \qquad \ldots\ldots(5)$$

where

$$f(\mathbf{r}_1, \mathbf{r}_2)=r_1^{-2}\left\{1-\exp\left(\frac{-\delta r_1}{a_0}\right)\right\}^3(\tfrac{1}{2}r_2^2+a_0 r_2)\cos\Theta_{12}, \qquad \ldots\ldots(6)$$

$$F(r_1)=r_1^{-1}\left[\left\{\alpha+\beta\exp\left(-\frac{r_1}{a_0}\right)\right\}\left\{1-\exp\left(-\frac{r_1}{a_0}\right)\right\}-r_1\right], \qquad \ldots\ldots(7)$$

and α, β, γ, δ are arbitrary parameters.

The trial function (5) has the asymptotic form (3) for large r_1 and behaves properly in the limits of vanishing r_1 and r_2. The value of the parameter δ determines the rate at which f tends to zero as r_1 becomes small.

Spruch and Rosenberg (1960) have shown that

$$a \leqslant \alpha+\frac{1}{4\pi}\left(\frac{2m}{\hbar^2}\right)L_t \qquad \ldots\ldots(8)$$

where

$$L_t = \int \Psi_t(\mathbf{r}_1, \mathbf{r}_2)(H-E)\Psi_t(\mathbf{r}_1, \mathbf{r}_2)\, d\mathbf{r}_1 d\mathbf{r}_2. \qquad \ldots\ldots(9)$$

The optimum value of the right-hand side of (8) may be obtained by using Kohn's variational method which involves the solution of the equations

$$\frac{\partial L_t}{\partial \alpha} = -4\pi\left(\frac{\hbar^2}{2m}\right) \qquad \ldots\ldots(10)$$

and

$$\frac{\partial L_t}{\partial \beta} = \frac{\partial L_t}{\partial \gamma} = \frac{\partial L_t}{\partial \delta} = 0. \qquad \ldots\ldots(11)$$

Alternatively, we may use Hulthén's variational method which determines the parameters α, β, γ, δ by employing the equations (11) together with

$$L_t = 0 \qquad \ldots\ldots(12)$$

in place of (10). Because Hulthén's method imposes a restriction on L_t the value of the scattering length given by its application will always be inferior to that obtained with Kohn's method.

Since it is not possible to derive an exact unperturbed helium wave function it is necessary to use an approximate function in order to investigate the elastic scattering of positrons by helium. We have chosen the variational wave function obtained by Green, Mulder, Lewis and Woll (1954) which is a close approximation to the Hartree–Fock wave function for helium.

It has the form

$$\psi_0(r_2, r_3) = u(r_2)u(r_3) \qquad \ldots\ldots(13)$$

where

$$u(r) = N\left\{\exp\left(\frac{-Zr}{a_0}\right) + c\exp\left(\frac{-2Zr}{a_0}\right)\right\} \qquad \ldots\ldots(14)$$

with $Z = 1{\cdot}4558$ and $c = 0{\cdot}6$. N is a normalizing factor given by

$$N = 2{\cdot}96847/(4\pi a_0^3)^{1/2}.$$

The trial function of the system of incident positron and helium atom was taken to have the form

$$\Psi_t(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3) = \psi_0(r_2, r_3)\{1 + \gamma f(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3)\}F(r_1) \qquad \ldots\ldots(15)$$

where

$$f(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3) = r_1^{-2}\left\{1 - \exp\left(\frac{-\delta Z r_1}{a_0}\right)\right\}^3 \{r_2 \cos\Theta_{12}(p_0 a_0 + p_1 r_2) + r_3 \cos\Theta_{13}(p_0 a_0 + p_1 r_3)\} \qquad \ldots\ldots(16)$$

and $\cos\Theta_{ij} = \hat{\mathbf{r}}_i \cdot \hat{\mathbf{r}}_j$. The constants p_0 and p_1 were chosen so that for large r_1, $\psi_0(r_2, r_3) f(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3)$ should be the first-order correction to the wave function of the helium atom arising from the dipole term of the perturbation due to the positron. Calculations by Dalgarno (private communication) give $p_0 = 0{\cdot}242$ and $p_1 = 0{\cdot}395$.

§ 3. DISCUSSION OF RESULTS

If polarization is neglected the scattering length a may be readily calculated by numerical integration of the appropriate differential equation. It is found that $a = 0{\cdot}582a_0$ and $0{\cdot}422a_0$ for hydrogen and helium atoms respectively in close accord with the values, given in Tables 1 and 2, of the scattering length calculated using variational methods with γ taken to be zero in the trial functions (5) and (15).

Table 1. Elastic Scattering of Positrons by Hydrogen Atoms

Values of the scattering length a and the parameters γ and δ calculated using variational methods

	Kohn's variational method			Hulthén's variational method		
	γ	δ	a	γ	δ	a
(i)	0	—	$0{\cdot}58_4$	0	—	$0{\cdot}58_4$
(ii)	1	$0{\cdot}55_3$	$-0{\cdot}77_4$	1	$0{\cdot}54_5$	$-0{\cdot}62_6$
(iii)	$1{\cdot}08_3$	$0{\cdot}49_1$	$-0{\cdot}78_5$	$1{\cdot}09_6$	$0{\cdot}48_4$	$-0{\cdot}63_7$

Table 2. Elastic Scattering of Positrons by Helium Atoms

Values of the scattering length a and the parameters γ and δ calculated using variational methods

	Kohn's variational method			Hulthén's variational method		
	γ	δ	a	γ	δ	a
(i)	0	—	$0{\cdot}42_5$	0	—	$0{\cdot}42_6$
(ii)	1	$0{\cdot}56_7$	$-0{\cdot}16_0$	1	$0{\cdot}56_2$	$-0{\cdot}10_8$
(iii)	$1{\cdot}05_6$	$0{\cdot}51_8$	$-0{\cdot}16_3$	$1{\cdot}06_7$	$0{\cdot}51_0$	$-0{\cdot}11_0$

Row (i): $\gamma=0$, α and β varied.
Row (ii): $\gamma=1$, α, β and δ varied.
Row (iii): α, β, γ and δ varied.

By comparing the coefficient of $F(r_1)$ in the trial function (5) with the polarized hydrogen atom wave function given by expression (4) we see that the parameter γ should be close to unity. Similarly the parameter γ arising in the trial function (15) for the case of helium should also be approximately unity. The values of the scattering length obtained with Kohn's and Hulthén's variational methods, putting $\gamma=1$ in the trial functions (5) and (15), are displayed in Tables 1 and 2 for hydrogen and helium respectively. It is evident that the effect of polarization is very important, the sign of the scattering length being reversed in both cases. This means that the overall field of the atom is attractive towards the positron. If γ is now permitted to vary the value of the scattering length is not greatly altered, the value of γ corresponding to the optimum value of a being just slightly greater than unity.

When polarization is neglected there is very close agreement between the values of the scattering length obtained with Kohn's and Hulthén's variational methods. With allowance for polarization the agreement between the two variational methods becomes less satisfactory. This implies that the form of trial function which was chosen to describe the system of incident positron and atom is inadequate in some way for small r_1. In the case of hydrogen, Spruch and Rosenberg (1960) obtained $-1{\cdot}397a_0$ as an upper bound to the scattering length. This is considerably smaller than the best value $-0{\cdot}785a_0$ obtained with the trial function (5). Spruch and Rosenberg made allowance for virtual positronium formation. This must therefore make a greater contribution to polarization effects than allowance for the dipole polarizability of the atom. However it is clear that in a full treatment of the problem both types of polarization effect should be taken into account.

In the case of the elastic scattering of positrons by helium atoms, the effect of dipole polarizability is to change the sign of the scattering length as for hydrogen. However, the absolute magnitude of the scattering length is decreased. Noting that the total elastic cross section for incident particles of zero energy is given by

$$Q(0)=4\pi a^2 \qquad \ldots\ldots(17)$$

we see from Table 2 that $Q(0)$ is decreased from $0{\cdot}72\pi a_0^2$ to $0{\cdot}10\pi a_0^2$ as a result of polarization. The latter value is about four times larger than the experimental cross section $0{\cdot}023 \pm 0{\cdot}006\pi a_0^2$ derived by Teutsch and Hughes (1956) for 18 ev positrons in helium. Allowance for virtual positronium formation will increase $Q(0)$ above 0·10†. Consequently, unless the elastic cross section decreases considerably with increasing energy, there is discord between theory and experiment for helium.

ACKNOWLEDGMENTS

It is a pleasure to thank Professor A. Dalgarno for his interest in this investigation.

† However, it should be noted that the existence of a bound to the scattering length has been rigorously established only when exact atomic wave functions are employed.

Electron Spin Resonance Absorption for Polycrystalline Substances: II

By J. W. SEARL[†], R. C. SMITH[‡] AND S. J. WYARD[‡][§]

[†] Mathematics Department, Northampton College, London, E.C.1
[‡] Physics Department, Guy's Hospital Medical School, London, S.E.1

MS. received 19th May 1961

Abstract. Calculations have been made of the electron spin resonance line shapes for polycrystalline substances showing uniaxial g-value anisotropy. The calculations have been made for the Lorentzian and Gaussian line shapes of various line widths. Empirical rules are given for determining $g_\parallel$, $g_\perp$ and the line width from the experimental line shapes. Line shapes calculated to fit experimental curves from irradiated deuterium peroxide are given.

CALCULATIONS of the line shapes for a random polycrystalline assembly of uniaxial crystals have been reported in part I (Searl *et al.* 1959). The following assumptions were made for these calculations:

(i) The absorption line shape for the single crystal is the Lorentzian[||]

$$I=\frac{AK}{1+\pi^2K^2(x-c)^2}\,.$$

(ii) The line width for the single crystal is independent of orientation in the magnetic field.

(iii) The variation of c with the crystal orientation in the magnetic field, angle θ, is given by $c=(c_\parallel-c_\perp)\cos^2\theta+c_\perp$, where $c=g$ for sweeping with frequency, or $c=1/g$ for sweeping with field.

(iv) The total absorption A is independent of θ.

Searl *et al.* (1960) have also performed calculations using the same assumptions but with the Gaussian line shape

$$I=\pi^{1/2}AK\exp\left[-(x-c)^2\pi^2K^2\right]$$

(the factor $\pi^{1/2}$ is introduced to ensure that the total absorption is the same for both the Lorentzian and the Gaussian). The calculation must then be performed numerically.

The assumptions (iii) and (iv) above have been altered to improve the accuracy of the calculations as follows:

(iii) The variation of g with angle θ obeys the formula derived by Bleaney (1951) for a uniaxial crystal, $g^2=g_\parallel^2\cos^2\theta+g_\perp^2\sin^2\theta$.

(iv) Bleaney (1960) has shown that a variation of factor A with g occurs. For a linearly polarized oscillatory field he finds that A is proportional to

$$\tfrac{1}{2}g_\perp^2\left[\left(\frac{g_\parallel}{g}\right)^2+1\right].$$

This variation is used in the calculations below.

The integration

$$\mathcal{I}=\int_0^{\pi/2} I\sin\theta\, d\theta$$

[§] Now at Biophysics Laboratory, Stanford University, Stanford, California.

[||] In part I, a factor of 4π was included in error.

can still be performed exactly for the Lorenztian but, because of the complicated nature of the result, it has been found more convenient to evaluate both line shapes numerically. The calculations can be performed for sweeping with either frequency or field. A set of curves thus obtained is given in Fig. 1, where they are shown as the first derivative $d\mathscr{I}/dx$ for sweeping with field. The calculations were made for both single crystal line shapes, using the same $g_{\parallel}$ and $g_{\perp}$ throughout. In Fig. 1 the calculated polycrystalline line shapes for the two different line shapes are compared for three different line widths.

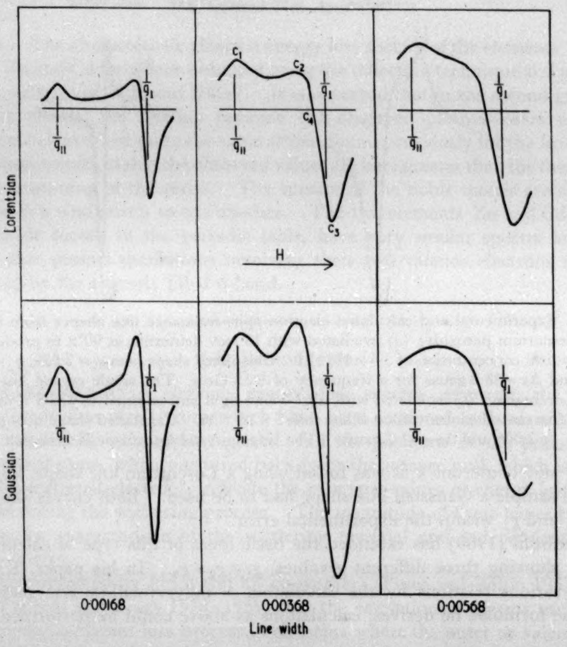

Fig. 1. First derivatives of absorption in polycrystalline substances. The curves are shown for sweeping with field. For all the curves $g_{\parallel} = 2{\cdot}039$ and $g_{\perp} = 2{\cdot}006$. The line widths are in units of $1/g$.

It is seen that peaks 1 and 3 correspond to $g_{\parallel}$ and $g_{\perp}$ respectively. A general rule for the fitting of these peaks is that the closest fit occurs for $c_{\parallel}$ or $c_{\perp}$ whichever has the lower value. Thus for the curves of Fig. 1, c_1 is very close to $1/g_{\parallel}$, except for the Gaussian of the widest line width. The location of $1/g_{\perp}$ to c_3 is less close and for the range of curves shown $1/g_{\perp} = c_3 - \lambda\Delta x$, where Δx is the single crystal line width and λ is a constant of value 0·15 for the Lorentzian, and 0·2 for the Gaussian. The distance $c_3 - c_4$ is related to the single crystal line width. For the curves of Fig. 1, $\Delta x = \mu(c_3 - c_4)$, where μ is a constant of value 2·28 for the Lorentzian and 1·80 for the Gaussian.

Even though these calculations have been described for a random arrangement of uniaxial crystallites, they would hold equally well for a random arrangement of free radicals showing uniaxial symmetry in a magnetic field. Such an arrangement of free radicals would be expected in a glass or similar material.

Calculations have also been made to fit the shapes of spectra recorded experimentally. Fig. 2 (*a*) and (*b*) shows the results for spectra obtained from irradiated deuterium peroxide (Smith and Wyard 1960). For the sample heavily irradiated with 15 Mev deuterons a fit was found using a Lorentzian line shape, but for the warmed sample a Gaussian line shape had to be used. Both curves showed the same $g_{\parallel}$ and $g_{\perp}$ within the experimental error.

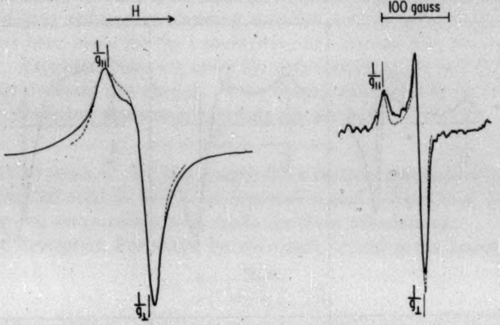

Fig. 2. Experimental and calculated electron spin resonance line shapes from irradiated deuterium peroxide: (*a*) irradiated with 15 Mev deuterons at 90°K to produce a free radical concentration of $3{\cdot}6 \times 10^{-1}$ M. Calculated shape uses $g_{\parallel} = 2{\cdot}039$, $g_{\perp} = 2{\cdot}0045$, and $\Delta x = 38{\cdot}0$ gauss for a frequency of 9·35 Gc/s. The single crystal line shape is Lorentzian; (*b*) irradiated with ultra-violet light and warmed to 133·5°K to produce a free radical concentration of less than 5×10^{-3} M. Calculated shape uses $g_{\parallel} = 2{\cdot}039$, $g_{\perp} = 2{\cdot}006$ and $\Delta x = 11{\cdot}2$ gauss. The single crystal line shape is Gaussian.

Kneubühl (1960) has extended the basic ideas of this type of calculation to crystals showing three different *g*-values, $g_1 \neq g_2 \neq g_3$. In his paper, Kneubühl derives various relations for the calculation of polycrystalline line shapes and, using the formulae he derives, calculations as above could be performed.

ACKNOWLEDGMENTS

The numerical integrations described above were performed on the ‘ Pegasus ’ at Northampton College, and we wish to express our thanks to the members of the Computer Section of the Mathematics Department for their assistance in this work. Characteristic Electron Energy Loss Spectra of the Noble Metals and their Neighbours

By J. L. ROBINS†

Department of Physics, University of Western Australia, Nedlands, Western Australia

MS. received 24*th April* 1961

Abstract. The characteristic electron energy loss spectra of the elements Zr, Pd, Ag, Au, Zn and Cd have been obtained using the reflection technique and primary electron energies of 1500 and 800 ev. It is observed that in the second group of transition metals, the relation between the observed plasma losses and the theoretical values is not quite the same as that found previously for the first group of transition metals, in that the observed values are here greater than the theoretical near the beginning of the series. The spectra of the noble metals are complex and show few similarities to one another. The two elements Zn and Cd, which follow noble metals in the periodic table, have very similar spectra and it is obvious that plasma oscillations involving their two valence electrons are still influenced by the recently filled d band.

§ 1. INTRODUCTION

CHARACTERISTIC electron energy loss spectra represent the energy distribution of electrons which have been scattered both elastically and inelastically in a given material, and the positions of the peaks in the energy distribution, when measured back from the intense peak which is due to elastically scattered electrons, indicate the principal values of energy lost by the electrons during the scattering process. The magnitude of these losses has been found to be characteristic of the scattering material and independent of the primary energy.

It was suggested by Pines and his co-workers (Pines and Bohm 1952, Pines 1956, Nozières and Pines 1958, 1959) that the excitation of plasma oscillations would be the dominant loss process in elements where the outer or valence electrons are loosely bound and the core electrons are tightly bound, and this has been verified experimentally (Powell 1960). However, in elements such as the transition metals, the electrons in the incompletely filled d band can neither be considered as 'free' valence electrons nor 'bound' core electrons and the spectra are much more complex.

In a recent study of the characteristic electron energy loss spectra of the elements of the first group of transition metals, Ti to Cu (Robins and Swan 1960), it was found that the experimental value of the plasma loss agreed with the theoretical value, assuming all 3d and 4s electrons to be 'free', for the first two elements of the series but fell below the predicted value in the following elements. Terminating the transition series of each long period are the noble metals, which are generally considered to have the outermost d level full and one s electron.

---

† Now at National Research Council, Ottawa, Canada.

The binding energy of the electrons within the d band increases when this stage is reached. The plasma loss in Cu, however, is still not equal to the theoretical value, assuming only one free electron, which quite obviously indicates that the d electrons cannot be considered to be 'tightly bound' at this stage.

The present work was intended to extend the measurement of characteristic energy loss spectra to elements in the other series of transition metals which are terminated by noble metals, and also to study the elements following the noble metals in order to determine whether the d electrons can be considered as 'bound' for these elements.

It was considered desirable that the elements should be studied under as nearly identical conditions as possible, and that these conditions should be the same as those used for the previous work. This was to allow a more valid comparison between the results obtained and any theory which considers the elements as a unified series. In the previous work, target surfaces were prepared by evaporation *in situ*, and the spectra obtained immediately after the deposition of a new layer were considered to be representative of a clean surface of the metal.

In the second group of transition metals the only metals suitable for deposition as clean target surfaces by evaporation within the vacuum were Zr, Pd and Ag. Although only three in number, they fortunately represent both ends of the series and it was felt that they might indicate whether similar trends occur in this series to those seen in the first group of transition metals, particularly the relationship between the observed plasma losses and their theoretical values.

In the third group of transition metals, only the last two elements, Pt and Au, were available and suitable for study in the form of evaporated target surfaces. The element Pt has already been studied by Powell (1960), using the same equipment as used in this present work.

The elements following the noble metals Cu, Ag and Au, are Zn, Cd and Hg respectively. Zinc and cadmium were suitable for study and their spectra were recorded although Cd had also been investigated previously by Powell.

§ 2. Experimental Procedure

The characteristic electron energy loss spectra of these elements were obtained using the reflection technique whereby electrons which have been elastically and inelastically scattered through 90° at the target surface are collimated and analysed with a 127° electrostatic energy analyser. The equipment and procedure were the same as previously described (Robins and Swan 1960). Primary energies of both 1500 and 800 ev were used with each metal to investigate changes in the relative intensities of the peaks.

Targets were prepared by vacuum evaporation *in situ*, and were examined immediately after deposition. With each metal studied the observed spectrum changed with time after the deposition of a clean surface and the change was particularly rapid with Zr, Zn and Cd. This change was generally slowed down by 'gettering' the chamber with prior evaporations of the metal concerned. Many evaporations and observations were made with each element, scanning in both directions along the energy scale, and spectra were found to be reproducible provided they were recorded directly after a new evaporation and thus may be considered characteristic of the clean metals.

The change with time is attributed to oxidation of the target surface but no attempt has been made to verify this, and there is also the possibility that it is due to gas adsorption. In an earlier study (Powell, Robins and Swan 1958) under somewhat different conditions, it was observed that the main effect of the adsorption of gas on tungsten was to alter slightly the characteristic loss values for that metal without seriously altering the spectrum. Thus a radical alteration of the spectra tends to indicate a chemical change rather than gas adsorption, but it should be noted that elements such as zirconium and titanium do adsorb gas rapidly. With liquid air in the cold trap around the target no trouble due to the formation of carbonaceous contamination was experienced.

Spectrographically pure metals obtained from Johnson, Matthey and Co. Ltd. were used for the evaporation of all the metals except Cd. The Cd was obtained from the Imperial Smelting Corporation Ltd., and was stated to be of 99·98% purity. The Zr was evaporated from multi-strand tungsten helical coils whilst the remaining elements were evaporated from single or multi-strand conical baskets. A system of buckets and hoppers allowed the evaporating furnaces to be reloaded in the vacuum in the cases where basket-type filaments were used. The pressure was normally less than 2×10^{-6} mm Hg though it rose above this value during evaporation.

The energy distribution curves presented in this work have all been normalized to compensate for the inherent variation of the effective aperture of the analyser with energy, though this effect is small over the energy ranges involved. The intensity scales are arbitrary and have been adjusted so that the intensities of the 25 ev peaks in the Ag spectra are six units whilst those of the dominant peaks in the Zn and Cd spectra and the 18 to 25 ev peaks in the remaining spectra are eight units. The spectra for Pd, Ag and Au were not extended beyond about 40 ev loss due to technical difficulties. The intense peak at zero energy loss, due to elastically scattered electrons, is not shown, but its width at half maximum intensity was about 1·8 and 2·0 ev at primary energies of 800 and 1500 ev respectively.

§ 3. RESULTS

The characteristic energy losses observed in Zr, Pd, Ag, Au, Zn and Cd are presented in Table 1, where the values quoted are the means of measurements made on a number of different spectra taken for each element and the errors shown are the probable errors of the means. Where possible, allowance has been made for the slope of the background when locating the positions of the peaks. The numbers in parentheses indicate the number of measurements used in the determination of the particular loss value.

Zirconium

The element Zr comes near the beginning of the second group of transition metals in the periodic table and occupies the same position in that series as Ti occupies in the first group of transition metals. Difficulty was experienced both in the evaporation of Zr and in obtaining a spectrum of the clean surface before some change, presumably oxidation, occurred. Similar difficulties had been experienced with Ti (Robins and Swan 1960).

The spectra obtained at the two primary energies are shown in Fig. 1, and the similarity between the general form of these spectra and that of Ti is striking.

There is no record of a previous study of this element. The 18·2 ev loss is interpreted as the plasma loss. No lowered plasma loss is observed and this is difficult to explain though the reason may possibly be connected with the extremely rapid rate of oxidation of the surface of this metal. The 3·4 ev loss was not clearly defined in many of the spectra and was rarely observed with a primary energy of 1500 ev. It could be a modified lowered plasma loss but is more likely to be due to an intraband transition or to ionization of the $O_{4,5}$ band. The losses of 32·2 and 57·1 ev are fairly definitely due to ionization of the $N_{2,3}$ and N_1 levels respectively. These values are somewhat greater than would be expected from the x-ray energy-level data (Sandström 1957) but the x-ray values for this element seem slightly low when compared with the values for the neighbouring elements. In addition it should be noted that the ionization values observed in characteristic energy loss work have been found to be systematically greater by a few electron volts (Robins and Swan 1960) than the energy level values which are based on

Table 1. Characteristic Energy Losses as Found in the Present Work (in ev)

The numbers in parantheses indicate the number of measurements used in the determination of the particular loss value. The suggested identification of the energy losses is as follows: LP lowered plasma, P plasma, C combination, I ionization, U unidentified.

Zr	3·4 ± 0·1 (10) I	18·2 ± 0·2 (28) P	32·2 ± 0·4 (13) I	41·6 ± 0·3 (23) U	57·1 ± 0·4 (17) I
Pd	6·8 ± 0·2 (43) LP	16·0 ± 0·3 (38) U	20·2 ± 0·4 (33) U	25·5 ± 0·2 (39) P	31·9 ± 0·3 (39) C
Ag	4·1 ± 0·1 (68) U	7·3 ± 0·2 (67) LP	17·2 ± 0·3 (59) U	25·0 ± 0·2 (65) P	33·5 ± 0·4 (57) C
Au	6·3 ± 0·2 (44) LP	16·0 ± 0·4 (40) U	25·8 ± 0·2 (43) P	32·6 ± 0·3 (39) C	
Zn	8·6 ± 0·1 (74) LP	17·0 ± 0·3 (70) P			
Cd	7·5 ± 0·1 (39) LP	15·1 ± 0·2 (39) P	68·2 ± 0·4 (7) I		

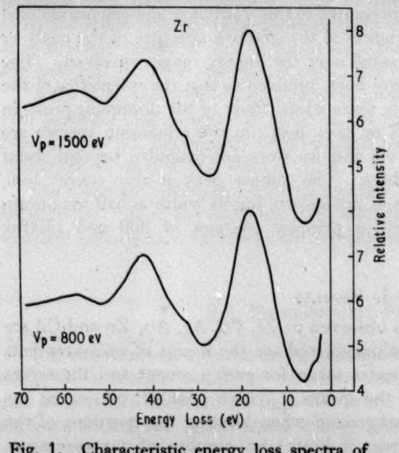

Fig. 1. Characteristic energy loss spectra of zirconium for primary electron energies of 1500 and 800 ev.

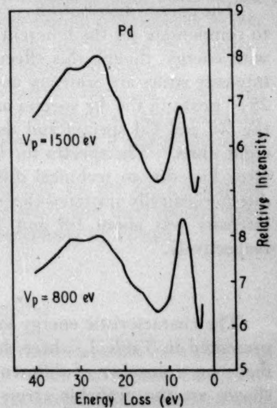

Fig. 2. Characteristic energy loss spectra of palladium for primary electron energies of 1500 and 800 ev.

x-ray absorption edges. In x-ray absorption the transition is to the first vacancy above the Fermi surface, whilst in ionization the electron is completely removed from the neighbourhood of the atom.

The broad intense loss peak of 41·6 ev is in many ways similar to the 48·3 ev loss in Ti and no doubt it has a similar origin. Peaks such as these have been observed in a number of other metals and will be discussed in a forthcoming publication (Robins and Best 1962).

Palladium

The spectrum for Pd, as observed with both primary energies, is shown in Fig. 2. The peaks at 6·8, 25·5 and 31·9 ev loss are much more intense and more clearly defined than those at 16·0 and 20·2 ev, which appear on the steep slope of the 25·5 ev loss peak. Our observed loss values, together with those of Marton and Leder (1954) and Gauthé (1958), are shown together in Table 2 for comparison. The agreement with Marton and Leder is not good as they only observe peaks corresponding to our two least intense peaks. The agreement with Gauthé is better for the more intense peaks, especially as it appears from his published spectrum that a peak near 6 or 7 ev may be present although not resolved from his intense peak of elastically scattered electrons.

Table 2. Characteristic Energy Losses in Palladium as Found in the Present Work and by Other Authors (in ev)

Present work	6·8	16·0	20·2	25·5	31·9	
Marton and Leder (1954)		15·7	21·5			
Gauthé (1958)				23·1	34·5	56 (?)

The peak at 6·8 ev could possibly be explained as a lowered plasma loss, and the fact that its intensity is relatively greater for the lower primary energy is in agreement with this interpretation (Powell 1960). The peaks at 16·0 and 20·2 ev loss remained unexplained. The other two intense peaks show a similarity to the form of the spectra observed for the later elements in the first group of transition elements. If we consider the 25·5 ev loss to be the plasma loss, then the 31·9 ev loss corresponds, within the limits of error, to a combination of the plasma and lowered plasma losses. It would, of course, also be possible for it to be interpreted as resulting from an interband transition.

Silver

The spectrum obtained for Ag, as shown in Fig. 3, is unlike that of any of the other transition metals studied in that it contains two very intense, narrow peaks at small energy loss values. Silver has been studied by a large number of workers and their results are compared with our own in Table 3. There appears to be good general agreement amongst these results if one allows that some experimenters may not have been able to resolve the 17·2 and 25·0 ev loss peaks.

A comparison of this spectrum with those of other transition metals (Robins and Swan 1960) would lead to the interpretation that the 25·0 ev loss is the plasma loss. Based on similar considerations, the 7·3 ev loss could be the lowered plasma loss and the 33·5 ev loss could be due to the combination of plasma and lowered plasma losses. This leaves the 17·2 and 4·1 ev losses unexplained. Evidence which has recently been put forward to suggest that the loss of about 4 ev might be the plasma loss will be discussed later.

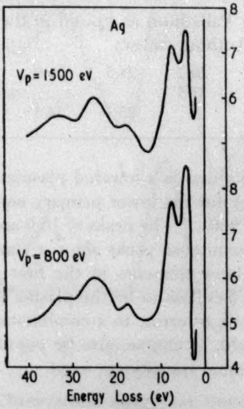

Fig. 3. Characteristic energy loss spectra of silver for primary electron energies of 1500 and 800 ev.

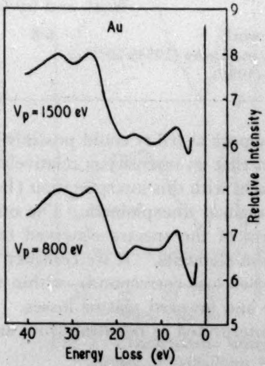

Fig. 4. Characteristic energy loss spectra of gold for primary electron energies of 1500 and 800 ev.

Gold

The spectrum for Au, as observed with the two primary energies, is given in Fig. 4. The suggested interpretation is that the 6·3 and 25·8 ev losses are a lowered plasma and a plasma loss respectively, whilst the 32·6 ev loss could be due to a combination of the two. No explanation of the 16 ev loss can be offered. Our results are compared in Table 4 with those of the many other workers who have studied gold.

Zinc

Extreme difficulty was experienced in obtaining spectra representative of the clean metal surface of Zn. Rapid oxidation, which causes the growth of an intense peak at 18·5 ev loss, made the positioning of the relatively weak peak at 17·0 ev very difficult. However, the curves presented in Fig. 5 are considered representative of the clean metal surface. The agreement between our values and those of other workers, as shown in Table 5, is poor, but this is understandable when the difficulty of maintaining a clean surface is considered. Although Gauthé's values show some agreement, the shape of his curve is completely different and is similar to the spectra of our oxidized target.

Table 4. Characteristic Energy Losses in Gold as Found in the Present Work and by Other Authors (in ev)

Table 5. Characteristic Energy Losses in Zinc as Found in the Present Work and by Other Authors (in ev)

Present work	8·6		17·0	
Kleinn (1954)	6·2			23·1
Gauthé (1959)	5·0	13·8	17·8	

The 17·0 and 8·6 ev losses are considered to be the plasma and lowered plasma losses respectively. This interpretation is reasonable when it is considered that the influence of the not too tightly bound d electrons will be more likely to shift the plasma loss to a value which is greater, rather than less, than the value of 13·2 ev which is predicted theoretically by assuming only the two s electrons to be free. Another argument against assuming the 8·6 ev loss to be the plasma loss, with the 17·0 ev loss as a multiple, is the width of the peak, as it has been found (Robins 1962) that plasma peaks are rarely narrow except when they occur close to their theoretically predicted positions. A very slight peak at about 13·9 ev loss was observed in a number of the measured spectra and might possibly be due to $M_{4,5}$ shell ionization.

Cadmium

The spectrum of cadmium, as shown in Fig. 6, is extremely similar to that of Zn, and the interpretation of the peaks is based on the same considerations as those discussed for that metal. The 15·1 and 7·5 ev losses are interpreted as the plasma and lowered plasma losses respectively. A peak observed at 68·2 ev loss

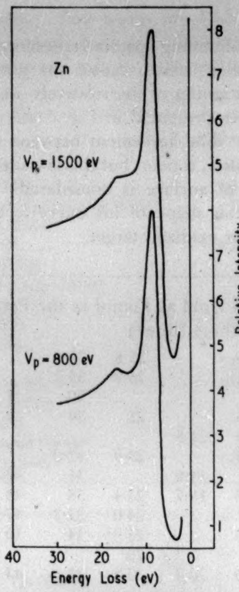

Fig. 5. Characteristic energy loss spectra of zinc for primary electron energies of 1500 and 800 ev.

could be due to $N_{2,3}$ shell ionization, and another barely detectable peak at 12·3 ev loss, which appeared in a few of the spectra, might possibly be associated with ionization of the $N_{4,5}$ shell. These results are compared with those of previous workers in Table 6. The results of Powell (1960) were taken with the same equipment as that used in the present work.

§ 4. Discussion

As mentioned previously, it was found that in the first group of transition metals, Ti to Cu, the plasma loss agreed with the theoretical value for the first two elements Ti and V, and then fell below the theoretical value for later elements in the series, assuming all the 3d and 4s electrons to be 'free'. This was not in agreement with the prediction of Pines (1956) and Nozières and Pines (1958) who reasoned that the effect of interband transitions would cause the experimental values to be higher than the theoretical values at the beginning of the transition group and then to become less than them as one proceeds through the series.

In this present study of some of the elements in the second group of transition metals, it is found that the plasma loss in Zr, an element near the beginning of the series, is 18·2 ev which is considerably higher than the theoretical value of 15·3 ev. The last two elements, Pd and Ag, have plasma losses notably lower than the theoretical values of 30·7 and 29·8 ev respectively. Here, of course, all the 4d and 5s electrons are considered 'free' as in the discussion of Nozières and Pines.

Although it would have been more satisfactory to have been able to study under similar conditions more elements of the series, the present work definitely indicates a difference in the case of these two transition groups. The 'accidental cross-over', as Nozières and Pines term it, will occur later in the second group than in the first. This is possibly related to the fact that the binding energies of the 4d electrons in the second group are relatively higher than those of the 3d electrons in the first group, and this fact may have more significance than a mere consideration of the number of d electrons. It is realized that the elements Nb(Cb) and Mo, which follow Zr in the periodic table, have previously been studied by other workers, but they are not considered here as our aim has been to compare the theory with a set of results taken with the same equipment and under as nearly identical conditions as possible. A consideration of the tables in this and the previous paper will indicate the considerable variation in the results obtained with different techniques, apparatus and experimental procedure.

Interest in the study of silver has been heightened recently by a number of correlated studies. Some time ago, from a consideration of its optical properties, Fröhlich and Pelzer (1955) predicted a loss of about 4 ev in this metal and they implied that this should be the plasma loss, although this is much lower than the values of 9·0 or 29·8 ev which are predicted by the unmodified plasma theory (Pines 1956) if either one or eleven electrons per atom respectively are considered to be 'free'. More recent optical work by Taft and Philipp (1961) leads to the prediction of two energy losses, one at 3·75 ev which could be associated with collective oscillations and another at about 8 ev. Added to this, Steinmann (1960) and Brown, Wessel and Trounson (1960) have observed photon radiation from silver films under electron bombardment, which is considered to arise from plasma oscillations within the metal and this work also indicates a plasmon energy of 3·75 ev.

This would lead to the conclusion that the 4·1 ev loss which is observed in the spectrum of silver in the present work is the plasma loss. The general shape of the spectrum however does not tend to confirm this. If the 4·1 ev loss is the plasma loss, this would represent the only case so far recorded in which the plasma loss peak in the characteristic energy loss spectrum of a pure element is narrow and well defined when its position does not agree fairly closely with the loss value predicted by the unmodified plasma theory. Also, comparison of the spectrum of silver with the spectra of other noble and transition metals tends to indicate that the 25·0 ev loss would be the plasma loss.

Quite obviously some very pronounced phenomenon with an excitation energy of about 3·75 ev does occur in silver, but we feel that the question still remains as to whether this is indeed the same collective oscillation of the free electrons which is generally described by the term 'plasma oscillation'. For example, Hubbard (1955) indicates that there can be more than one frequency at which energy can be absorbed from the incoming electrons.

Following the procedure of Gauthé (1958) some correlation was previously found (Robins and Swan 1960) between the fine structure of X-ray absorption edges and certain characteristic losses in some metals of the first transition group. A similar comparison was attempted with Pd, Ag and Au but no correlation could be found with the X-ray data quoted by Gauthé.

For the elements following the noble metals, namely Zn and Cd, two factors are immediately apparent. Firstly, the inner d electrons are obviously still having an effect on the two outer valence electrons, causing the plasma losses to be shifted from their theoretically predicted values of 13·2 and 11·3 ev for Zn and Cd respectively, assuming only the two valence electrons to be 'free'. This is understandable as the binding energies of the d electrons in these metals are approximately the same as the plasma excitation energies. Secondly, the relative intensity of the lowered plasma loss in each of these elements is exceptionally large. It may be significant that the relative intensity of the peak interpreted as the lowered plasma loss peak increased in the later elements of the first group of transition metals leading up to Zn and again may be considered to increase relatively from Pd through Ag to Cd.

Nozières and Pines (1959) have pointed out that a large increase in the optical transmissivity with increasing frequency is to be expected at the plasma frequency and this has been observed in a number of elements where the plasma loss agrees with the theoretical value (Robins and Swan 1960, Powell 1960, Robins 1962). For the elements Ag, Au and Cd, however, Walker, Rustgi and Weissler (1959) have reported that transmissivity values greater than 0·1 to 0·3% could not be obtained in the ultra-violet. This is interesting as the observed plasma losses in these elements are not in agreement with the theoretically predicted values and the two phenomena may be related.

§ 5. CONCLUSION

The characteristic electron energy loss spectra of the elements Zr, Pd, Ag, Au, Zn and Cd have been obtained using the reflection technique and primary energies of 1500 and 800 ev. It is observed that in the second group of transition metals, the relation between the observed plasma losses and the theoretical values is not quite the same as that found previously for the first group of transition metals in that the observed values are here greater than the theoretical near the beginning of the group. The degree of agreement is probably related to the binding energies of the electrons in the incompletely filled d band rather than the number of electrons in that band.

The spectrum of silver was examined in the light of recent related studies which indicate the plasmon energy in that metal to be 3·75 ev. Although a loss peak is observed at 4·1 ev, it is felt that this loss does not have all the characteristics which it would be expected to have if it were indeed the plasma loss. In general, the spectra of the noble metals are complex and show few similarities to one another. The two elements Zn and Cd, which follow noble metals in the periodic table, have very similar spectra and it is obvious that plasma oscillations involving their two valence electrons are still influenced by the filled d band.

ACKNOWLEDGMENTS

The author wishes to express his thanks to Professor C. J. B. Clews and Dr. J. B. Swan for their encouragement and interest in the work and also to acknowledge the tenure of a Commonwealth Postgraduate Award. The work was financed by the Research Grants Committee of the University of Western Australia.

The Luminescence of CsBr(Tl) and CsI(Tl) as a Function of Temperature

By J. C. ROBERTSON, J. G. LYNCH AND W. JACK
Department of Natural Philosophy, University of Glasgow

MS. received 29*th December* 1960, *in revised form* 10*th April* 1961

Abstract. The luminescent efficiencies and decay times of CsBr(Tl) and CsI(Tl) have been studied as a function of temperature in the range −150°c to 150°c. Protons of energy 14 Mev, and alpha particles of energy 5·3 Mev were used as the exciting radiation. In general, at any one temperature, the luminescence appears to consist of the sum of a fast and a slow exponential component. It is shown that for optimum particle discrimination by pulse shape analysis, there is no advantage to be obtained by maintaining the crystal of CsI(Tl) or CsBr(Tl) at temperatures other than room temperature.

Activation energies for the electron traps in the crystal corresponding to the decay time components τ_i have been obtained.

---

§ 1. INTRODUCTION

It has been shown, (Storey, Jack and Ward 1958) that the decay time of the luminescence produced in CsI(Tl) by ionizing particles is dependent on the ionization density produced by the exciting particle. Robertson and Ward (1959) have used this effect to discriminate between different particles entering a CsI(Tl) crystal, and Robertson and Lynch (1961) have shown that of the commonly available inorganic crystals CsI(Tl) and CsBr(Tl) are most suitable for use with this technique. The present measurements on CsI(Tl) and CsBr(Tl) were made in the hope that a more favourable particle discrimination might be obtained at temperatures other than room temperature. The behaviour of the decay times and efficiencies of the luminescence as a function of temperature is also important when the mechanism of the luminescence is considered. Measurements of this type have been made by Bonanomi and Rossel (1952), Hahn and Rossel (1953) and Enz and Rossel (1958) in pure CsI, and by Knoepfel, Loepfe and Stoll (1957) in pure and thallium-activated CsI.

§ 2. EXPERIMENTAL METHOD

The CsI(Tl) and CsBr(Tl) crystals were obtained from the Harshaw Chemical Company, the thallium concentration in each case being 0·1% molar.

The particles producing high and low ionization density in these measurements were respectively, alpha particles of energy 5·3 Mev from ^{210}Po, and protons of energy 14 Mev from the reaction ^{3}He(d, p)^{4}He.

It was necessary to mount the crystals *in vacuo* to avoid condensation of water vapour on the crystal at low temperatures. The assembly used is shown in Fig. 1. It consists of a cylinder of stainless steel (1/32 in. thick and 2 in. in diameter) lined with aluminium foil reflectors. The ^{210}Po source was mounted inside the cylinder, while the protons entered by a thin (2 mg cm^{-2}) nickel window N in the detachable brass top plate B of the cylinder. The base of the cylinder was closed with a disk of lucite L which was optically coupled to an RCA 6810 photomultiplier with silicone grease. A thin aluminium foil (0·2 mg cm^{-2}) backed the crystal X which was clamped between two copper rings R both of which had aluminized surfaces. The lower ring was attached to a copper rod C which protruded through the wall of the vessel where it could be cooled with liquid nitrogen or heated with an electrical element El as required.

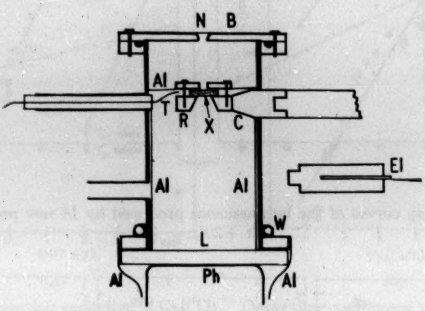

Fig. 1. Crystal mounting.

A thermocouple T was used to measure the crystal temperature. All heating and cooling was carried out slowly and no hysteresis effect was observed. The range of temperatures obtainable was −160°C to +160°C. Finally, water cooling pipes W ensured that the temperature of the photo-cathode Ph remained constant.

The current pulses from the photomultiplier were integrated with a leakage time constant of 205 μsec. These 'voltage' pulses were displayed on a Tektronix type 541 oscillosope and photographed at fixed temperature intervals.

§ 3. ANALYSIS

The decay of the luminescence was obtained by the method described by Storey, Jack and Ward (1958). Photographs of the voltage pulses were projected and traced on fine graph paper, and after slight correction for the finite leakage time constant ($\tau = 205$ μsec) the pulses were carefully differentiated to obtain the original 'current' pulse. This provides a consistent method of averaging the statistical fluctuations in the current pulse. The analysis of the decay of the luminescence of CsBr(Tl) at 20°C, irradiated with protons of 14 MeV, is shown in Fig. 2. From Fig. 2 (*a*) it appears that an exponential component of time constant $\tau = 23$ μsec is present. Having estimated the lifetime and contribution of this component from Fig. 2 (*a*), we subtracted it from a pulse on a shorter time scale, Fig. 2 (*b*). The resulting points are in reasonable agreement with a pure exponential of time constant $\tau = 2{\cdot}6$ μsec.

In general, at any one temperature, the decay of the luminescence of CsI(Tl) and CsBr(Tl) may be described by the sum of a fast and a slow exponential component. Fig. 3 shows one of the exceptional cases where three exponential components appear to be present in the luminescence produced by fast proton irradiation of CsBr(Tl).

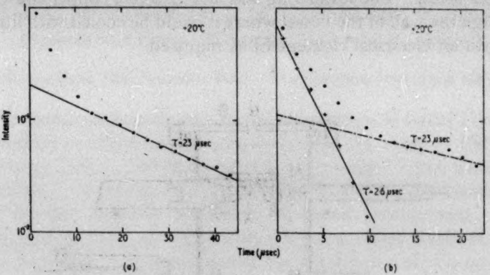

Fig. 2. The decay curves of the luminescence produced by 14 MeV protons in CsBr(Tl) at +20°c.

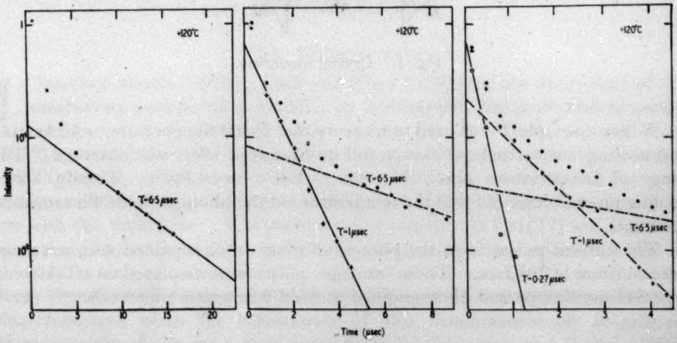

Fig. 3. The decay curves of the luminescence produced by 14 MeV protons in CsBr(Tl) at +120°c.

In CsI(Tl) the contribution from the slow exponential component is small over most of the temperature range. Accordingly, the pulse has been analysed by an alternative method which assumes that the decay of the luminescence is a pure exponential at times short compared with the lifetime of the slow exponential component. Values derived by this method are denoted by τ'. The subscripts α and p denote excitation of the crystal by alpha particles and protons respectively.

§ 4. RESULTS

If the logarithm of the decay time components is plotted against the reciprocal of the absolute temperature (Figs 4 (*a*), (*b*) and 5 (*a*), (*b*)) it is seen that the components obtained by the above analysis are not distributed randomly, but, in

The variation with temperature of the pulse height per unit energy or luminescent efficiency $\infty\mathscr{E}_{\alpha,\mathrm{p}}$ is shown in Figs 6 and 7. In these efficiency measurements it was assumed that all the components contributing to the light output were observed. The results have been corrected for the effect of the electronic differentiation time constant of the pulses.

Tables 1 (*a*), (*b*) and 2 (*a*), (*b*) give the values of R_1, R_2 etc., the ratios of the light present in components 1, 2 etc. to the total light output observed.

§ 5. DISCUSSION AND CONCLUSIONS

The temperature dependence of the ratio $\tau_{1\mathrm{p}}/\tau_{1\alpha}$ for CsI(Tl) is shown in Fig. 8. It can be seen from this figure that, for particle discrimination, there is no advantage in maintaining the crystal at temperatures above room temperature, since, although the ratio $\tau_{1\mathrm{p}}/\tau_{1\alpha}$ increases slightly, the efficiencies $\infty\mathscr{E}_{\alpha,\mathrm{p}}$ show a marked decrease. A similar type of behaviour is observed in CsBr(Tl).

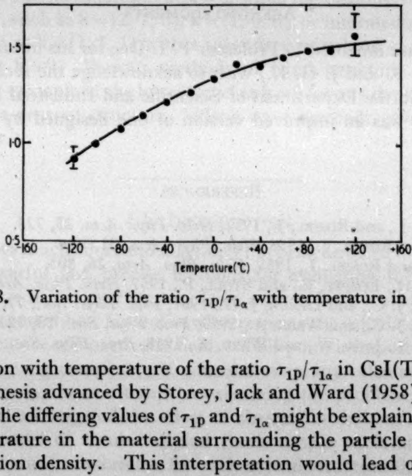

Fig. 8. Variation of the ratio $\tau_{1\mathrm{p}}/\tau_{1\alpha}$ with temperature in CsI(Tl).

The variation with temperature of the ratio $\tau_{1\mathrm{p}}/\tau_{1\alpha}$ in CsI(Tl) is not in accord with the hypothesis advanced by Storey, Jack and Ward (1958). These authors suggested that the differing values of $\tau_{1\mathrm{p}}$ and $\tau_{1\alpha}$ might be explained by an increased effective temperature in the material surrounding the particle track for particles of high ionization density. This interpretation would lead one to expect that the ratio $\tau_{1\mathrm{p}}/\tau_{1\alpha}$ would increase as the crystal temperature was lowered.

In Figs 6 and 7, it is seen that the luminescent efficiencies of CsI(Tl) and CsBr(Tl) have a maximum value in the neighbourhood of room temperature. An interesting feature is the temperature range -70°c to -140°c in CsI(Tl) where the luminescent efficiency for alpha-particle excitation is greater than that for proton excitation. This effect is also observed to a lesser degree in CsBr(Tl).

We must conclude that there is no advantage to be gained from the point of view of particle discrimination by pulse shape analysis by maintaining the crystal at temperatures other than room temperature.

From Figs 4 (*a*) and 5 (*a*) for the alpha-particle excitation of the crystals, it appears that the decay time components in these cases have an exponential dependence on $1/T$, where T is the absolute temperature. It is customary

(Bonanomi and Rossel 1952, Enz and Rossel 1958) to derive from these plots a value for the activation energies of the electron traps associated with the luminescence. The assumption is made that the probability of a luminescent transition is proportional to $e^{-E/kT}$ where E is the electron trap activation energy and k is Boltzmann's constant. For CsI(Tl) we obtain $E_{1\alpha} = 0{\cdot}092 \pm 0{\cdot}01$ ev, while CsBr(Tl) yields values $E_{2\alpha} = 0{\cdot}22 \pm 0{\cdot}02$ ev and $E_{3\alpha} = 0{\cdot}19 \pm 0{\cdot}02$ ev. Although the decay time components for proton excitation of CsI(Tl) τ_{1p} and τ_{2p} show an approximately exponential dependence on $1/T$ yielding electron trap activation energies $E_{1p} = 0{\cdot}079 \pm 0{\cdot}01$ ev and $E_{2p} = 0{\cdot}062 \pm 0{\cdot}02$ ev, there is no evidence of this exponential behaviour in the proton excitation of CsBr(Tl). This throws doubt on the validity of the above simple picture in the case of proton excitation of the crystals.

It is possible that the phenomena which account for the variation of decay time τ with ionization density due to the particle producing the luminescence also account for the dissimilar behaviour of τ with $1/T$ for different types of particle.

ACKNOWLEDGMENTS

The authors are indebted to Professor P. I. Dee for his interest in this work. Two of us (J. C. R. and J. G. L.) wish to acknowledge the receipt of Research Studentships from the Department of Scientific and Industrial Research. The crystal mounting was an improved version of one designed by G. D. Wells in this department.

The Electronic Band Structure of a Model of a Cubic Crystal

By L. PINCHERLE and P. M. LEE
Bedford College, University of London

MS. received 9th May 1961

Abstract. The electronic band structures of a simple cubic and a face-centred cubic array of square potential wells were calculated by a plane wave method for various depths of the potential wells. Certain features of the band structure depend only on the symmetry of the crystal and not on the details of the potential: in a simple cubic monatomic substance an s-type band has its minimum at $\mathbf{k}=0$ and its maximum at $\mathbf{k}=(1, 1, 1)$; a p-band has its minimum at $\mathbf{k}=(1, 0, 0)$ and almost certainly its maximum at $\mathbf{k}=(1, 1, 0)$. In a face-centred monatomic crystal an s-band has its minimum at $\mathbf{k}=0$, while its maximum may be at any of several positions, such as $\mathbf{k}=(2, 1, 0)$, $\mathbf{k}=(1, 0, 0)$, or intermediately. A p-band has its minimum at $\mathbf{k}=(1, 1, 1)$ with a secondary minimum at $\mathbf{k}=(1, 0, 0)$, and its maximum at $\mathbf{k}=0$. Various methods of band structure calculation were compared on the example of the lowest level at $\mathbf{k}=0$ for any depth of the potential wells for the face-centred structure. Plane wave methods gave reliable results with least labour.

---

§ 1. INTRODUCTION

WHEREAS much effort and ingenuity has been directed to the development of powerful and precise methods for evaluating the electronic band structure of a crystal starting from a given field, less attention has been given to the question of how far and in what respects the calculated band structure depends on the choice of a particular field. This point is important in view of the difficulty of achieving complete self-consistency in any calculation of this kind, and the present paper is an attempt at examining the problem in a simple case. That is, we have investigated the effect of changes in the potential on the band structure of a model of a cubic crystal (both simple cubic and face-centred). The general aim was to determine for each crystal structure the possible distributions of energy levels, to see whether some general features are independent of the particular field; and also to study the effect of various characteristics of the potential in displacing levels of a certain symmetry with respect to others. The philosophy of the present approach is thus similar to that of investigations such as Callaway's (1959) on the d-bands of transition metals and Howland's (1958) on the energy bands of KCl. That the crystal structure is fundamental in determining the electronic energy levels is indicated by the fact that a hypothetical sodium with the diamond structure would have bands very similar to those of silicon (Bassani 1959) and that a hypothetical face-centred carbon would be a standard metal (Casella 1958).

Another aim of the investigation was to compare on a simple model the various methods available for band structure calculation, in order to ascertain how quickly they converge to the correct result and how justifiable it is to stop at a certain approximation.

§ 2. MODEL

The model consists of a simple, or face-centred cubic array of square potential wells. That is, in each Wigner–Seitz cell the potential is taken to be constant and equal to $-\phi$, for $r \leqslant b$, b having any value less than the radius of the inscribed sphere, and zero otherwise. This model was first considered by Engelmann (1956) and was chosen to facilitate calculations with certain methods. Several procedures for band evaluation are designed for a potential which is constant outside atomic spheres; and matters are drastically simplified if inside such spheres the potential is spherically symmetric.

If a is some fundamental lattice distance to be used as unit of length, the characteristics of the model are expressed through the two dimensionless parameters $R_0 = b/a$; $V_0 = 2ma^2\phi/\hbar^2$. The energy W will also be expressed through the dimensionless quantity $E = 2ma^2W/\hbar^2$ (for $a = 2{\cdot}5$ atomic units, $= 1{\cdot}3$ Å, $E = 1$ corresponds to $W \simeq 2{\cdot}2$ ev) and the wave vector $\mathbf{q}$ through $\mathbf{k} = a\mathbf{q}$.

If nearest neighbours are at (2, 0, 0) in the simple cubic lattice and at (2, 2, 0) in the face-centred lattice, the radius of the sphere inscribed in the Wigner–Seitz cell is 1 for the former and $2^{1/2}$ for the latter. For the simple cubic lattice the first Brillouin zone is a cube (Fig. 1), k_x, k_y, k_z varying between $-\frac{1}{2}\pi$ and $\frac{1}{2}\pi$; for the face-centred structure it is a truncated octahedron (Fig. 2), the centres of the square faces being at points such as $(\frac{1}{2}\pi, 0, 0)$.

The $(E, \mathbf{k})$ relation, for the first few bands, was determined for the two structures for a number of values of V_0. Since a and ϕ enter through the combination $a^2\phi$, one obtains in principle the effect of the variation of both the lattice distance and the depth of the potential wells, but in fact, to study the effect of a change in lattice distance alone, one must vary also R_0. Here instead R_0 was taken in all cases equal to the radius of the sphere inscribed in the Wigner–Seitz cell; the study of the effect of variations of this quantity, for constant V_0, did not seem of much physical significance. Attention was mainly concentrated on the determination of the values of V_0 at which the various energy gaps appear and of the position in $\mathbf{k}$-space of the corresponding band edges. The model is thus relevant to the theory of semiconductors, but not to that of metals, where the details of the often very complicated Fermi surfaces depend generally on the characteristics of the potential.

Similar calculations on more realistic models may serve as a guide to the possible band structures of real crystals, especially to the variation of the band structure along a series of similar crystals or in mixed crystals; for instance, one might study the effect of deviations of the potential from spherical symmetry on the position of the various levels in diamond and zincblende type crystals.

§ 3. LIMITING CASES

The energy levels are known exactly in the two limiting cases of $V_0 = 0$ and $V_0 = \infty$. In the first case (completely free electrons) $E_n(\mathbf{k}) = |\mathbf{k} + \mathbf{K}_n|^2$, $\mathbf{K}_n$ being any fundamental vector of the reciprocal lattice; these fundamental vectors are therefore used to label the free electron bands. In the other limiting case (infinite square well potential) the levels can be labelled as in well-known nuclear models.

The energies of the lowest levels, independent of **k**, measured from the bottom of the well, are

Level	1s	1p	1d	2s	1f	2p
ER_0^2	9·87	20·19	33·22	39·48	48·83	59·68

In the general case, if the crystal is without glide planes or screw axes, the energy levels at any point in **k**-space are classified according to the irreducible representations of the group of the corresponding **k**-vector. Each **k**-point of prominent symmetry is traditionally denoted by a Greek or Latin capital letter, indicated in Figs 1 and 2. The various representations will be denoted by the spectroscopic suffices s, p, d . . . , indicating the first term of the expansion in spherical harmonics of the corresponding wave function (Bell 1954). p, p′, p″ . . . will be used when there is more than one representation which is predominantly p-type, etc. The methods of group theory permit one also to decide to which of the free electron or tightly bound levels the various states reduce in the two limiting cases.

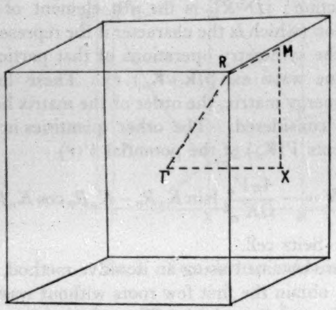

Fig. 1. Brillouin zone for the simple cubic lattice, with prominent symmetry points and path along which the $(E, \mathbf{k})$ relations were evaluated.

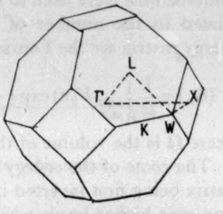

Fig. 2. Brillouin zone for the face-centred cubic lattice, with prominent symmetry points and path along which the $(E, \mathbf{k})$ relations were evaluated.

§ 4. METHOD OF CALCULATION

It would be desirable to have a single method of calculation applicable for all values of V_0; but clearly at one end of the scale $(V_0 \rightarrow 0)$ plane wave methods must be vastly superior, while at the other end $(V_0 \rightarrow \infty)$ the tight binding procedure will yield the energy values with least labour. However a complete calculation was carried out only with the method of simple plane waves, because the region of relatively small values of V_0 seemed physically the most interesting. The tight binding formalism may then be used, particularly for fairly large V_0, to interpolate results calculated at **k**-points of prominent symmetry, and also, with additional assumptions, to extrapolate results to $V_0 \rightarrow \infty$. Application of other methods is described in § 7.

In the method of plane waves, the wave function is expanded in a Fourier series. Enough terms were inserted to obtain the correct ordering of the levels at each point, though not enough to ensure a convergence of the eigenvalues better than about 0·1 (0·2 ev for a lattice spacing, in the simple cubic lattice, of 2·6 Å). The convergence becomes worse, as one would expect, on increasing V_0.

The function of the correct symmetry for any irreducible representation j of the group of a $\mathbf{k}$-vector was obtained by standard methods using the projection operator

$$\Psi^{(j)}_{\text{sym}} = \sum_R [D^{(j)}R]_{ii} R\psi$$

where $\Psi^{(j)}_{\text{sym}}$ is the symmetrized function; $[D^{(j)}R]_{ii}$ is the iith element of the matrix for the representation in question (which is the character if the representation is one-dimensional), and R are the symmetry operations of that particular group. ψ is normally a simple plane wave $\exp\{i(\mathbf{k}+\mathbf{K}_n).\mathbf{r}\}$. These linear combinations were used to form the energy matrix, the order of the matrix being related to the number of $\mathbf{K}$-vectors considered. The other quantities in the energy matrix are the Fourier coefficients $V(\mathbf{K}_n)$ of the potential $V(\mathbf{r})$

$$V(\mathbf{K}_n) = \frac{1}{\Omega}\int_{\substack{\text{unit}\\ \text{cell}}} V(\mathbf{r}) \exp(-i\mathbf{K}_n.\mathbf{r})\, d\mathbf{r} = -\frac{4\pi V_0}{\Omega K_n{}^3}[\sin K_n R_0 - K_n R_0 \cos K_n R_0]$$

where Ω is the volume of the Wigner–Seitz cell.

The roots of the energy matrix were obtained using an iterative method, the matrix being first inverted in order to obtain the first few roots without wasting time over higher levels which often were not required. The calculations were performed on the University of London 'Mercury' computer. The largest matrix used was of order 12, but at many points convergence was good with a smaller number of waves. At some points, particularly on the zone boundary, the wave functions were almost plane waves, whilst at other points they were more atomic like, and at such points the convergence was poorer.

§ 5. RESULTS FOR SIMPLE CUBIC LATTICE

Figures 3, 4 and 5 give the lowest bands, along the directions in $\mathbf{k}$-space indicated in Fig. 1, for the simple cubic lattice and for $V_0 = 0$ (free electrons), 5 and 25 respectively. All energies are measured from the bottom of the potential well. The various broken lines indicate bands of different symmetry.

A point that immediately emerges is that the quasi free-electron ordering of the levels persists up to relatively high values of V_0, a circumstance often noted in real crystals (see, for instance, Callaway's (1956) discussion for body-centred cubic crystals). Deviations occur mainly because bands of the same symmetry cannot cross. From results obtained for a few values of V_0, it is possible to interpolate in the whole range $0 \leqslant V_0 \leqslant \infty$, since the relative displacement of the various levels occurs quite smoothly. With the tight binding interpolation procedure it is also possible to plot the bands along other directions in $\mathbf{k}$-space. At $V_0 = 25$ (Fig. 5), the two lowest bands have already almost exactly the form given by the simplest tight binding calculation.

Thus in a simple cubic crystal the lowest band, s-type, has its lowest energy at $k = 0$ and its highest at the corners of the cubic Brillouin zone. No reasonable form of the potential could lead to any other result. The first and second bands

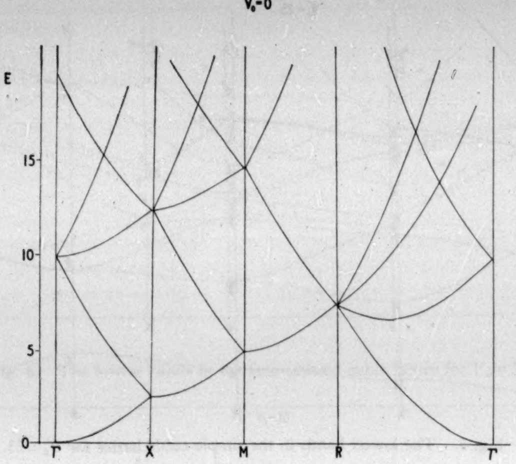

Fig. 3. Free electron bands for the simple cubic lattice.

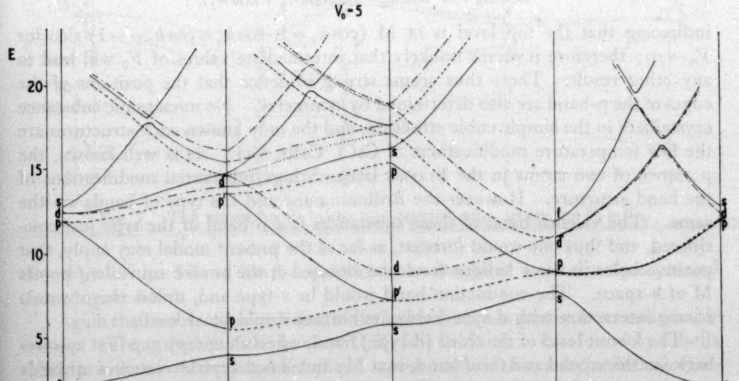

Fig. 4. The lowest bands in the simple cubic lattice for $V_0=5$.

become separated at $V_0=11{\cdot}4$. The lowest level of the second (p-type) band is at X, as indicated both by the free electron and by the tight binding models, and again this may be considered a general property of simple cubic crystals. When the second energy gap first appears, at about $V_0=18{\cdot}6$, the level M_p (non-degenerate) has the highest energy. Now, according to the simplest tight

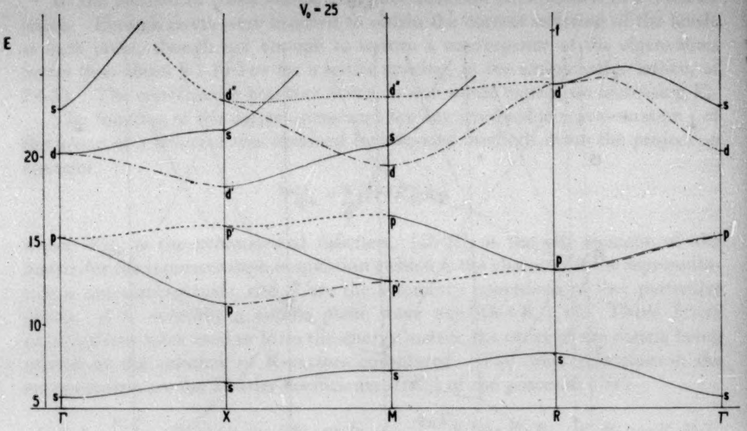

Fig. 5. The lowest bands in the simple cubic lattice for $V_0 = 25$.

binding approximation, the energy of this band is given by

$$E = E_0 + A^2 \cos k_x - B^2 (\cos k_y + \cos k_z),$$

indicating that the top level is at M ($\cos k_x = 1$, $\cos k_y = \cos k_z = -1$) also for $V_0 \to \infty$; therefore it seems unlikely that intermediate values of V_0 will lead to any other result. There thus seems strong evidence that the positions of the edges of the p-band are also determined by symmetry. No monatomic substance crystallizes in the simple cubic structure, and the only known such structures are the low temperature modifications of CsCl, CsBr, CsI. As is well known, the presence of two atoms in the Bravais lattice brings substantial modifications of the band structure. However the Brillouin zone and the type of bands are the same. The valence band of these substances is a p-band of the type just considered, and thus one would forecast, as far as the present model may apply, that positive holes in these halides would be situated at the twelve equivalent points M of $\mathbf{k}$-space. The conduction band would be s-type and, unless there were a strong interaction with d-type levels, its bottom would be at $\mathbf{k} = 0$.

The lowest level of the third (d-type) band, when an energy gap first appears between the second and third band, is at M; but this d-type level moves upwards rapidly on increasing V_0 and for V_0 greater than 25 the lowest level is at X. For higher levels the worsening convergence of the results does not warrant any firm conclusion. As the bands become increasingly separated, all levels in a band tend to become predominantly s, or p, or d . . . according to the type of level to which the band reduces for $V_0 \to \infty$.

§ 6. RESULTS FOR FACE-CENTRED CUBIC LATTICE

Figures 6 and 7 show results for the face-centred lattice for, respectively, $V_0 = 5$ and $V_0 = 10$. In this case the bands were calculated only at Γ, X, W, L and have been sketched in what seemed a reasonable way at intermediate points.

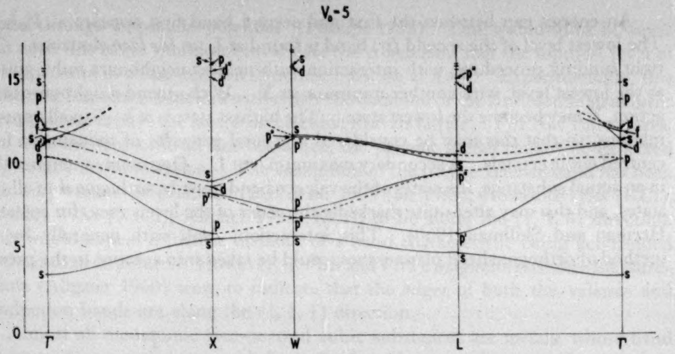

Fig. 6. The lowest bands in the face-centred cubic lattice for $V_0 = 5$.

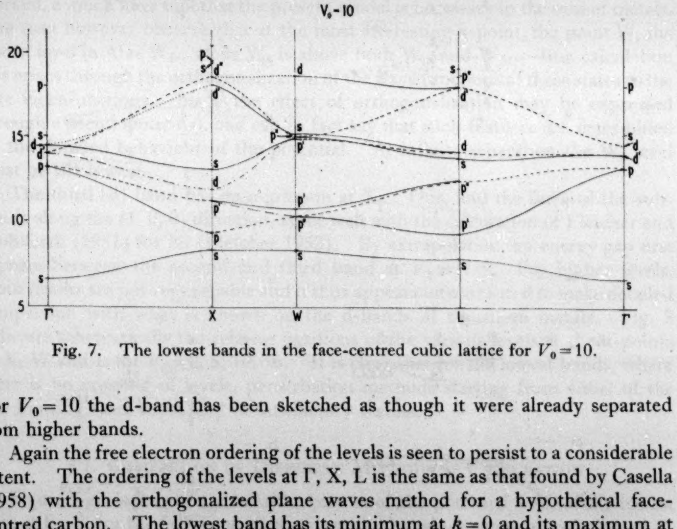

Fig. 7. The lowest bands in the face-centred cubic lattice for $V_0 = 10$.

For $V_0 = 10$ the d-band has been sketched as though it were already separated from higher bands.

Again the free electron ordering of the levels is seen to persist to a considerable extent. The ordering of the levels at Γ, X, L is the same as that found by Casella (1958) with the orthogonalized plane waves method for a hypothetical face-centred carbon. The lowest band has its minimum at $k = 0$ and its maximum at W, but a second maximum of about the same height exists at X. At the point K, at the end of the (1, 1, 0) direction, the energy is also found not to be much lower. Thus in this case the characteristics of the potential must be the deciding factor. In the tight binding approximation, considering interaction with nearest neighbours only, the energies at X and W, and at all points along the diagonals of the square faces of the Brillouin zone, are the same. Interaction with second nearest neighbours makes W higher. In face-centred solid He, a recent calculation has in fact given the top level at W (Simcox and March, private communication).

An energy gap between the first and second band first appears at $V_0=5{\cdot}4$. The lowest level of the second (p) band is found at L, as for free electrons. The tight binding procedure, with interaction with nearest neighbours only, gives L as the lowest level, with another minimum at X. With second neighbours interaction, X may become the lowest state. The highest state is at $k=0$ in all approximations, so that this may be considered a general property of monatomic face-centred cubic crystals. A secondary maximum is at L. One must remember that, in an actual substance, the states of the valence band must be orthogonal to all core states, and this may alter quite markedly the order of the levels (see, for instance, Herman and Skillman 1960). This interaction, dealt with generally by the method of orthogonalized plane waves, could be taken into account in the present

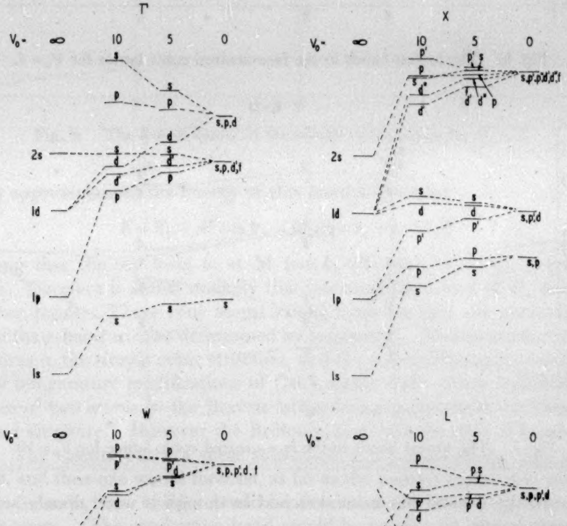

Fig. 8. Displacement of levels with varying V_0 at prominent **k**-points for the face-centred cubic lattice.

model through a 'pseudo-potential' (Phillips 1958). One would think however that even this effect would not invalidate the conclusion that the topmost level of a p-type band in a face-centred structure must be at $k=0$. Experimentally, this is the case for semiconductors with either the diamond or the zinc blende structure: these structures have the face-centred cubic Bravais lattice. For NaCl structures, also with the face-centred Bravais lattice, the present model cannot be expected to give any firm indication. The maximum of the p-type valence band has been found by various calculations (Bell *et al.* 1953 (on PbS), Howland 1958 (KCl), Grimley 1958 (NaCl), Kucher 1958 (KCl)) to be along the (1, 1, 0) direction. This would appear a further instance of a band characteristic being determined by the crystal structure. However, in PbS and PbTe magnetoresistance measurements (Allgaier 1960) seem to indicate that the edges of both the valence and conduction bands are along the (1, 1, 1) direction.

Almost all monatomic face-centred cubic substances are metals, whose band structure does not deviate much from the free electron scheme. Aluminium is on whose band structure has been particularly well examined theoretically and experimentally (Heine 1957, Harrison 1960, and references). As already remarked, a much finer tool that the present model is necessary in the case of metals. One may however observe that at the most interesting **k**-point, the point W, the lowest level in Al is $W_{p'}$, while W_s is above both $W_{p'}$ and $W_{p''}$. In a calculation this arises through the orthogonalization of the wave functions of these states to the core eigenfunctions. Since the effect of orthogonalization may be expressed through a pseudopotential, one can in fact say that such features are determined by the detailed behaviour of the potential. At infinite separation the W_s level must be the lowest.

The third (d) band has its minimum at X. This, and the form of the subbands along the (1, 0, 0) direction, agree well with the calculation of Fletcher and Wohlfarth (1951) for Ni (Fletcher 1952). By extrapolation, an energy gap first appears between the second and third band at $V_0 \simeq 11 \cdot 5$. For higher levels, again results are not very reliable and it thus appears unwarranted to make detailed comparison with what is known on the d-bands of transition metals. Fig. 8 indicates schematically the relative positions of the various levels at the **k**-points Γ, X, W and L for $V_0=0, 5, 10, \infty$. It is clear that for the lowest bands, where there is no crossing of levels, perturbation methods starting from either of the two limiting cases must lead to satisfactory results.

§ 7. COMPARISON OF DIFFERENT METHODS OF CALCULATION

Figure 9 gives the energy, over the bottom of the potential well, of the lowest state at $\mathbf{k}=0$, for the face-centred structure, in the whole range of variation of V_0 (for convenience the abscissa is $\log_{10}(1+V_0)$), as calculated with the most important available procedures. Curve 1 (exact) gives the lowest energy for an isolated well. Curve 2 gives the energy obtained by applying to the crystal the method of tight binding, taking into consideration only the interaction with nearest neighbours (Slater and Koster 1954). Curve 3 gives the results obtained by using the Kohn–Rostoker (1954) procedure based on the Green function formalism. For the level in question the actual formula was given explicitly by Raychaudhuri (1957). Curve 4 gives the energy according to the cellular method in its simplest form, that is substituting equivolume spheres to the actual Wigner–Seitz cells and

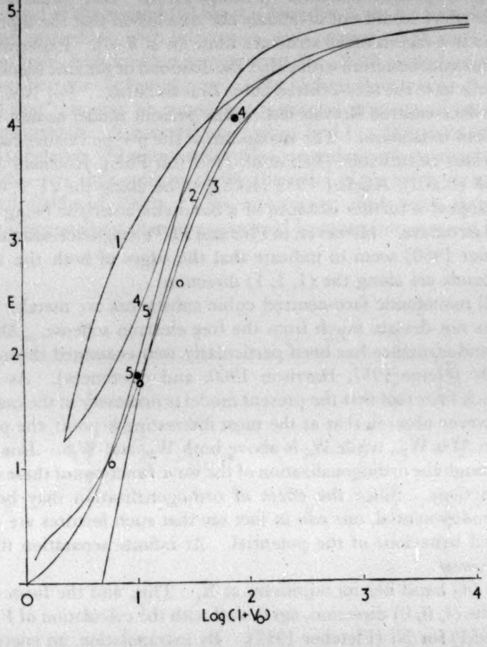

Fig. 9. Energy of lowest level at **k** = 0 in the face-centred cubic lattice as function of $\log_{10}(1+V_0)$. Curve 1: isolated well, exact. Curve 2: tight binding method (nearest neighbours only). Curve 3: *S*-matrix method, spherically symmetric term only. Curve 4: cellular method, matching at equivolume sphere. Curve 5: augmented plane wave (one wave only). Circles: results of main calculation. For other points, see text.

satisfying the boundary conditions at the surface of such spheres using only the spherically symmetric term. The point marked 4 refers to an application of Kohn's (1952) variational procedure for the cellular method, with two terms in the expansion of the wave function. The results of the plane wave calculation are marked with circles. Curve 5 gives the energy according to the augmented plane wave procedure (Saffren and Slater 1953) with one single augmented plane wave. A value obtained with two augmented plane waves is also given (point marked 5).

While all methods, pushed to high approximations, would give the same result, the advantage of using the more appropriate methods in the region of almost free electrons and in that of strongly bound ones respectively is very clear. The simple cellular procedure is not very good, except for strongly bound electrons, and the complications over the boundary conditions make it cumbersome to push it to higher approximations. The augmented plane wave method is very good for almost free electrons, but has the drawback that, with one wave, the asymptotic behaviour of the energy for $V_0 \to \infty$ is wrong, a displeasing feature in view of the fact that this is the only approximation that one can immediately extend to the non-periodic case (energy levels in liquids).

In this artificial and oversimplified example the results given by the Green function (or scattering matrix, Korringa 1947) formalism are quite good with very little labour, but the labour increases tremendously at other points in **k**-space and for other forms of potential. With plane wave methods, on the other hand, different **k**-points and different potentials are taken into account much more readily.

In conclusion, this example confirms that in cases of practical interest the methods more likely to lead to reliable results without the necessity of pushing them to a high approximation are those based on the use of plane waves, orthogonalized or augmented, or on one of the variations and extensions of such methods.

ACKNOWLEDGMENTS

Warm thanks are extended to the Director and Staff of the University of London Computer Unit for the facilities provided, and to Dr. N. H. March and Mr. L. N. Simcox for communicating to us their results. One of us (P. M. L.) is indebted to the Department of Scientific and Industrial Research for a research grant, and the other (L. P.) to the Central Research Fund of the University of London for providing a desk calculating machine.

The Efficiency of Production of Characteristic X-radiation in Thick Targets of a Pure Element

By M. GREEN and V. E. COSSLETT
Cavendish Laboratory, University of Cambridge

MS. received 30*th March* 1961

Abstract. A simple theoretical expression is proposed for K quanta production in directions at large angles to the surface of a thick target, neglecting absorption. Direct and indirect production are calculated and the ratio of indirect to total production is shown to be in agreement with experimental results both in magnitude and in independence of over-voltage U_0. Total production is expressed as a function of atomic number Z and over-voltage U_0, and is found to vary as $(U_0-1)^{1\cdot 67}$. Values for total production are in fair agreement with experimental values.

§ 1. Introduction

The efficiency of production of K quanta by monoenergetic electrons incident normally on a thick target of a pure element has been given in graphical form by Worthington and Tomlin (1956) and Archard (1960) for a range of elements. Both papers combine theoretical and experimental evidence in their calculations and use the Bethe energy loss relation. In the present calculation, by using the Thomson–Whiddington energy loss equation, which has been more fully tested than the Bethe form in the range 0–100 kev, an analytic expression is derived for K production before target self-absorption. For a useful range of conditions this absorption is small and total K production before absorption may be approximately equated to production as measured at the target surface. The fluorescent contribution to K production arising from the absorption of the continuous radiation was estimated by Worthington and Tomlin and Archard from experimental evidence. Here it is calculated from a known expression for the efficiency of continuous x-ray production.

§ 2. The Relation of K Quanta Production to the Total Number of K Ionizations

K quanta may be produced by an atom when an electron from the L, M or N shells falls into a vacancy in the K shell caused by ionization. The alternative to the emission of a K quantum is an internal conversion process resulting in Auger electron emission. The relative probability of these two processes is described by the fluorescence yield of the K shell ω_K, the fraction of K ionizations resulting in K quantum emission.

If n_K is the total number of K ionizations caused in a thick target by an electron of initial energy E_0 (kev), then the total number of K quanta per electron is N_K where

$$N_K = \omega_K n_K. \qquad \ldots\ldots(1)$$

In a thick target bombarded by electrons, ionization of the K shell is caused in two ways. The first process is the direction ionization of the atoms of the target material by the incident electron. This gives rise to a component which will be referred to as direct ionization and n_K(direct) is the number of direct ionizations per electron.

Continuous radiation is produced by the deceleration of the incident electrons in the target. Those quanta of the continuous radiation which have energies greater than E_K (kev), the K ionization energy, and which are absorbed in the target, give rise to further K ionizations in the absorption process. This is the indirect ionization component where n_K(indirect) is the number per electron.

Equation (1) may be rewritten

$$N_K = \omega_K[n_K(\text{direct}) + n_K(\text{indirect})]. \qquad \ldots\ldots(2)$$

§ 3. K QUANTA ABSORPTION IN THE TARGET

Calculation of the observed intensities of K quanta production at various angles to the surface of the target is complicated by the penetration of the incident electrons into the target and by the absorption at varying depths of the continuous radiation producing indirect ionization. In general, (2) must be written in a differential form for the number of K quanta produced in a layer element of thickness dx:

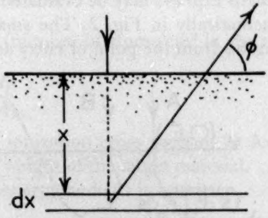

Fig. 1.

$$dN_K = \omega_K\ [dn_K(\text{direct}) + dn_K(\text{indirect})]$$

where dn_K(direct) and dn_K(indirect) are the ionization contributions from the layer element.

Then the number of quanta per unit solid angle per electron at an angle ϕ (defined in Fig. 1) is

$$\frac{1}{4\pi}\int_0^\infty \frac{dN_K}{dx}\{\alpha \exp(-\mu_\alpha x \operatorname{cosec}\phi) + \beta \exp(-\mu_\beta x \operatorname{cosec}\phi)\}\,dx. \qquad \ldots\ldots(3)$$

The assumption is made that only Kα and Kβ quanta are emitted and α is the fraction of α quanta and μ_α the Kα linear absorption coefficient. Similar definitions hold for Kβ quanta. The quantities $dn_K(\text{direct})/dx$ and $dn_K(\text{indirect})/dx$ are complicated functions of x depending on the electron scattering processes in the target and the angular distribution of the continuous radiation. Even with simple models of the electron scattering processes in the target, previous authors (Worthington and Tomlin 1956, Archard 1960, Kirkpatrick and Baez 1947) have found that numerical methods are required for the evaluation of integrals similar to (3). Thus an analytic expression for K quanta production can only be found if certain simplifications are made.

In the present work the absorption correction is neglected and the K quanta production $N_K/4\pi$ per electron per unit solid angle at large values of ϕ is written from (2) as

$$\frac{\omega_K}{4\pi}\left[n_K(\text{direct})+n_K(\text{indirect})\right]. \qquad \ldots\ldots(4)$$

This avoids the need for the form of dn_K/dx to be known. Apart from the convenience of producing an analytic expression for K quanta production, this approximation is based on two further considerations. (i) It may be shown from experimental evidence that for $\phi = 45°$, if $ZU_0 < 100$ the absorption correction is less than 10%, which for most elements provides a useful range of E_0. Here U is the 'over-voltage', i.e. the ratio E/E_K, and $U_0 = E_0/E_K$. (ii) Values of fluorescence yield, ionization cross section and electron energy loss used in all K quanta production calculations are uncertain for many values of Z, making the neglect of the absorption correction a relatively unimportant contribution to the error in the final result.

§ 4. DIRECT IONIZATION CONTRIBUTION

The direct contribution to Eqn (4) may be evaluated by a consideration of the electron paths shown schematically in Fig. 2. The small element of path ds in A is at a point of path length s from the point of entry and an electron traversing the element has an energy E. If $dn_K(\text{direct})$ is the number of direct ionizations per electron in ds, then

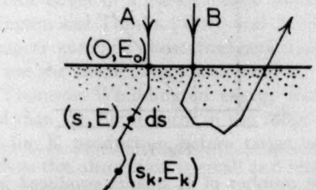

Fig. 2.

$$\int_0^{s_K}\frac{dn_K(\text{direct})}{ds}\,ds \qquad \ldots\ldots(5)$$

is the total number of direct ionizations per electron for a path of type A where the electron reaches a point where $E = E_K$ and $s = s_K$ without leaving the target material. The path of the electron beyond the point gives rise to no K ionization, as E is now less than E_K.

Relation (5) is true for all electrons which complete their path of length s_K in the material irrespective of the particular shape of the trajectory. Thus the shape factor which makes the evaluation of $dn_K(\text{direct})/dx$ difficult is avoided. However, consideration must be given to paths of the form B where the electron leaves the target through back scattering before its energy has fallen to E_K. Relation (5) is rewritten

$$n_K(\text{direct}) = R\int_0^{s_K} \frac{dn_K(\text{direct})}{ds}\,ds \qquad \ldots\ldots(6)$$

where R is introduced to allow for this back scattering effect. $1-R$ is the fractional loss of ionization due to back scattering. The fraction of electrons with energies greater than 50 ev back scattered from a thick target is given the symbol η and is found to be nearly constant with respect to variations in E_0 for a particular element. Typical values taken from the work of Sternglass (1954) are 6% for carbon, 29% for copper and 38% for silver. In general, $1-R$ varies with E_0 and is always less than η, as any electron back scattered with an energy less than E_0 has made some contribution to ionization. The energy distribution of back scattered electrons has been investigated by several workers (Sternglass gives many useful references) and from their results $1-R$ may be deduced by a numerical method. In the present work a value of 12% has been found by this method for copper at $U_0=3$, and Kirkpatrick and Baez (1947) quote experimental values taken from the work of Webster, Hansen and Duveneck (1933) of 19% at $U_0=2$ and 21% at $U_0=3$ for a silver target.

Proceeding with the evaluation of (6), $dn_K(\text{direct})/ds$ is written

$$\frac{dn_K(\text{direct})}{ds} = Q_K \times (\text{number of atoms/cm}^3 \text{ in the target material})$$

$$= Q_K \frac{N\rho}{A}$$

where Q_K is the K shell ionization cross section, **N** Avogadro's number, ρ the density and A the atomic weight of the target material. Q_K is conveniently given as a function of electron energy and (6) is rewritten

$$n_K(\text{direct}) = -R\int_{E_K}^{E_0} \frac{N\rho}{A} Q_K \frac{ds}{dE}\,dE \qquad \ldots\ldots(7)$$

to facilitate integration.

§ 5. IONIZATION CROSS SECTION

Bethe's (1930) non-relativistic formula for total ionization cross section is the starting point for finding a suitable form for Q_K. From Bethe's expression, Mott and Massey (1949) write

$$Q_K = \frac{2\pi e^4}{EE_K}\, b \ln\frac{4E}{B}$$

and conclude

$$B = 1{\cdot}65E_K, \quad b = 0{\cdot}35. \qquad (a)$$

Worthington and Tomlin (1956) point out that this is only true for large U and use for their numerical integrations

$$B = (1{\cdot}65 + 2{\cdot}35\,e^{1-U})E_K, \quad b = 0{\cdot}35 \qquad (b)$$

and for their exact integration the limiting value of B in (b) as U tends to unity with b modified to fit the experimental results at $U=3$:

$$B=4E_{\mathrm{K}},\quad b=0{\cdot}35\times1{\cdot}73. \qquad (c)$$

Three curves of the function $Q_{\mathrm{K}}E_{\mathrm{K}}{}^2$ produced by the substitution of the values (a), (b) and (c) in the Bethe expression for Q_{K} are shown in Fig. 3, where they are compared with the experimental results of Kirkpatrick and Baez (1947) for silver, and of Pockman *et al.* (1947) for nickel. Values from (c) are seen to agree with experiment as well as values from (b) without the complexity of the latter's form which precludes exact integration. For this calculation values (c) are used leading to

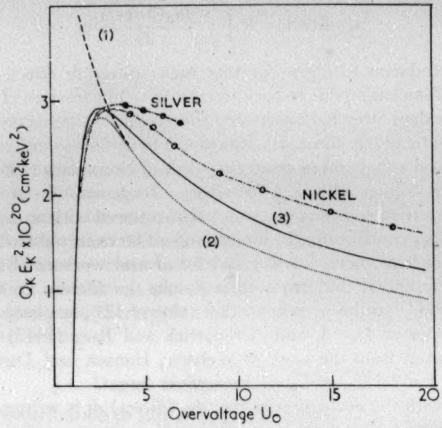

Fig. 3. Comparison of modified forms of the ionization function with experimental values. Curves (1), (2) and (3) are produced by substitution of values (a), (b) and (c) respectively in the Bethe expression for Q_{K}.

$$Q_{\mathrm{K}}E_{\mathrm{K}}{}^2=7{\cdot}92\times10^{-20}\frac{1}{U}\ln U\,(\mathrm{cm}^2\,\mathrm{kev}^2). \qquad \ldots\ldots(8)$$

§ 6. ENERGY LOSS RELATION

Worthington and Tomlin use the Bethe (1930) energy loss relation in their calculations. This leads to a form for n_{K} (direct) involving the logarithmic integral in which the variation of n_{K} with U_0 and E_{K} is not easily deducible without reference to tables†.

---

† Worthington and Tomlin give

$$n_{\mathrm{K}}(\text{direct})=\frac{b}{Z}\left\{(U_0-1)+\frac{J}{4E_{\mathrm{K}}}\left(\ln\frac{2J}{B}\right)\left[\overline{\mathrm{Ei}}\left(\ln\frac{2E_0}{J}\right)-\overline{\mathrm{Ei}}\left(\ln\frac{2E_{\mathrm{K}}}{J}\right)\right]\right\}$$

where B is constant with respect to U. An examination of the integration would suggest that

$$n_{\mathrm{K}}(\text{direct})=\frac{b}{Z}\left\{(U_0-1)+\frac{J}{2E_{\mathrm{K}}}\left(\ln\frac{2J}{B}\right)\left[\overline{\mathrm{Ei}}\left(\ln\frac{2E_0}{J}\right)-\overline{\mathrm{Ei}}\left(\ln\frac{2E_{\mathrm{K}}}{J}\right)\right]\right\}$$

is a more correct form.

In this calculation it is proposed to use the experimental Thomson–Whiddington (Whiddington 1912) energy loss relation in the form

$$E_0{}^2 - E^2 = c\rho x. \qquad \ldots\ldots(9)$$

c is found to vary with E and Table 1 has been compiled from the experimental values of Whiddington (1912), Terrill (1923), Klemperer (1925) and Klemperer, Thetford and Lenz (1960). The latter authors show that the Bethe formula, which is derived from theoretical considerations, predicts greater energy losses for aluminium (and hence larger values of c when expressed in a suitable form) than the experimental values embodied in the Thomson–Whiddington equation.

Table 1. Constant c in Thomson–Whiddington Energy Loss Equation

E (kev)	1	2	5	10	20	50
c (kev^2 cm^2 g^{-1})	$1{\cdot}0 \times 10^5$	$1{\cdot}3 \times 10^5$	$1{\cdot}8 \times 10^5$	$2{\cdot}3 \times 10^5$	$2{\cdot}9 \times 10^5$	$4{\cdot}4 \times 10^5$

For the purposes of this calculation (9) is required as a function of s the electron path length. Substitution of s for x leads to the given values of c being larger than those appropriate to the new form of the relation, as the path length s is always greater than the penetration x of the electrons measured in a direction normal to the surface. Eqn (9) may be written in a differential form, thus

$$\frac{ds}{dE} = -\frac{2E}{c\rho} \qquad \ldots\ldots(10)$$

and combined with (7) and (8)

$$n_{\mathrm{K}}(\text{direct}) = \frac{2RN}{Ac}\int_{E_{\mathrm{K}}}^{E_0} 7{\cdot}92 \times 10^{-20}\,\frac{1}{E_{\mathrm{K}}{}^2 U}(\ln U)\,E\,dE$$

$$= 9{\cdot}535 \times 10^4\,\frac{R}{Ac}\int_1^{U_0} \ln U\,dU.$$

If $\boldsymbol{N} = 6{\cdot}02 \times 10^{23}$

$$n_{\mathrm{K}}\ (\text{direct}) = 9{\cdot}535 \times 10^4\,\frac{R}{Ac}\,[U_0 \ln U_0 - (U_0 - 1)] \qquad \ldots\ldots(11)$$

§ 7. INDIRECT IONIZATION

Let N(cont) be the number of continuous quanta per electron with energies greater than the K ionization energy. Then if it is supposed that the continuous radiation is effectively isotropic and that the origin of the continuous radiation is close to the surface of the target compared with the range of the continuous quanta in the target, $\frac{1}{2}N$(cont) is absorbed in the target. Now if r_{K} is the ratio of the photoelectric absorption coefficient on the high energy side of the K absorption edge to that on the low side, then the fraction of absorptions which cause K shell ionization is $(r_{\mathrm{K}} - 1)/r_{\mathrm{K}}$. It follows that

$$n_{\mathrm{K}}(\text{indirect}) = \tfrac{1}{2}N(\text{cont})\,\frac{r_{\mathrm{K}} - 1}{r_{\mathrm{K}}}. \qquad \ldots\ldots(12)$$

Dyson (1959) shows that to a close approximation the energy distribution in the continuous radiation may be written

$I_{\mathrm{E}} = 2{\cdot}76 \times 10^{-6} Z(E_0 - E)$ (kev per electron per kev energy interval).

Following the method of Dyson (1956) the number of continuous quanta between E and $E+dE$ is

$$dN_E = 2{\cdot}76\times10^{-6}Z\,\frac{(E_0-E)}{E}\,dE$$

and the number of quanta $E > E_K$ is

$$N(\text{cont}) = 2{\cdot}76\times10^{-6}Z\int_{E_K}^{E_0}\left(\frac{E_0}{E}-1\right)dE$$
$$= 2{\cdot}76\times10^{-6}ZE_K[U_0 \ln U_0-(U_0-1)].$$

Writing $(r_K-1)/r_K = 0{\cdot}85$ for all Z involves an error of less than 5% for $30 < Z < 80$, and below $Z = 30$ indirect production is unimportant. Further, $E_K = 1{\cdot}263\times10^{-2}(Z-2)^2$ kev with little error. Substituting these values in (12), if follows that

$$n_K(\text{indirect}) = 1{\cdot}46\times10^{-8}(Z-2)^2Z[U_0 \ln U_0-(U_0-1)]. \quad \ldots\ldots(13)$$

§ 8. RATIO OF INDIRECT TO DIRECT PRODUCTION

From Eqns (11) and (13) it follows immediately that the ratio of indirectly to directly produced K quanta for a particular value of Z is dependent only on c/R, a very slowly varying function of U_0. This ratio, following Kirkpatrick and Baez's definition, is $1/P$.

$$\frac{1}{P} = 1{\cdot}62\times10^{-13}(Z-2)^2Z\,\frac{Ac}{R};$$

approximating further,

$$\frac{1}{P} = 3{\cdot}24\times10^{-13}Z^4\,\frac{c}{R}. \quad \ldots\ldots(14)$$

Agreement with experiment both in the magnitudes of the quantities and their relative independence of U_0 is shown in Table 2 giving values of $1/(1+P)$, the ratio of indirect to total production.

Table 2. Ratio of Indirect to Total Production

Atomic No.	Element	Theory	Experiment
6	Carbon	0·004%	
13	Aluminium	0·02%	
30	Zinc	7%	6% ($U_0 = 2{\cdot}0$) (1)
47	Silver	44%	35% ($U_0 = 1{\cdot}5$); 33% ($U_0 = 5$) (2)
79	Gold	89%	82% ($U_0 = 1{\cdot}5$); 78% ($U_0 = 2{\cdot}5$) (3)

(1) Castaing (1955); (2) Webster (1928); (3) Stoddard (1935).

Taking values of c smaller than those tabulated, as has been previously suggested would be appropriate, would bring $1/(1+P)$ more closely in agreement with the experimental values.

§ 9. TOTAL K QUANTA PRODUCTION

The substitution of (11) and (13) in (4) gives

$$\frac{N_K}{4\pi} = \frac{\omega_K}{4\pi}\left(9{\cdot}54\times10^4\,\frac{R}{Ac}+1{\cdot}46\times10^{-8}(Z-2)^2Z\right)[U_0 \ln U_0-(U_0-1)] \quad \ldots\ldots(15)$$

total K quanta per electron per unit solid angle. Duncumb (1957) showed that a function of the form $[U_0 \ln U_0 - (U_0 - 1)]$ may be expressed as a power of $U_0 - 1$. For the present calculation $[U_0 \ln U_0 - (U_0 - 1)]$ is written as $0{\cdot}365(U_0 - 1)^{1{\cdot}67}$ with an error of less than 10% for $1{\cdot}5 < U_0 < 16$; then

$$\frac{N_{\mathrm{K}}}{4\pi} = \omega_{\mathrm{K}} \left(2{\cdot}80 \times 10^3 \frac{R}{Ac} + 4{\cdot}27 \times 10^{-10} (Z-2)^2 Z \right) [U_0 - 1]^{1{\cdot}67}. \qquad \ldots\ldots(16)$$

Experimental work referred to by Compton and Allison (1935) has yielded values of the power of $U_0 - 1$ of 1·6–1·7, where absorption is unimportant, and this is confirmed by the authors' work.

In Table 3 values are calculated from (16) and compared with five experimental values available for K quanta production in thick targets at large values of ϕ where absorption is less than 10%. The values of ω_{K} are calculated from the semi-empirical equation of Laberrigue–Frolow and Radvanyi (1956)

$$\omega_{\mathrm{K}} = \frac{(A + BZ + CZ^3)^4}{1 + (A + BZ + CZ^3)^4}$$

where

$$A = -0{\cdot}0217, \quad B = 0{\cdot}03318, \quad C = -1{\cdot}14 \times 10^{-6}.$$

R for aluminium is an estimated value.

Table 3. Total K Quanta per Electron per Unit Solid Angle

Element	Z	ω_{K}	E(kev)	U_0	c(kev² cm² g⁻¹)	R	$N_{\mathrm{K}}/4\pi$ Theory	$N_{\mathrm{K}}/4\pi$ Experiment
Carbon	6	1×10^{-3}	0·849	3	$0{\cdot}8 \times 10^5$	1	$9{\cdot}3 \times 10^{-6}$	$16{\cdot}3 \times 10^{-6}$ (1)
Aluminium	13	0·0267	4·68	3	$1{\cdot}6 \times 10^5$	0·95	$5{\cdot}2 \times 10^{-5}$	$5{\cdot}7 \times 10^{-5}$ (1)
Copper	29	0·425	27·0	3	$2{\cdot}8 \times 10^5$	0·88	$2{\cdot}0 \times 10^{-4}$	$2{\cdot}2 \times 10^{-4}$ (2)
Silver	47	0·810	51·0	2	$4{\cdot}0 \times 10^5$	0·81	$7{\cdot}5 \times 10^{-5}$	$6{\cdot}4 \times 10^{-5}$ (2) $6{\cdot}3 \times 10^{-5}$ (3)

(1) Dolby (1960); (2) Authors (unpublished); (3) Kirkpatrick and Baez (1947).

Figure 4 shows values of $N_{\mathrm{K}}/4\pi$ plotted against Z at $U_0 = 3$. The indirect component which increases rapidly with Z is produced at greater depths in the target than the direct component of the K radiation. Consequently it suffers more absorption and for values of Z greater than 40 at $U_0 = 3$ the condition that the target self-absorption is less than 10% is not satisfied.

§ 10. CONCLUSION

Agreement between theory and experiment may be regarded as satisfactory when consideration is given to the following factors:

(i) The value of c is an uncertain quantity, particularly for elements of lower atomic numbers at small electron energies. The validity of the Thomson–Whiddington form of the energy loss relation is also uncertain at low energies.

(ii) The K ionization cross section values are based by extrapolation on only two actual measurements, both on elements of large atomic number compared with aluminium and carbon.

(iii) The experimental values are few in number and little checking by different workers making similar measurements has been carried out.

(iv) Values of ω_K for aluminium and carbon have not been checked experimentally and may be considerably in error.

(v) In the development of the theory, certain approximations have been made.

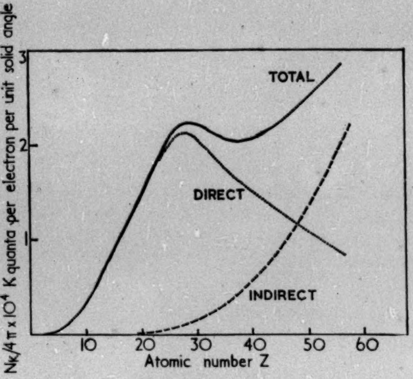

Fig. 4. K quanta per electron per unit solid angle at $U_0 = 3$.

A Search for Vibrational Energy Effects in the Dissociation of H_2^+ Ions by Hydrogen Gas

By A. C. RIVIERE and D. R. SWEETMAN
Atomic Weapons Research Establishment, Aldermaston, Berks.

MS. received 23rd June 1961

Abstract. The dissociation cross section on interaction with hydrogen gas was measured for H_2^+ ions with energies between 280 and 670 kev and with both high and low vibrational excitation. An increase of 7 ± 4% was found for the cross section for simple dissociation in the case of the more highly vibrationally excited ions. For dissociation into two protons the difference between the cross sections was certainly less.

Riviere and Sweetman (1960) have found that the uppermost vibrational levels ($v=17$, 18) of H_2^+ are about five times more populated when the ion is formed by the break-up of an H_3^+ ion than when formed by electron collision in an ion source. Though the results referred to only 0·3 per cent of all the ions, this increased population of the uppermost levels almost certainly corresponds to a higher average excitation. The equilibrium separation of the nuclei in the H_3^+ ion is 1·79 Å (Hirschfelder 1938), and this is considerably greater than the ground state separation of the H_2^+ ion of 1·06 Å. Presumably the H_2^+ ion is highly vibrationally excited when formed from H_3^+ at this wide nuclear separation. The absorption cross section for photons by H_2^+ ions calculated by Buckingham, Reid and Spence (1952) would suggest that the cross section for dissociation of H_2^+ ions by gases might depend on the degree of vibrational excitation, and this has been suggested as a possible explanation of the discrepancies between different workers for the value of the latter cross section. The discrepancies may well have a less fundamental experimental origin, but the importance of vibrational excitation has not been established.

For these reasons the dissociation cross section was measured for H_2^+ ions with both high and low vibrational excitation on interaction with hydrogen gas and with energies between 280 and 670 kev.

The equipment and method were identical with those used by Sweetman (1960). In making the comparison it was necessary to ensure that at each energy point the H_2^+ ions of both high and low vibrational excitation were of the same energy. For H_2^+ direct from the source the 3 Mev Van de Graaff was set to a voltage E_0 and the ions were selected by a bending magnet whose field was set to a value H_0. The magnet current was stabilized to 1 part in 10^4 and the field measured by a proton resonance technique. The accelerator was stabilized against the field value by means of a conventional slit system beyond the magnet. Two methods were used to obtain H_2^+ ions of the same energy E ev but which arose from the break-up of accelerated H_3^+ ions. Firstly, a machine voltage of $\frac{3}{2}E_0$ and magnetic field of $\frac{3}{2}H_0$ were set so that H_3^+ ions were selected by the magnet and the H_2^+

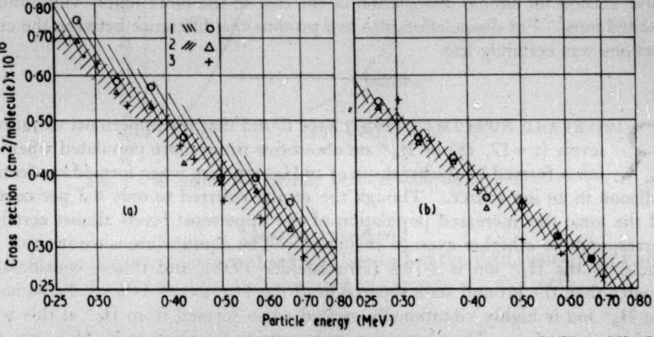
ions were obtained by the break-up of H_3^+ in the drift tube to the apparatus. Secondly, a machine voltage of $\frac{2}{3}E_0$ and magnetic field of H_0 were used so that H_2^+ ions were selected which arose from the break-up of H_3^+ ions before the magnet. No difference was observed between these systems in the results but the second method was preferred since the magnetic field was not changed between measurements. At each energy point a cycle of measurements was made by passing from one type of ion to the other and back. The results are shown in the figure for the processes

$$H_2^+ \rightarrow H^0 + H^+ \qquad \ldots\ldots(1)$$

and

$$H_2^+ \rightarrow H^+ + H^+ \qquad \ldots\ldots(2)$$

respectively. The results obtained by Sweetman (1960) for H_2^+ ions direct from the source are also shown. A least squares analysis was carried out for



The cross section for dissociation of H_2^+ ions in hydrogen for the processes (*a*) $H_2^+ \rightarrow H^0 + H^+$ and (*b*) $H_2^+ \rightarrow H^+ + H^+$. 1, H_2^+ ions obtained from the break-up of H_3^+ ions; 2, H_2^+ ions obtained direct from the ion source; 3, results of Sweetman (1960) for H_2^+ ions direct from the ion source. Shading indicates region covered by least squares analysis of experimental points.

processes (1) and (2) and for the ions of both low and high vibrational excitation by assuming that the cross section obeyed the law $\sigma = aE^{-b}$. For process (1) the results were

$$\sigma(H_2^+ \text{ direct}) \quad = (15{\cdot}6 \pm 0{\cdot}7)E^{-(0{\cdot}84 \pm 0{\cdot}05)} \times 10^{-17}\ \text{cm}^2$$

and

$$\sigma(H_2^+ \text{ from } H_3^+) = (16{\cdot}8 \pm 0{\cdot}9)E^{-(0{\cdot}84 \pm 0{\cdot}04)} \times 10^{-17}\ \text{cm}^2$$

where E is in units of 10^5 ev.

For process (2) the results were

$$\sigma(H_2^+ \text{ direct}) \quad = (10{\cdot}5 \pm 0{\cdot}4)E^{-(0{\cdot}69 \pm 0{\cdot}03)} \times 10^{-17}\ \text{cm}^2$$

and

$$\sigma(H_2^+ \text{ from } H_3^+) = (11{\cdot}3 \pm 0{\cdot}3)E^{-(0{\cdot}73 \pm 0{\cdot}02)} \times 10^{-17}\ \text{cm}^2.$$

The shaded areas on the figure indicate the regions covered by the results of the least squares analysis.

For process (1) the energy exponents are the same and a direct comparison shows that the cross section for the more highly vibrationally excited ions is 7 ± 4% greater than that for the other type of ion. For process (2) however this comparison cannot be made but the difference is certainly less than that for process (1) in the energy range considered. This result could be expected since the energy gap for process (2) of ionization and dissociation is about 13·6 ev greater than that for process (1) if formation of H^0 in excited states is neglected.

The cross section for the dissociation of H_2^+ ions by hydrogen certainly appears to be insensitive to the degree of vibrational excitation, and differences in the degree of excitation cannot account for the discrepancies between the results of different workers.

ACKNOWLEDGMENT

The authors wish to acknowledge the assistance of Mr. D. Coleby in carrying out the observations.

Abstract. The critical supersaturation for the precipitation of water droplets or ice crystals from the vapour was measured between 0°c and −75°c by an expansion-chamber technique. Nitrogen was used as the carrier gas, and measurements were made both in the presence and in the absence of an electric field. The temperature dependence of critical supersaturation was found to be the same in both situations. Thus existing critical supersaturation data for nucleation of water droplets from the vapour in the presence of an electric field probably represent heterogeneous nucleation on ions. Comparison of the data taken in the presence of a field with the Becker–Döring equation for homogeneous nucleation shows fair agreement at the higher temperatures but marked negative deviation at lower temperatures. The precipitate particles appeared to be spherical above −65°c, while at lower temperatures precipitation was in the form of ideomorphic ice crystals.

---

§ 1. Introduction

THE rate equation for homogeneous nucleation of droplets from a supersaturated vapour has been derived by Becker and Döring (1935) and by Zeldovich (1942)

$$J=\left(\frac{2\gamma vN^3}{\pi}\right)^{1/2}\left(\frac{p}{kT}\right)^2\exp\left\{\frac{-16\pi v^2\gamma^2}{3kT[RT\ln(p/p_0)]^2}\right\} \qquad \ldots\ldots(1)$$

where v is the molar volume of the liquid, N Avogadro's number, p partial pressure of vapour at supersaturation, p_0 equilibrium vapour pressure and R the gas constant. Inasmuch as the liquid–vapour interface is the only one whose specific free energy γ can be measured directly and accurately, experiments on the nucleation of droplets from vapour provide the best check of nucleation theory (Volmer 1945). It is well known that there is remarkable agreement between critical supersaturations[¶] calculated from Eqn (1) and the measurements of Volmer and Flood (1934) on water vapour and a number of organic vapours. In the case of water vapour at 0°c, the critical supersaturation for homogeneous nucleation of droplets is given as 4·2. However, there are reasons to doubt the correctness of this interpretation of the Volmer and Flood results. These

[¶] Critical supersaturation is defined as the value of p/p_0 required for appreciable nucleation rate of droplets, a rate of the order of one per cm³ sec.

results are inconsistent with the work of C. T. R. Wilson (1897) and Powell (1928) on water vapour in air. Wilson found that for a terminal temperature of about 0°c the critical supersaturation ratio is 4·2 in the presence of negative ions and about 6 in the presence of positive ions alone. These 'ion limits' were characterized by 'rain-like' condensation, i.e. the concentration of droplets produced was not high and of the order of magnitude of the concentration of ions in the air. He considered that homogeneous nucleation did not occur until the 'fog limit' was reached at a supersaturation of about 8 where a very dense fog of tiny droplets was produced. Wilson did not actually try to measure the critical supersaturation for homogeneous nucleation in the presence of a strong electric field. However, it is difficult to see how he could observe the positive-ion limit (sixfold supersaturation) if it were not below the critical supersaturation) for homogeneous nucleation. Further, the present interpretation of Volmer and Flood's results is questionable from a theoretical point of view. There is serious doubt that the macroscopic thermodynamic concepts of surface tension and free energy can be applied to aggregates as small as 100 molecules (Farley 1952, Reiss 1950). Accordingly, it was decided to measure the critical supersaturation of water vapour in very pure nitrogen in the presence of an electric field over a wide range of temperatures and compare the results with the predictions of the Becker–Döring equation. Such a study was undertaken by Sander and Damköhler (1943), but their results at room temperature were sufficiently different from Volmer and Flood's to be considered not entirely conclusive.

§ 2. Experimental Procedures

A full description of the apparatus and its operation has been presented in a previous publication by Madonna (1957). Briefly, gas was purified, humidified and collected in the cloud chamber, which was maintained at a constant low temperature (10°c to −80°c). The cloud chamber was connected by means of a large valve to a vacuum reservoir system. When the valve was suddenly opened, adiabatic expansion of the gas caused a reduction in temperature which produced a supersaturation of the vapour given by

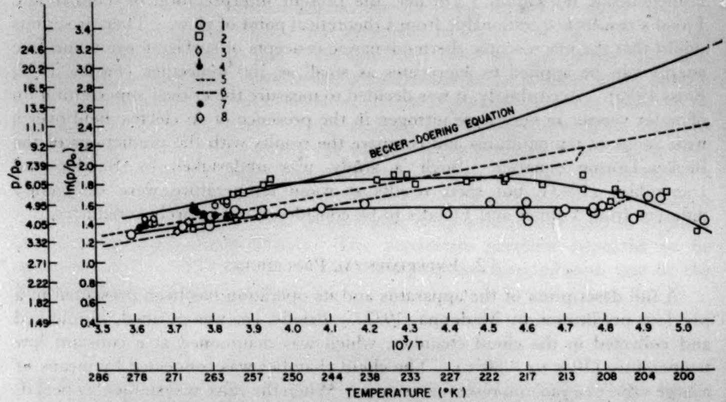
$$S=p/p_0=p_1P_2/p_0P_1, \qquad \ldots\ldots(2)$$

where p_1 is the partial pressure of vapour prior to expansion and P_1 and P_2 are the initial and final total pressures respectively. That supersaturation which was just sufficient to cause visually observable precipitation was recorded as the critical supersaturation.

The assumption of reversibility and adiabaticity of moderate expansions at ordinary temperatures has been carefully checked by a number of workers (Makower 1903, Sander and Damköhler 1943, Volmer and Flood 1934) and found to be correct within the precision of measurement. However, the present results were checked at both high and low temperatures by varying the conditions of expansion. Changing the size of the vacuum reservoir, cloud-chamber volume and bore of the expansion stopcock did not affect the results. Equilibrium saturation of the carrier gas with water vapour was checked and carefully controlled. The assumption of thermal equilibrium with the thermostat was also checked by means of a thermocouple in a 'dummy' cloud chamber. The presence of a small amount of condensate in the bottom of the cloud chamber and the humidity of the gas in the reservoir had no effect on the results.

§ 3. Discussion of Results

All of the critical supersaturation data for water vapour obtained in the present work are presented in the Figure, together with the data of Volmer and Flood (1934) and Sander and Damköhler (1943) who used air as the carrier gas. It is seen that there is fair agreement between the present data and those of Volmer and Flood at higher terminal temperatures (around 0°c) regardless of the carrier gas used. However, the data of Sander and Damköhler are appreciably lower at these higher temperatures. Also, over the temperature range down to about −65°c, their gap between critical supersaturations with and without a field is only about $\frac{1}{3}$ of that found in the present work (approximately 1·3). Further, it is seen that there is considerable disagreement of the present data with the results of Sander and Damköhler at low temperatures. This discrepancy cannot be attributed to foreign nuclei, because the ion limits disagree in the same way as do the data taken with an electric field. Accordingly, some difference in technique must be responsible. The writers are not prepared to say that their work is correct and that the other work is wrong. However, some experimental effort was made to resolve the difference. It was considered that their smaller chamber (0·7 l.) might not have been as adiabatic with respect to heat transfer through the vacuum stopcock from the warm room as the 2-litre chamber used in the present work. Accordingly, an apparatus similar to theirs was constructed and tried at low temperatures using nitrogen as the carrier in the absence of a field. This smaller apparatus gave an apparent ion limit which was almost as high as that reported by Sander and Damköhler. Therefore, it is possible that their apparatus was not adiabatic at low temperatures. Possibly the chamber used in the present work



Assembled critical supersaturation data for water vapour including Madonna–Sciulli–Canjar–Pound data using N_2 carrier gas. 1, Madonna–Sciulli–Canjar–Pound, without field, N_2; 2, Madonna–Sciulli–Canjar–Pound, with field, N_2; 3, Madonna–Sciulli–Canjar–Pound, without field, O_2; 4, Madonna–Sciulli–Canjar–Pound, with field, O_2; 5, Sander–Damköhler, with field, air; 6, Sander–Damköhler, without field, air; 7, Volmer–Flood, without field, air; 8, Volmer–Flood, with field, air.

was not entirely adiabatic at low temperatures either. However, this possibility does not affect the general conclusions to be drawn from the present investigation.

The authors feel that the most significant result from both sets of data is that the temperature dependence of critical supersaturation is about the same with or without a field. Although the critical supersaturation for nucleation of droplets on ions has not yet been calculated from theory (Volmer 1945), it seems evident that the temperature dependence should be less than for homogeneous nucleation. Accordingly, one would conclude that the most reasonable explanation of the observations is that nucleation is catalyzed by residual ions even in the presence of an electric field, the higher critical supersaturation being due to a lower ion concentration.

In order to test the applicability of the Becker–Döring equation (1) for homogeneous nucleation to the data taken in the presence of a field, theoretically calculated values of critical supersaturation are included in the plot of the Figure. It is seen that there is fair agreement at the higher temperatures but wide divergence at lower temperatures where the calculated values are much higher than those observed. Also, it is evident that the predicted temperature dependence of critical supersaturation for homogeneous nucleation is much higher than that observed. Again, this indicates that the nucleation in the presence of a field was heterogeneous.

In another test of the applicability of homogeneous nucleation theory to the data taken with a field, the specific interfacial free energy was computed from the Becker–Döring equation and the present data. It was found that calculated and measured surface free energies are in fair agreement at the higher temperatures but that there is considerable deviation at lower temperatures. Further, the temperature dependence suggests that the agreement at higher temperatures is fortuitous. Finally, it should be emphasized that the present data, or any other data which represent heterogeneous nucleation on ions, constitute no test of the Becker–Döring equation.

Until a terminal temperature of about -65°c was reached, the precipitate appeared to be in the form of droplets. This does not necessarily mean that they were liquid, because critical supercooling experiments recently conducted on pure water droplets indicated that these 'droplets' may have been frozen to ice balls for terminal temperatures below -41°c (Schaefer 1952). At about -65°c, the appearance of the precipitate exhibited a striking change. A cloud of flickering ice crystals was obtained directly on expansion to all lower terminal temperatures. The scatter of the present data below -65°c (see Figure) is too great to confirm or deny the results of Sander and Damköhler, namely that the effect of the electric field disappears and the slope of the curve increases abruptly at -65°c. However, the present authors are inclined to agree with the conclusion of Sander and Damköhler that the direct nucleation of ice crystals from vapour occurs below terminal temperaures of about -65°c.

§ 4. CONCLUSIONS

1. Existing critical supersaturation data for nucleation of water droplets from the vapour in the presence of an electric field probably represent heterogeneous nucleation on ions.

2. The Becker–Döring equation describes the present data taken in the presence of an electric field using nitrogen as the carrier gas fairly well at the

higher temperatures (−10°c), but there are wide deviations at low temperatures. Further, the temperature dependence suggests a fortuitous agreement at the higher temperatures. However, it is emphasized that the present data, or any other data (including the Volmer and Flood data on water) which represent heterogeneous nucleation on ions, constitute no test of the Becker–Döring equation.

3. In the present work, direct nucleation of ice crystals from the vapour began at −65°c.

Vacuum Ultra-violet Spectra of Multiply Ionized Inert Gases

BY B. C. FAWCETT, B. B. JONES AND R. WILSON
Atomic Energy Research Establishment, Harwell

MS. received 29th May 1961

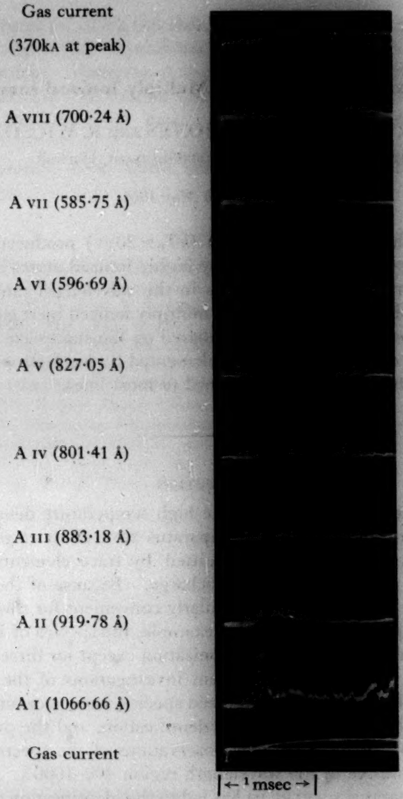
Abstract. The high temperature plasma ($kT_e \simeq 20$ ev) produced in ZETA is a copious source of spectral lines emitted by highly ionized atoms in the vacuum ultra-violet. Spectroscopic investigations in the wavelength range 400–1000 Å have revealed several new lines due to the multiply ionized inert gases Ne, A, Kr and Xe. The method of identification is based on the successive appearance of the ionization states of each element, supplemented by isoelectronic calculations which also allowed transitions to be assigned to most lines.

§ 1. INTRODUCTION

ONE of the methods of studying the high temperature deuterium plasma produced in the experimental apparatus ZETA (Butt *et al.* 1958) is the observation of spectral lines emitted by trace elements, deliberately introduced in small quantities into the discharge. Because of their availability in gaseous form, the inert gases are particularly convenient for this purpose, but knowledge of their spectra is limited; for example, the spectra of Kr and Xe are undocumented above the fourth stage of ionization except for three lines of Kr IX in the 100 Å region (Moore 1952). Recent investigations of the ZETA plasma, requiring the use of lines from highly ionized species, have necessitated a limited approach to the problem of spectral line identification, and the purpose of this communication is to present some new observations of the spectra of multiply ionized Ne, A, Kr and Xe in the wavelength region 400–1000 Å. Work on the similar discharge apparatus SCEPTRE III has led to the identification of lines due to Ne IV, V, VI and F VI in the quartz ultra-violet (Kaufman *et al.* 1960).

§ 2. METHOD

The line identifications were made as follows. Using a 3-metre normal incidence vacuum spectrograph, having a reciprocal linear dispersion of 2·78 Å mm^{-1} and an aperture of f/30, a photograph of the ZETA spectrum was obtained for a discharge in deuterium. This was repeated after the introduction of a small quantity ($\simeq 5\%$) of the inert gas to be studied, and the additional lines observed were then assigned to this element. Typically, 200 discharges are required to give a well exposed spectrogram on Ilford Q2 emulsion. Wavelength values were obtained from the spectrograms, and each line was then monitored during the discharge period using a 1-metre normal incidence vacuum monochromator, equipped with photoelectric recording, giving the variation of spectral line intensity with time. Previous work by Burton and Wilson (1961) has led to a clear interpretation of this type of observation, and has shown that



Temporal variation of the intensities of spectral lines due to A I to A VIII inclusive showing the successive appearance of the ionization states in the ZETA plasma. The argon is introduced as a 5% impurity in deuterium with a total gas pressure of 0·5 millitorr.

for a given element the ascending stages of ionization appear in successive time sequence. This is illustrated by the Figure which reproduces oscillograms of the intensity variations of eight lines due to A I to A VIII inclusive, together with the current waveform. The oscillograms are aligned on a common time scale by means of a timing signal, indicated by arrows and derived from the ZETA firing circuit. Observations of this type enable the spectral lines of the element being studied to be assigned to its various stages of ionization.

By extrapolation along isoelectronic sequences, wavelengths were calculated for several lines of each element expected to appear in the observed region. Comparison between calculated and observed values provided confirmation of the identifications made on the basis of time of appearance, and also allowed the line transitions to be determined.

Newly observed lines of multiply ionized inert gases in the wavelength range 400–1000 Å.

†These lines are tabulated by Paul and Polster (1941). They are included here because the present observations give significantly different wavelengths.

‡ Blend with Ne VI. Calculated wavelength.

§ 3. RESULTS

The results are shown in the Table. The successive columns give, respectively, the element and degree of ionization, the observed vacuum wavelength, an estimate of the line intensity, and the transition when known. The wavelengths were measured by normal methods, using as standards some of the lines of Ne IV, V and VI previously observed in this region by Paul and Polster (1941) and Boyce (1934). A trace of neon was maintained in the discharge when making measurements of lines due to argon, krypton and xenon. The accuracy of the wavelength values is limited by the shortage of suitable standards and the large Doppler widths of the lines, the latter being caused by the high energies attained by ions in ZETA, of the order of a few hundred electron volts. The probable error of wavelength measurement is estimated to be ± 0·03 Å.

The line intensities were obtained directly from the photographic plates with no attempt to correct for variations of emulsion sensitivity or instrumental transmission with wavelength. They are included only as a guide and are on a linear scale with the strongest tabulated line for each element given arbitrarily as ten. The values give only an approximate indication of the relative intensities of lines of the same element.

Transitions are not tabulated for all lines given in the Table. In some cases either the isoelectronic data was insufficient to establish the identity of the line, or ambiguity occurred due to overlapping of possible multiplets. In two cases, the isoelectronic data predicted the observed wavelength sufficiently accurately but corresponding lines of the same multiplet, expected to be faint, could not be identified. There is therefore some doubt about the classifications in question and they have been bracketed in the table.

The data given in the table are not meant to represent an exhaustive survey of the spectra of the inert gases in the range 400–1000 Å, and a more complete survey, covering a wider spectral range, may be attempted later. However, the observations are believed to be the first made in the laboratory, although the Ne VIII resonance doublet has been detected in the solar spectrum obtained from rocket flights. (Friedman 1960).

ACKNOWLEDGMENTS

We are grateful for the co-operation of the ZETA Operations Team and the assistance of Mr. R. H. White. The work has benefited from discussions with Mr. W. M. Burton.

Magnetic Resonance in the Nitrogen Afterglow

By J. M. ANDERSON and J. N. BARRY†

Department of Physics, University of Toronto, Toronto, Canada

MS. received 17th June 1960, in revised form 5th April 1961

Abstract. The decay of a magnetic resonance absorption in the nitrogen after glow has been followed and compared with the decay of the afterglow itself. Afterglow was never, in any case, obtained without the presence of this absorption and vice versa. Simultaneous records of the two quantities showed that in all cases the absorption disappeared logarithmically at a rate which did not increase with nitrogen pressure while the afterglow intensity decayed according to an $I^{-1/2}$ law in a somewhat longer time. The rates of both processes are increased by addition of oxygen. The processes involved seem quite independent.

§ 1. Introduction

Previous papers (Anderson, Kavadas and McKay 1957, Anderson 1957) have shown that, in the earlier part of the decay of the nitrogen afterglow, the intensity falls off so that $I^{-1/2}$ is linear in time. It was also shown that small percentages of oxygen are necessary for the appearance of this initial decay and that an excitation energy of 900 cm^{-1} must be supplied in the final afterglow collision. The later stages of the afterglow in oxygen-free nitrogen were found to be due to a bimolecular process involving a nitrogen particle in a complex with an impurity presumed to be hydrogen. This complex had a dissociation energy of 5600 cm^{-1} and could show a final logarithmic decay.

In this work a magnetic resonance absorption was studied simultaneously with measurements of decay of the afterglow intensity.

§ 2. Apparatus

Since simultaneous measurements on afterglow intensity and absorption were required, the magnetic resonance measurements were made in the 10 cm microwave band rather than in the more usual 3 cm band. The lower frequency permitted larger volumes and hence greater afterglow intensities, but also required a larger volume of magnetic field sufficiently uniform to allow magnetic resonance at the same frequency at any point in the glowing gas. To fulfil this requirement a special magnet was constructed giving a field uniform to better than one part in 2000 over a cylindrical volume 4 cm in diameter by 6 cm long. The general design principles used were those described by Daniels (1950).

A block diagram of the apparatus is shown in Fig. 1. The cylindrical microwave cavity was excited in the H_{112} mode by a 707 A/B klystron for the magnetic resonance measurements. A periodic saw-tooth frequency modulation carried the frequency of this source through the cavity resonance frequency with which the magnetic resonance absorption frequency was made to coincide by magnetic field adjustments. The cavity with no excitation of the nitrogen was adjusted to be very slightly undercoupled to the 50 ohm coaxial feed line, so that the reflected output of the klystron, studied through the directional coupler, showed a dip almost to zero reflection at the resonance frequency. Using the crystal detector calibration and the amplitude reflected by the cavity at the resonance frequency when completely mismatched, the reflection coefficient of the cavity could be found, not only for the cavity with unexcited gas but also with any degree of added losses due to energy absorption at any time following a discharge. The patterns were photographed using a Tektronix 532 oscilloscope with a dual trace amplifier, type 53/54C using no timebase but a modified Cossor moving film camera as in the previous work. Using the usual equivalent circuit relations it is easily shown that the number of absorbing centres A is proportional to $(\bar{Y}-\bar{Y}_0)/(1-\bar{Y})$ where $\bar{Y}$ and $\bar{Y}_0$ are amplitude reflection coefficients at the cavity resonance frequency with and without the presence of added losses.

Fig. 1. Block diagram of apparatus.

The nitrogen gas was contained in a cyclindrical quartz vessel 4·5 cm long and 4 cm in diameter. Losses due to the quartz were so small that Q's above 10^4 were measured for the cavity with no gas excitation. Attempts were made to excite the nitrogen using a pulsed magnetron (100 kw peak) operating in the E_{010} mode of the cavity. This successfully avoided interference in the klystron mode but completely failed to produce active nitrogen. Rather weak glow discharges in the bottle were easily obtained but all attempts to increase the power fed to the cavity to increase the excitation were complete failures. It is suspected that increase in ionization so disturbed the field distributions in the cavity that complete mismatch occurred for the greater part of each pulse. Since this was unsuccessful, tungsten electrodes were inserted in the glass vacuum system well outside the cavity in opposite directions and afterglow was easily excited using the two-microsecond 175 A d.c. pulses from the magnetron supply. Use of electrodes unfortunately made it impossible to assess accurately the purity of the gas and prevented use of the prolonged conditioning found essential in the previous work for exact quantitative study of impurities.

The nitrogen gas as before was prepared by the bromine ammonia method and purified by passage over phosphorus pentoxide, hot copper and sodium. It was impossible to flame the quartz tube in its microwave cavity and purity in this work never reached the levels of the earlier paper. Gas which gave intense but very short afterglows with the radar pulse excitation has been found to show no glow with the continuous wave excitation previously used until much more drastic purification procedures are applied.

The afterglow intensity was followed using a 931A photomultiplier tube as in the earlier work. Light reached this tube which was placed well outside the magnetic field through a light guide made of Pyrex glass tubing wrapped in aluminium foil. This light guide was set in a position to view the afterglow obliquely across the cavity to be sure that only gas in a position to give magnetic resonance could contribute to the afterglow record. With these arrangements it was not possible to follow the glow to nearly such low intensities as in the previous work.

It was found that in the presence of the electrodes the composition of the gas with oxygen impurity added changed rapidly and attained an equilibrium value only after a very large number of discharge pulses. Measurements taken in this equilibrium condition were quite repeatable but the actual behaviour depended somewhat on the previous history of the tube. Measurements at different impurity concentrations were attempted both by adding to the quartz vessel known volumes and pressures of a suitable mixture of oxygen and nitrogen and taking a record after the practical minimum of three discharge pulses and by using a larger number of discharges in each case. The two methods gave results which showed similar behaviour with added oxygen. Duration constants differed by as much as 15% depending on treatment of the tube preceding the readings. Since it was impossible in this case to carry out the prolonged periods of conditioning, found in the earlier work to be essential for obtaining consistent quantitative agreement, the impurity percentages quoted are at best qualitative estimates in which actual impurity content increases monotonically with addition of oxygen but has otherwise little relation to it.

Several sets of measurements made at different times were found to be in close agreement. Due to the presence of the electrodes and the impossibility of proper outgassing procedures the absolute impurity level is quite uncertain but the results serve to establish the trend of the effects with change in molecular nitrogen population.

Measurements of width and exact frequency of the magnetic resonance line were carried out using a small a.c. modulation superposed on the steady magnetic field by a single layer solenoid surrounding the cavity. A phase-sensitive detector was used to measure the energy transmitted by the cavity and hence it was possible to obtain a measure of the first derivative of the absorption with change of field. The line widths were found to be about ten to twelve gauss at the pressures used. They were independent of the strength of the absorption. The centre of the absorption was found to occur at $2{\cdot}9087 \times 10^9$ c/s at a field in which the proton nuclear magnetic resonance frequency was $4{\cdot}4192 \times 10^6$ c/s. The quotient of these results is 658·19 which differs from the much more accurate result 658·1631 of Heald and Beringer (1954) for the nitrogen atom by rather less than our expected reading error. It corresponds equally well with the cyclotron resonance of the free electron.

§ 3. PROCEDURE

Each series of measurements was taken after a preliminary period in which all excitation and sweep procedures were carried out automatically and cyclically while the magnetic field was adjusted so that the microwave absorption frequency coincided with the cavity resonance. This was easily done by watching the oscilloscope pattern of the reflection from the cavity with the time base on. When the field was either too low or too high the absorption dip in the reflected wave was slightly displaced relative to the position on the time base occupied by the dip with no absorption present. The field was easily adjusted so that the dip came at precisely the same point with and without previous excitation of the gas.

Gas conditions were then adjusted for the series desired, the intensity measuring equipment and its gating circuit were checked, the camera film was started, and the cavity completely mismatched to record a reflected wave corresponding to unit reflection coefficient. After a chosen pulse of excitation the excitation pulses were cut off and records of resonance absorption and intensity allowed to run until both effects had completely disappeared. This last part of the magnetic resonance record was used to give the necessary measure of $\bar{Y}_0$ the reflection coefficient of the cavity with no absorption due to the gas.

In the measurements with impurity added this procedure was varied in two different ways. In the first of these preliminary adjustments were made as above, impurity was added and given time to mix thoroughly, the film was started and after the third discharge pulse recording was carried out as before, more impurity was added and again following the third pulse the record was made, and so forth. In the second method impurity was added and the record made as before but before the next impurity addition twenty discharge pulses were allowed to pass in an attempt to condition the gas.

It was found possible to excite very much more intense afterglows and absorption after prolonged excitation at 20 pulses per second than was obtainable after each regular pulse in the 2 c/s sequence. The rapid repetition rate caused complications with the automatic gating of the photomultipler so that it was not feasible to get simultaneous recordings of the afterglow intensity. A few measurements were taken of the decay of absorption alone to check the law of decay over a wider range than was possible with the simultaneous measurements.

§ 4. RESULTS

In every case in which afterglow was observed, absorption was also found, and absorption was never found in this work without accompanying afterglow. These statements include many months of work with microwave discharges which produced neither, as well as trials with the d.c. pulse discharge under the widest conditions of pressure, impurity, and discharge intensity. Since impurity content was not under complete control it is impossible to make any statement concerning the cases of very pure gas observed to give no glow in the earlier work.

Results of a series of simultaneous measurements of decay of afterglow intensity and absorption with time for different nitrogen pressures are shown in Fig. 2. Similar series of measurements made at different times agreed qualitatively with this in every way.

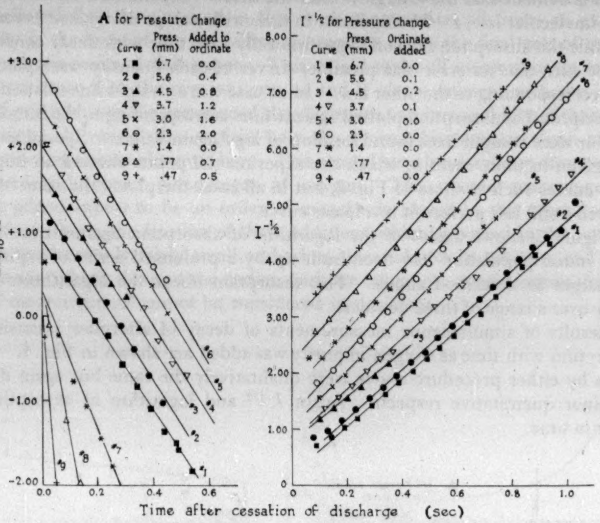

Fig. 2. Decay curves with variation of pressure.

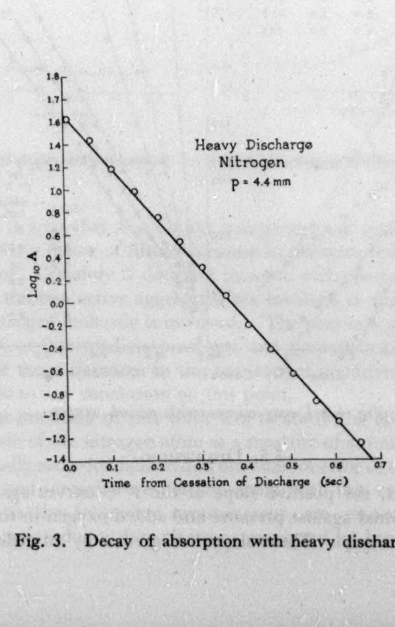

Fig. 3. Decay of absorption with heavy discharge.

It is evident that the afterglow after the first 0·1 second falls off according to the bimolecular law, $I^{-1/2}$ being linear in time with a slope designated hereafter as S, while the absorption falls off logarithmically with time with decay constant K. To be sure that no error was possible, curves of each quantity were plotted on axes corresponding to the other law. In no case was a straight line relation found for reciprocal of absorption plotted against time corresponding to the bimolecular law nor were straight lines found for plots of log I against time. Special attention was given to those cases in which the experimental points showed an imperfect fit to curves such as those of Fig. 2, but in all cases the plot of the other function showed a still less perfect fit to a linear curve.

Figure 3 shows a plot of the logarithm of absorption against time after a large initial population had been built up by a prolonged series of rapid pulse discharges as described above. The absorption obeys the logarithmic law of decay over a range of three decades.

Results of simultaneous measurements of decay of afterglow intensity and absorption with time as oxygen impurity was added are shown in Fig. 4. Other series by either procedure above were qualitatively the same but again differed in minor quantitative respects. Again $I^{-1/2}$ and logarithm of absorption are linear in time.

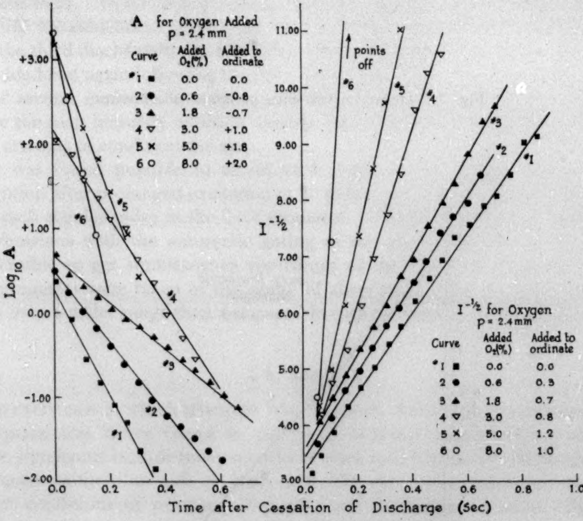

Fig. 4. Decay curves with added oxygen.

§ 5. DISCUSSION

The values of S, the positive slope of the $I^{-1/2}$ curves against time, from Figs 2 and 4 are plotted against pressure and added oxygen in the upper part of Figs 5 and 6 respectively. These slopes are greater by an order of magnitude than most of the slopes S_1 for the first bimolecular process of the earlier papers. It is believed that the gas used in this work contained at all times an oxygen impurity in the body of the gas falling between or above the final pair of curves of the oxygen series of that paper. This would make all measurements in this work consistent with the previous results and is also consistent with the lower level of purity due to the presence of the electrodes and impossibility of thorough outgassing. It would also explain why the second bimolecular slope of the earlier work was never observed here. This second bimolecular decay disappeared at considerably lower percentages of oxygen. The quoted percentages of oxygen added appear to be an order of magnitude higher in this work but, as pointed out above, the fraction of these additions which appeared in the body of the gas was certainly fairly small and when uncertainties in volumes and concentrations in both this and the earlier work are taken into consideration the two sets of measurements cannot be considered inconsistent.

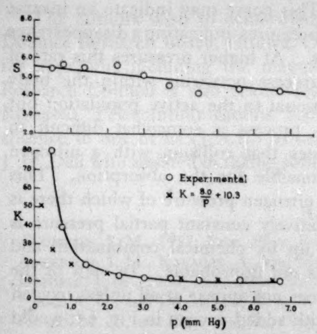

Fig. 5. Variation of slopes with pressure.

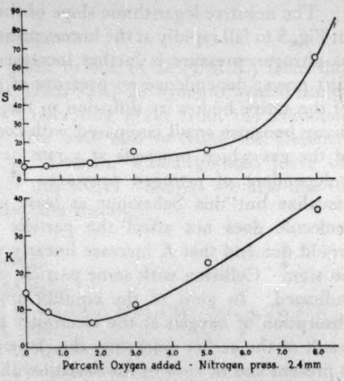

Fig. 6. Variation of slopes with added oxygen.

In Fig. 5 it is seen that S is almost independent of pressure, the small decrease of 20% for a factor of fifteen increase in pressure being probably within the limit of error. Certainly S does not increase with pressure so that it would seem that only the two active aggregates are involved in the afterglow collision and no other nitrogen molecule is involved. The previous work showed a small maximum in S_1 at intermediate pressures and no explanation was found. In consideration of the differences in the two sets of conditions it does not seem possible to come to any conclusion on this point.

The original intention of this work was to study the absorption due to the $^4S_{3/2}$ ground state of the nitrogen atom as a measure of atomic population. The absorption actually recorded falls within our limit of error of the correct frequency but line width and intensity are not consistent with this explanation. Both of these, as well as the frequency measurement, are consistent with cyclotron resonance absorption due to free electrons measured by Jones (1956).

At all times, and for all types of discharge in all gas samples during our measurements free electrons left over from the discharge could be observed by extending the measurements to very short times after the excitation ceased. These always fell below the limit of experimental observation within ten milliseconds after the discharge. This is consistent with the many papers on recombination of ions such as Faire and Champion (1959) and also with the theory of such recombination.

Thus it is evident that the absorption is not caused by free electrons left over from the discharge since no points have been recorded at less than twenty milliseconds and in assessing the results little weight is assigned to points at less than one hundred milliseconds after the discharge ceased. The absorption must be associated with an energy-carrying particle different from that whose bimolecular reaction gives rise to the afterglow since it has been shown that a logarithmic decay is not consistent with the afterglow results while the reciprocal absorption curve is not linear in time.

The negative logarithmic slope of the absorption curves of Figs 2–4 is shown in Fig. 5 to fall rapidly at the lowest pressures and then to become nearly constant as nitrogen pressure is further increased. This curve may indicate an inverse first power dependence on pressure at low pressures indicating a disappearance of the active bodies by diffusion to the walls. At higher pressures this rate of decay becomes small compared with some process occurring within the body of the gas which proceeds at a rate proportional to the active population but independent of nitrogen pressure. Such a process is somewhat difficult to visualize but this behaviour at least indicates that collision with a nitrogen molecule does not affect the particle responsible for the absorption. This would demand that K increase linearly with nitrogen pressure of which there is no sign. Collision with some particle of relatively constant partial pressure is indicated. In view of the equilibrium set up by chemical combination and absorption of oxygen at the electrodes this is not improbable. In view of the result of the earlier work that the slope S_1 does not appear at all unless oxygen is present and in view of the variation of K with added oxygen in Fig. 6 it would seem that this other particle must involve oxygen in some form.

In Fig. 5 the crossed points correspond to the equation $K=(8{\cdot}0/p)+10{\cdot}3$. On the mechanism outlined above, this equation represents $K=D/\lambda^2p+B$ where D is the diffusion coefficient of the active particle responsible for absorption in nitrogen gas at one millimeter pressure, λ is the diffusion length as in the earlier paper while B is the number of collisions per second made by this energy carrier in the body of the gas which remove its activity in producing absorption. The value of B for the number of collisions per second by a nitrogen molecule in nitrogen at one millimeter pressure is of the order of 5×10^6. Thus the number of effective collisions in the gas is down by a factor of 5×10^5 below this value. Since the particle necessary for the destructive collision is certainly not nitrogen but is independent of nitrogen pressure this indicates a partial pressure of the required particles which is greater than 2×10^{-6} millimeters and, making an allowance of a factor of 100 for collision efficiency, may be as high as 2×10^{-4} millimeters. Thus the particles in question may occur as an impurity of between 2 and 200 parts per million. This population by comparison with nitrogen at approximately 3×10^{16} molecules per cm^3 could rise as high as 6×10^{12} per cm^3. This particle presumably containing oxygen is a rather scarce species.

In Fig. 6, *K* appears to fall with small additions of oxygen and this also occurs in other sets of results. This may possibly be due to the added oxygen inhibiting the destruction of particles at the wall as above. The final rise at higher oxygen addition indicates that the destruction of the active particle is by oxygen collision.

Thus it seems that the early stages of the nitrogen afterglow are due to a bimolecular recombination of two similar particles assumed in previous papers to be nitrogen atoms, one at least of which involves a complex with oxygen. At the same time a different energy carrier exists giving rise to absorption at the free electron frequency, giving no glow, but destroyed logarithmically by collision with oxygen within the gas and only very slowly at the walls. These two energy-carrying particles seem from these measurements to be quite independent since the curves of decay are so regular that common population must be at most extremely small. These observations are consistent with those of Rayleigh (1942) which indicated that the lifetime of the ionization due to active nitrogen was unconnected with the decay of the glow.

The Effect of Particle Streams on Transverse Hydromagnetic Waves†

By E. R. HARRISON

Atomic Energy Research Establishment, Harwell

MS. received 7th November 1960, *in revised form 5th May* 1961

Abstract. A magnetic field is 'frozen' into a moving conducting fluid when certain conditions are fulfilled, as for example, when the frequency of the fluid disturbance is small compared with the cyclotron frequencies of the fluid particles. If the fluid contains streams of moving particles, parallel to the magnetic field, the magnetic field is also 'frozen' into the streams when there are transverse perturbations. The condition now is that the Doppler shifted frequency of the disturbance must be small compared with the cyclotron frequency of the stream particles. It follows that the phase velocity of transverse hydromagnetic waves is modified if such streams are present. In effect, the momentum flux of the streams reduces the 'tension' of the magnetic flux lines. When the kinetic energy density relative to the centre-of-mass system exceeds the magnetic energy density, the phase velocity in an infinite medium has complex conjugate values and the hydromagnetic wave grows in amplitude. In the case of a stream of finite radius the phase velocity shows dispersion for wavelengths greater than the stream radius and there is an increase in the domain of stability.

§ 1. INTRODUCTION

In a conducting fluid transverse waves are propagated along a uniform magnetic field with a phase velocity of $(B^2/4\pi\rho)^{1/2}$, as was first shown by Alfvén (1950), where B is the magnetic field strength and ρ is the fluid density. Chandrasekhar, Kaufman and Watson (1958) and others have since shown that if the pressure is anisotropic the phase velocity is modified and under certain circumstances can have complex values.

In plasma physics one finds that the situation is often complicated by the presence of streams of charged particles which are guided along the magnetic lines of force. For example, the streams which produce the auroral effects are in all probability guided along the geomagnetic flux-lines and pass through an atmospheric plasma whilst still at large distances from the Earth. Other examples where such a situation might occur are found in stellar atmospheres, astrophysical objects with a filamentary structure such as the Crab nebula, plasma neutralized accelerators of the kind proposed by Budker (1956), and thermonuclear discharge devices in which a fraction of the electron population is accelerated and forms a circulating stream that is contained by the flux-lines embedded in the plasma. It is shown below that such streams affect the phase velocity of transverse hydromagnetic waves, and in the case of an infinite medium the phase velocity has complex values and the hydromagnetic wave grows in amplitude when the mean kinetic energy density exceeds the magnetic energy density. For a stream of finite radius the phase velocity is modified for wavelengths which are no longer small in comparison with the radius of the stream. These results are similar in principle to those of Chandrasekhar *et al.* provided one interprets the appropriate part of the anisotropic pressure as a momentum flux.

---

† This paper was written whilst the author was temporarily at CERN, Geneva.

§ 2. TRANSVERSE WAVES IN AN INFINITE MEDIUM

We commence by assuming that a uniform magnetic field is embedded in an infinite, neutralized, conducting medium of uniform density, and that the medium consists either entirely or partly of streams moving parallel to the magnetic field. Let the uniform field $\mathbf{B}_0$ and the stream velocities $\mathbf{u}_i$ be parallel to the z axis, and let

$$\mathbf{B}=\mathbf{B}_0+\mathbf{b}\,; \quad \mathbf{V}_i=\mathbf{u}_i+\mathbf{v}_i, \qquad \ldots\ldots(1a,b)$$

where $\mathbf{b}$ and $\mathbf{v}_i$ are the perturbations in the field and the velocities transverse to the z axis. Neglecting second-order quantities the equation of motion of the ith stream, of charge density n_ie_i and mass density ρ_i, is

$$\rho_i\left(\frac{\partial}{\partial t}+u_i\frac{\partial}{\partial z}\right)\mathbf{v}_i=n_i\frac{e_i}{c}(\mathbf{E}+\mathbf{V}_i\wedge\mathbf{B})-\nabla p_i+\sum_k \mathbf{P}_{ik} \qquad \ldots\ldots(2)$$

where the pressure p_i is assumed to be isotropic and $\mathbf{P}_{ik}$ is the rate of momentum transfer from the kth stream due to collisions. Since transverse perturbations do not affect p_i we shall set ∇p_i equal to zero in the usual way (Cowling 1957).

We suppose now that the variables are Fourier analysed in z and t with typical components proportional to $\exp i(\omega t-kz)$, where ω is the frequency and k the wave number. Thus if $\boldsymbol{\xi}_b$ is the displacement of the magnetic flux-lines, then Maxwell's equations for a neutral medium take the form

$$\operatorname{div}\mathbf{E}=0, \qquad \ldots\ldots(3a)$$

$$\operatorname{div}\mathbf{B}=0, \text{ or: } \mathbf{b}=B_0\frac{\partial\boldsymbol{\xi}_b}{\partial z}=-ikB_0\boldsymbol{\xi}_b \qquad \ldots\ldots(3b)$$

$$\operatorname{curl}\mathbf{E}=-\frac{\partial\mathbf{b}}{\partial t}, \text{ or: } \mathbf{E}\wedge\mathbf{B}_0=-\frac{\omega}{k}B_0\mathbf{b}=i\omega B_0{}^2\boldsymbol{\xi}_b \qquad \ldots\ldots(3c)$$

$$\operatorname{curl}\mathbf{b}=4\pi\mathbf{j}. \qquad \ldots\ldots(3d)$$

where $\mathbf{E}$ is the electric field, $\mathbf{j}$ is the current density, and the displacement current is neglected in the usual way.

Equation (2) can be simplified by further supposing that the collision frequencies are small compared with the cyclotron frequencies Ω_i. Thus, if

$$\alpha_i=i(\omega-ku_i)/\Omega_i, \qquad \ldots\ldots(4)$$

the equation of motion now takes the form

$$\alpha_iB_0\mathbf{v}_i=\mathbf{E}+\mathbf{V}_i\wedge\mathbf{B}.$$

On taking the vector product of this equation with $\mathbf{B}_0$, and using Eqns (1), it follows that the velocity components parallel and perpendicular to $\mathbf{b}$ are

$$\mathbf{v}_{i\parallel}=\frac{\mathbf{E}\wedge\mathbf{B}_0+u_iB_0\mathbf{b}}{(1+\alpha_i{}^2)B_0{}^2} \qquad \ldots\ldots(5a)$$

$$\mathbf{v}_{i\perp}=\frac{\alpha_i}{1+\alpha_i^2}\,\frac{\mathbf{E}+\mathbf{u}_i\wedge\mathbf{b}}{B_0} \qquad \ldots\ldots(5b)$$

since, according to Eqn (3c), $\mathbf{E}$ has no component parallel to $\mathbf{b}$. Again, taking the vector product of Eqn (5a) with $\mathbf{B}_0$, and using Eqn (5b), it is seen that

$$\mathbf{v}_{i\perp}=-\frac{\alpha_i}{B_0}\,\mathbf{v}_{i\parallel}\wedge\mathbf{B}_0. \qquad \ldots\ldots(6)$$

Thus, if the Doppler shifted frequency is small compared with the cyclotron frequency, or $\alpha_i \ll 1$, the component of the velocity perpendicular to **b** is relatively small. One notices that the contributions to the electric current, which produces the magnetic field perturbation, are proportional to $n_i m_i$, and therefore come mainly from the heavier particles. Combining Eqns (5*a*) and (5*b*) one obtains

$$\mathbf{E} + \mathbf{u}_i \wedge \mathbf{b} + (1+\alpha^2)\mathbf{v}_{\parallel} \mathbf{B}_0 = 0 \qquad \ldots\ldots (7a)$$

or, when $\alpha_i \ll 1$,

$$\mathbf{E} + \mathbf{V}_i \wedge \mathbf{B}_0 = 0. \qquad \ldots\ldots (7b)$$

In magnetohydrodynamics it is well known that an equation of the form (7*b*) means that the magnetic field is 'frozen' into a fluid conducting medium. It is less well known, though equally obvious, that when a neutral medium consists of streams of particles with velocities parallel to the magnetic flux-lines, the streams and flux-lines also have identical displacements. This is easily shown, for if $\boldsymbol{\xi}_i$ is the transverse displacement of the *i*th stream, then

$$\mathbf{v}_{i\parallel} = \frac{d\boldsymbol{\xi}}{dt} = \left(\frac{\partial}{\partial t} + u_i \frac{\partial}{\partial z}\right) \boldsymbol{\xi}_i = i(\omega - ku_i)\boldsymbol{\xi}_i.$$

But from Eqn (5*a*), and using Eqns (3*b*) and (3*c*), it also follows that

$$\mathbf{v}_{i\parallel} = \frac{i(\omega - ku_i)}{1+\alpha_i^2} \boldsymbol{\xi}_b.$$

Hence, if $\alpha_i \ll 1$, then $\boldsymbol{\xi}_i = \boldsymbol{\xi}_b$ + a constant vector, but since the constant must be zero, the *i*th stream and the field have identical displacements. This means that all streams have equal displacements.

Summing the equations of motion (2) over all particles yields, for a neutral medium,

$$\sum_i \rho_i \left(\frac{\partial}{\partial t} + u_i \frac{\partial}{\partial z}\right)^2 \boldsymbol{\xi} = \mathbf{j} \wedge \mathbf{B}, \qquad \ldots\ldots (8)$$

where all fluid displacements are equal, as shown above. On linearizing the right-hand side of this equation, and using Eqn (3*d*), we have

$$\mathbf{j} \wedge \mathbf{B} = \mathbf{j}_0 \wedge \mathbf{b} + \frac{B_0^2}{4\pi} \frac{\partial^2 \boldsymbol{\xi}}{\partial z^2} \qquad \ldots\ldots (9)$$

where $\mathbf{j}_0$ is the electric current of the streams parallel to the uniform field $\mathbf{B}_0$.

Strictly speaking, the original assumption that the unperturbed field $\mathbf{B}_0$ is uniform can only be true when the streams make no contribution, that is $\mathbf{j}_0 = 0$, and the individual streams are themselves neutral or they cancel out each others effect. We shall consider this possibility first.

2.1. *Stream Current* $\mathbf{j}_0$ *is Zero*

The equation of motion of the fluid is now simply

$$\sum_i \rho_i \left(\frac{\partial}{\partial t} + u_i \frac{\partial}{\partial z}\right)^2 \xi = \frac{B_0^2}{4\pi} \frac{\partial^2 \xi}{\partial z^2}, \qquad \ldots\ldots (10)$$

from Eqns (8) and (9). If ρ is the total density of the fluid, $\rho\langle u \rangle$ is the mean momentum, and $\rho\langle u^2 \rangle$ the mean momentum flux, the dispersion equation is

$$\omega^2 - 2\langle u \rangle \omega k - \left(\frac{B_0^2}{4\pi\rho} - \langle u^2 \rangle\right) k^2 = 0 \qquad \ldots\ldots (11)$$

for a typical Fourier component of $\xi \propto \exp i(\omega t - kz)$. The phase velocity of a disturbance is therefore given by

$$\frac{\omega}{k} = \langle u \rangle \pm \left(\frac{B_0^2}{4\pi\rho} + \langle u \rangle^2 - \langle u^2 \rangle \right)^{1/2}. \qquad \ldots\ldots (12)$$

When the streams have zero velocity we recover from Eqn (12) the Alfvén phase velocity. If all the particles have the same velocity, then $\langle u \rangle^2 = \langle u^2 \rangle$, and the frequency is merely Doppler shifted by an amount uk owing to the mass motion of the medium. However, when the streams have different velocities, unless

$$\frac{B_0^2}{4\pi} > \rho(\langle u^2 \rangle - \langle u \rangle^2), \qquad \ldots\ldots (13)$$

the phase velocity has complex conjugate values and there is transverse or sinuous instability in the form of time or space growing waves. Notice that in terms of momentum flux the pressure parallel to the field is $p_\parallel = p + \rho(\langle u^2 \rangle - \langle u \rangle^2)$ in the centre-of-mass system, where $p = p_\perp = \Sigma p_i$ is the isotropic pressure of Eqn (2). The stability condition (13) now takes the form

$$\frac{B_0^2}{4\pi} > p_\parallel - p_\perp, \qquad \ldots\ldots (14)$$

which has been obtained elsewhere (Chandrasekhar, Kaufman and Watson).

One can imagine a simple case in which a neutral stream of charged particles of density ρ_1, and velocity u_1, passes through a stationary plasma of density ρ_0. The phase velocity given by Eqn (13) is now

$$\frac{\omega}{k} = u_1 \frac{\rho_1}{\rho} \pm \left\{ \frac{B_0^2}{4\pi\rho} - u_1^2 \frac{\rho_0 \rho_1}{\rho^2} \right\}^{1/2}, \qquad \ldots\ldots (15)$$

where $\rho = \rho_0 + \rho_1$. It is noticed that this is also the phase velocity of small transverse oscillations of a string, of line density ρ_0 and tension $B_0^2/4\pi$, on which beds of line density ρ_1 slide without friction at velocity u_1. An infinitely flexible tube under tension and containing a moving fluid is an alternative model, and hence the name of 'hose-pipe instability' for complex wave phenomena of this type. The phase velocity has real roots only if

$$\frac{B_0^2}{4\pi} > \frac{\rho_0 \rho_1}{\rho} u_1^2, \qquad \ldots\ldots (16)$$

and from either Eqns (13) or (16) we see that there is stability when the magnetic tension $B_0^2/4\pi$ exceeds the 'negative tension' of the momentum flux measured relative to the system in which there is no mass flow (or centre-of-mass system), or, stated in an alternative way, when the magnetic energy density is greater than the kinetic energy density measured in the centre-of-mass system. A similar criterion to (16) in the form of $B_0^2/8\pi > \rho_1 u_1^2$ has been proposed (but without proof) by Finkelstein and Sturrock (1958) as a condition for stabilizing neutralized electron beams in accelerators of the Budker type.

2.2. *Stream Current* $\mathbf{j}_0$ *is Not Zero*

So far we have adopted the rather unrealistic assumption that the unperturbed stream current $\mathbf{j}_0$ is zero in the equation of motion (8). In most cases of interest this current is not zero, and in a stream of circular cross section a B_ϕ field is superimposed upon the uniform field B_0 and the flux lines are twisted into helices about the axis of the stream. But if the amount of twist is small per wavelength, or

$$|k^{-1}B_\phi| \ll |aB_0|, \qquad \ldots\ldots(17)$$

where a is the radius of the stream, this effect can reasonably be neglected. In this section boundary conditions are neglected and hence only relatively short wavelengths of $ak \gg 1$ are considered, and therefore the condition (17) should not be difficult to satisfy.

On including the current term $\mathbf{j}_0$ in the equation of motion (8), but assuming that $\mathbf{B}_0$ is uniform, it follows that

$$\sum_i \rho_i \left(\frac{\partial}{\partial t} + u_i \frac{\partial}{\partial z}\right)^2 \boldsymbol{\xi} = \mathbf{j}_0 \wedge B_0 \frac{\partial \boldsymbol{\xi}}{\partial z} + \frac{B_0^2}{4\pi}\frac{\partial^2 \boldsymbol{\xi}}{\partial z^2}. \qquad \ldots\ldots(18)$$

Resolving the displacement $\boldsymbol{\xi}$ in the x and y directions, one obtains for $\xi_x \pm i\xi_y$ the dispersion equation

$$\omega^2 - 2\langle u \rangle \omega k - \left(\frac{B_0^2}{4\pi\rho} - \langle u^2 \rangle\right) k^2 \mp j_0 B_0 \rho^{-1} k = 0, \qquad \ldots\ldots(19)$$

and the plus and minus signs correspond to right- and left-hand circularly polarized waves. The force $\mathbf{j}_0 \wedge \mathbf{b}$ twists each flux-line into a helix about the unperturbed flux-line. Using a characteristic value of $B_\phi = 2\pi a j_0$, one sees that the ratio

$$\frac{j_0 B_0 k}{B_0^2 k^2/4\pi} \simeq \frac{2B_\phi}{akB_0} \qquad \ldots\ldots(20)$$

is small according to (17). The phase velocity is therefore approximately the same as that given by Eqn (12), and the treatment in §2.1 applies also in those cases when the stream current j_0 is not zero.

§ 3. Wavelengths Large compared with the Stream Radius

So far we have considered only wavelengths short in comparison with the stream radius and have regarded the medium as infinitely extended. When the wavelength is comparable with or larger than the stream radius the previous treatment must be modified and the appropriate boundary conditions taken into account.

From Maxwell's equations, one has

$$\nabla^2 \mathbf{E} - 4\pi \frac{\partial \mathbf{j}}{\partial t} = 0 \qquad \ldots\ldots(21)$$

for a neutral medium in which the displacement current is neglected. The right-hand side is determined by using Eqns (5a) and (5b) for the velocity components, and by assuming that $\alpha_i \ll 1$.

$$\frac{\partial \mathbf{j}}{\partial t} = \sum n_i \frac{e_i}{c} \frac{\partial}{\partial t} (\mathbf{v}_{i\parallel} + \mathbf{v}_{i\perp})$$

$$= -\frac{j_0}{B_0} \operatorname{curl} \mathbf{E} + \sum i \frac{\rho_i}{B_0^2} (\omega - ku_i)(i\omega \mathbf{E} - \mathbf{u}_i \wedge \operatorname{curl} \mathbf{E}).$$

Since the $\mathbf{u}_i$ are constant vectors, and $\mathbf{u}_i \cdot \mathbf{E} = 0$, it follows that

$$\mathbf{u}_i \wedge \operatorname{curl} \mathbf{E} = -(\mathbf{u}_i \nabla)\mathbf{E} = iku_i \mathbf{E},$$

and Eqn (21) can therefore be written as:

$$\nabla^2 \mathbf{E} + \frac{4\pi}{B_0} j_0 \operatorname{curl} \mathbf{E} + \frac{4\pi}{B_0^2} \sum \rho_i (\omega - ku_i)^2 \mathbf{E} = 0. \qquad \ldots\ldots(22)$$

Before proceeding further it should be noticed that this equation neglects all thermal pressure gradients. This can be justified provided the magnetic pressure is large compared with the thermal pressure.

For the E_ϕ component of the electric field let

$$E_\phi = F(r) \exp i(\omega t - kz - m\phi)$$

for a typical wave number k and mode number m. Then in cylindrical polar coordinates, Eqn (22) is equivalent to

$$\frac{\partial^2 F}{\partial r^2} + \frac{1}{r}\frac{\partial F}{\partial r} + \left\{p_q{}^2 - \frac{(m \pm 1)^2}{r^2}\right\} F = 0, \qquad \ldots\ldots(23a)$$

$$(r < a): \quad p_1{}^2 = \frac{4\pi}{B_0{}^2}\left\{\sum_i \rho_i(\omega - ku_i)^2 - k^2\right\} \pm \frac{4\pi}{B_0} j_0 k, \qquad \ldots\ldots(23b)$$

$$(r > a): \quad p_2{}^2 = \frac{4\pi}{B_0{}^2}\left\{\sum_i \rho_i \omega^2 - k^2\right\}, \qquad \ldots\ldots(23c)$$

where, for $r > a$, the plasma contains only particles which have no streaming motion. Thus, the E_ϕ component is proportional to

$$\exp(-im\phi)\{A_m J_{m\pm1}(p_q r) + B_m N_{m\pm1}(p_q r)\}.$$

If there is a conducting boundary, coaxial with the unperturbed stream at $r = R$, then $E_\phi(R) = 0$. Also E_ϕ and its first derivatives are continuous at the boundary of the stream, but as the electric field is proportional to the transverse displacement to a first order, this is equivalent to requiring that E_ϕ and its first derivatives are continuous at $r = a$ for small displacements. These boundary conditions yield

$$\begin{aligned} &p_1 J_n'(p_1 a)\{J_n(p_2 a) N_n(p_2 R) - J_n(p_2 R) N_n(p_2 a)\} \\ &\quad = p_2 J_n(p_1 a)\{J_n'(p_2 a) N_n(p_2 R) - J_n(p_2 R) N_n'(p_2 a)\}, \qquad \ldots\ldots(24) \end{aligned}$$

where $n = m \pm 1$. For sinuous perturbations $m = \pm 1$, and it is sufficient in the present elementary treatment to consider only the zero-order mode of $n = 0$. For small arguments, Eqn (24) reduces to

$$(p_1 a)^2 \ln L/a = 2, \qquad \ldots\ldots(25)$$

where $L = R$. However, when the wavelength is still large in comparison with the stream radius a, but is small compared with R, then approximately $L = k^{-1}$.

Using Eqns (23b) and (25) the dispersion equation is now found to be

$$\sum_i \rho_i(\omega - ku_i)^2 - \frac{B_0}{4\pi}\left\{k^2 \pm \frac{4\pi}{B_0} j_0 k + \frac{2}{a^2 \ln L/a}\right\} = 0. \qquad \ldots\ldots(26)$$

The last three terms have the proportions

$$ak : 2\frac{B_\phi}{B_0} : \frac{2}{ak \ln L/a},$$

and for $ak < 1$, $B_\phi < B_0$, the significant term is the last. It follows that for real values of k the phase velocity is therefore

$$\frac{\omega}{k} = \langle u \rangle \pm \left\{\frac{B_0{}^2}{2\pi(ak)^2 \rho \ln L/a} + \langle u \rangle^2 - \langle u^2 \rangle\right\}^{1/2}, \qquad \ldots\ldots(27)$$

and ω is real (no time growing waves) when

$$\frac{B_0{}^2}{4\pi} > \tfrac{1}{2}(ak)^2 \rho(\langle u^2 \rangle - \langle u \rangle^2) \ln L/a. \qquad \ldots\ldots(28)$$

Comparing this expression with the stability condition (13) it is seen that in effect the density is reduced approximately to $\rho(ak)^2$ for long wavelengths of $ak < 1$. Also, for real values of ω, k is also real (no space growing waves) when

$$\frac{B_0^2}{4\pi} > \tfrac{1}{2}(a\omega)^2\rho\left\{\frac{\langle u^2\rangle - \langle u\rangle^2}{\langle u^2\rangle}\right\}\ln L/a. \qquad \ldots\ldots \quad (29)$$

From Eqn (27) it is noticed that the phase velocity is dependent on the wave number k; however, the group velocity is close to $\langle u\rangle$ when the stability conditions (28) or (29) are satisfied.

§ 4. CONCLUDING REMARKS

In this treatment the non-relativistic approximation has been used but the results are unchanged in form if the appropriate masses are increased by $\gamma_i = (1 - u_i^2/c^2)^{-1/2}$ and the cyclotron frequencies are replaced by Ω_i/γ_i in Eqn (4).

Although there is some justification for omitting the effect of binary collisions it is doubtful whether in many cases the momentum exchange due to collective electrostatic interactions can be neglected (Buneman 1959). In an infinite medium, consisting of electrons and ions of equal temperature, the collective interactions are negligible when the difference of the mean velocities of the electron and ion gases is less than the electron thermal speed (Penrose 1960), or

$$(u_+ - u_-)^2 < \frac{2kT_-}{m_-} \qquad \ldots\ldots (30)$$

approximately. In many plasmas the conduction electrons drift with a speed of less than $(2kT/m_-)^{1/2}$, and if the conduction current is parallel to a magnetic field B_0, there is stability when the current density satisfies

$$j^2 < \frac{B_0^2}{4\pi}\left(\frac{ne^2}{mc^2}\right) = 2{\cdot}2 \times 10^{-14}\,nB_0^2 \qquad \ldots\ldots (31)$$

from Eqn (16). For example, for a number of density $10^{14}\,\mathrm{cm}^{-3}$, and a field strength of $B_0 = 10^3$ gauss, the maximum stable current density is $1{\cdot}5 \times 10^4\,\mathrm{A\,cm}^{-2}$.

Taking the other extreme in the two-stream model, and assuming that the difference between the mean velocities is large compared with the thermal speeds, the dispersion equation for longitudinal electrostatic oscillations is (for example, see Pierce 1947)

$$\frac{\omega_+^2}{(\omega - ku_+)^2} + \frac{\omega_-^2}{(\omega - ku_-)^2} = 1$$

where ω_- and ω_+ are the plasma frequencies of the ions and electrons, u_+ and u_- are the mean ion and electron velocities, and ω and k now refer to longitudinal electrostatic perturbations. For real values of k, the frequencies are real when

$$|u_+ - u_-|k > \omega_- \qquad \ldots\ldots (32)$$

for $\omega_- \gg \omega_+$. One sees that in an infinite medium there is always a range of wave numbers (corresponding to long wavelengths) for which there is electrostatic instability. However, in a finite cylindrical stream of radius a, the plasma frequency for wavelengths greater than a (that is, $ak \ll 1$) is given by

$$\omega_-^2 = (ka)^2\frac{2\pi ne^2}{m_-}\ln\frac{R}{a} \qquad \ldots\ldots (33)$$

where b is the radius of a conducting coaxial boundary (Budker 1956, Finkelstein and Sturrock 1958). From Eqns (32) and (33) it follows that there is stability when

$$|u_+ - u_-| > a\left(\frac{2\pi ne^2}{m_-}\ln\frac{R}{a}\right)^{1/2}. \qquad \ldots\ldots(34)$$

It can be seen that this condition is also sufficient for wavelengths smaller than the radius of the stream (Harrison 1960). Thus, when the zero temperature approximation is justified, it is still possible under certain conditions to have electron and ion streams freely interpenetrating in the manner assumed in this paper.

The Magnetic Susceptibilities of Aluminium–rich Transition Metal Intermetallic Compounds

By M. A. TAYLOR†

Crystallographic Laboratory, Cavendish Laboratory, Cambridge

Communicated by W. H. Taylor; MS. received 29th December 1960, in revised form 24th May 1961

Abstract. In aluminium-rich transition-metal intermetallic compounds the behaviour of transition-metal atoms in an electron-rich environment can be studied. Electron-density maps, prepared from x-ray data, and considerations of Brillouin zones for these compounds have not, up to the moment, yielded accurate information on the state of the transition-metal atoms. The results of the measurements of the magnetic susceptibilities of some such compounds are given: from these measurements information on the 3d state of the transition-metal atoms is derived.

---

§ 1. INTRODUCTION

RAYNOR (1949) interpreted metallurgical investigations on the aluminium transition-metal intermetallic compounds by assuming that the aluminium-rich phases are analogous to electron compounds and that in the electron-rich surroundings provided by the aluminium atoms the transition-metal atoms will absorb electrons ... "if the electron/atom ratios are calculated for these compounds assuming that each aluminium atom contributes three electrons to the structure while each transition-metal atom absorbs electrons to the maximum extent‡ an approximately constant electron/atom ratio is maintained, except in the case of $FeAl_3$:

$CrAl_7$	$MnAl_6$	$FeAl_3$	Co_2Al_9	$NiAl_3$
2·05	2·05	1·58	2·12	2·09

This suggests that such compounds are a type of electron compound, whose formation is governed by the attainment of a given electron/atom ratio ".

This theory enabled many features of a number of phase diagrams to be correlated into a self-consistent scheme and permitted the prediction of the occurrence and stability of several new ternary phases.

Crystallographic research, directed at providing experimental evidence on electron absorption, has resulted in the accurate determination of the structures of the most aluminium-rich compounds, of several binary compounds less rich in aluminium and of several ternary phases. The structures are complex, but several common features have been discovered (e.g. Taylor 1954, Black 1956, Brown 1957). For known crystal structures, electron-density maps have been prepared from the observed x-ray data (e.g. Douglas 1950, Nicol 1953) and it appeared that absorption of electrons by the transition-metal atoms occurred to an extent roughly in agreement with Raynor's negative valency scheme. Black (1955 a), however, showed that due to limitations of the experimental techniques and the theoretical interpretations the existence of electron transfer had not been reliably established.

---

† Now at Solid State Physics Division, Atomic Energy Research Establishment, Harwell.

‡ The ' maximum extent ' corresponds to the number of atomic orbital vacancies of Pauling (1938).

The relationship of the first Brillouin zone planes to the strong x-ray reflections has been used to calculate the volumes of the zones for certain compounds and hence the effective valencies of the transition-metal atoms (Douglas 1950, Robinson 1953). In general, valencies in approximate agreement with Raynor's absorption hypothesis were obtained. Black (1955 b) then pointed out that for a structure with all interatomic distances approximately equal and with high coordination it can be shown that a set of strong reflections is necessarily observed. Therefore, if the empirical evidence from Brillouin zone calculations is to be significant, it must be shown that individual deviations in the electron/atom ratios correspond to differences in the compositions of the compounds: in most cases this detailed correlation is not found. It must be concluded that the electron absorption suggested by Raynor has not been confirmed experimentally.

Hume-Rothery and Coles (1954) have suggested that the negative valency scheme of Raynor is physically improbable, and have given reasons for this view.

The magnetic measurements described below were undertaken in order to obtain fresh experimental data relevant to this problem.

§ 2. THE APPLICATION OF MAGNETIC SUSCEPTIBILITY MEASUREMENTS

Information on the effectively localized magnetic moments associated with the transition-metal atoms may be obtained from magnetic susceptibility measurements over a temperature range. The magnetic susceptibility of an aluminium transition-metal alloy is made up of the following contributions:

(i) the orbital diamagnetism of the electrons localized on aluminium ions; (ii) the orbital diamagnetism of the electrons localized on transition-metal ions; (iii) the Pauli paramagnetism of the conduction electrons (this may be enhanced by correlation effects); (iv) the Landau diamagnetism of the conduction electrons; (v) the paramagnetism of the 3d electrons, if any, with unpaired spins effectively localized on transition-metal ions.

Contributions (i) to (iv) give rise to a small approximately temperature independent para- or diamagnetism, the accurate calculation of which is not possible. Effectively localized unpaired spins (v), however, define paramagnetism with Curie–Weiss temperature dependence.

When an effectively localized magnetic moment is associated with a transition-metal atom, the contribution (v) swamps the terms (i) to (iv) and the value of the moment can be deduced from the relationship

$$\chi_{\mathrm{A}} = \frac{N^2\mu_{\mathrm{B}}^2}{3R(T-\theta)} p_{\mathrm{eff}}^2$$

where χ_{A} is the molar susceptibility, $p_{\mathrm{eff}} = \{4S(S+1)\}^{1/2}$ (assuming the orbital moments are completely quenched) and θ is a parameter related to the intensity of the internal field.

§ 3. PREVIOUS MAGNETIC MEASUREMENTS

Foëx and Wucher (1954, 1956) reported $MnAl_6$, $CoAl_4$, Co_4Al_{13}, $CrAl_7$, $CrAl_4$, Co_2Al_5 and $NiAl_3$ to have a small temperature independent para- or diamagnetism and $FeAl_3$ to have a paramagnetism the temperature dependence of which followed a Curie–Weiss law with $p_{\rm eff} = 1{\cdot}67\,\mu_{\rm B}$ and $\theta = -103$°K. They interpreted these results as showing that in $MnAl_6$, $CoAl_4$, Co_4Al_{13}, $CrAl_7$, $CrAl_4$, Co_2Al_5 and $NiAl_3$ the transition-metal atoms have full 3d shells and that in $FeAl_3$ an iron ion has slightly less than nine 3d electrons.

Vogt (1954) also reported $MnAl_6$ to have a small approximately temperature independent paramagnetism.

§ 4. THE PREPARATION OF SPECIMENS

Aluminium transition-metal intermetallic compounds are in general formed as the result of successive peritectic reactions and Phillips (1943) found that even prolonged annealing is unable to remove completely the coring and inhomogeneity: the Aluminium Laboratories Ltd., Banbury, also reached this conclusion. The possibility of producing by normal methods homogeneous single-phase ingots suitable for magnetic measurements was therefore dismissed.

Attempts were made to measure the susceptibilities of samples of single crystals of $MnAl_6$ (obtained by electrolytic extraction from an aluminium-rich matrix) packed together in the specimen holder; the value of the susceptibility was not reproducible on removing the crystals and re-packing them into the specimen holder, nor could reproducible results be obtained by powdering the crystals. This behaviour is probably due to the anisotropy of the single crystals.

The specimens for the measurements reported below were prepared by a modification of the powder metallurigcal technique used at the Aluminium Laboratories Ltd., Banbury, by Goulding (1958, private communication). Fine powders of the pure metals were thoroughly mixed together in the correct proportions, and the compacts were pressed at 12 tons in^{-2} for periods of five minutes, fused successively at temperatures of 200, 400, 600 and 700°C *in vacuo* and pressed cold after each reaction. The compacts were then annealed for twenty-four hours at 800°C or at a temperature slightly below the decomposition temperature of the phase in question, whichever was lower. The specimens were examined metallographically and by X-ray powder photographs.

The impurities of the various metals, as quoted by their suppliers, are given in Table 1. Some gas was picked up during the sintering process and a typical analysis of a sample, $NiAl_3$, by the British Non-Ferrous Metals Research Association gave the weights per cent of oxygen, nitrogen and hydrogen as 0·15, 0·002 and 0·001 respectively.

§ 5. THE MEASUREMENT OF MAGNETIC SUSCEPTIBILITY

A Sucksmith balance was used to measure magnetic susceptibility between 77 and 293°K. The specimen was cooled with liquid nitrogen, which was then allowed to evaporate, susceptibility measurements being taken over a period of four hours as the temperature of the specimen rose to room temperature. The balance was calibrated with tantalum (Hoare and Walling 1951). The absolute accuracy of any susceptibility measurement was to ± 3%, and the relative accuracy of points on a given temperature run corresponded to an error in the susceptibility

of 10^{-8} e.m.u. g^{-1}. The absolute accuracy of the temperature measurement was to $\pm 1\%$.

The aluminium–iron intermetallic compounds contained traces of ferromagnetic impurities: the effects of these were eliminated by means of Honda–Owen plots.

§ 6. RESULTS

The results of the measurements of the magnetic susceptibilities of the aluminium transition-metal intermetallic compounds are given in Table 2.

Table 2. The Magnetic Susceptibilities of Aluminium Transition-metal Intermetallic Compounds

The first line in each entry gives $10^6\chi$ with χ in e.m.u. g^{-1} and the second line T in °K.

Table 3. The Effective Magneton Numbers, Curie–Weiss Temperatures and Spin Quantum Numbers for Aluminium-rich Transition-metal Intermetallic Compounds

	p_{eff}	θ(°K)	S	No. unpaired electron spins
$MnAl_4$	1·77	−163	0·51	1·02
Mn_3Al_{10}	1·66	−120	0·47	0·94
Mn_4Al_{11}	1·59	− 50	0·44	0·88
Fe_4Al_{13}	2·37	−300	0·79	1·58
Fe_2Al_5	2·47	−103	0·83	1·66
$FeAl_2$	1·32	− 80	0·33	0·66

The compounds may be divided into two groups on the basis of their susceptibilities: the compounds of the first group (VAl_{10}, V_7Al_{45}, V_4Al_{23}, VAl_3, V_5Al_8, Cr_2Al_{11}, $CrAl_7$, $CrAl_4$, $MnAl_6$, Co_2Al_9, Co_4Al_{13}, $CoAl_3$, $NiAl_3$ and Ni_2Al_3) show a small approximately temperature independent paramagnetism (see Fig. 1); the compounds in the second group ($MnAl_4$, Mn_3Al_{10}, Mn_4Al_{11}, Fe_4Al_{13}, $FeAl_2$ and

Fe_2Al_5) show large susceptibilities obeying the Curie–Weiss law; however, μ(AlMn)($\sim Mn_{11}Al_{40}$ (Taylor 1960)) (see Fig. 2), has a large temperature dependent paramagnetism which does not obey the Curie–Weiss law.

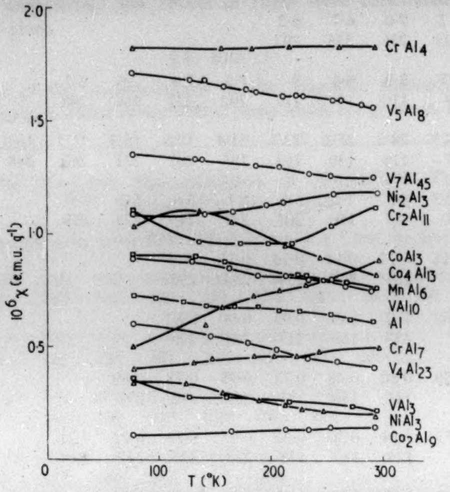

Fig. 1. The temperature dependence of the magnetic susceptibility of some aluminium-rich transition-metal intermetallic compounds.

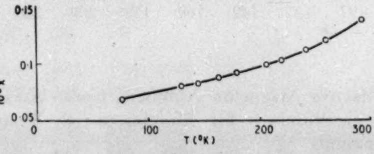

Fig. 2. The reciprocal of the temperature dependence of the magnetic susceptibility of μ (AlMn).

Table 3 gives, for the compounds obeying the Curie–Weiss law, the values of the effective magneton numbers p_{eff}, the Curie–Weiss temperatures θ, the total spin quantum numbers of the atoms S and the numbers of unpaired electron spins. These have been derived from plots of the reciprocal of the susceptibility against

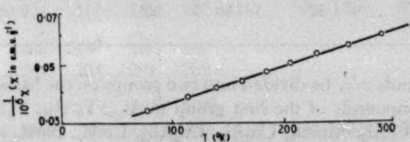

Fig. 3. The temperature dependence of the reciprocal of the magnetic susceptibility of Fe_2Al_5.

temperature (Fig. 3). The magneton numbers have been derived on the assumption that no moments are localized on the aluminium ions, and orbital contributions to the moments of the transition-metal ions have been neglected.

Ideally, one should subtract contributions (i) to (iv) (§2) from the observed susceptibility; since these contributions cannot be accurately calculated this has not been done. In the case of, for example, $MnAl_4$ neglect of a temperature independent paramagnetism of 10^{-6} e.m.u. g^{-1} would introduce errors, relative to the values given in Table 3, in p_{eff} and θ of 12% and 23°K respectively.

The paramagnetism of μ(AlMn) is anomalous; it is relatively large and the temperature dependence is marked but does not follow a Curie–Weiss law. It is possible that the multiplet intervals are comparable with kT so that the treatment of narrow multiplets is not applicable: then the Boltzmann distribution of the various states would produce striking departures from a Curie–Weiss law (as, for example, in samarium and europium). Another possibility is that θ and/or p_{eff} varies with temperature.

The Curie–Weiss θ gives an indication of the freedom of a spin to orientate in an applied magnetic field. The values of θ (see Table 3) lie between -50 and -300°K and indicate that the spins are relatively free to orientate themselves. The absence of a strong temperature dependent susceptibility in Al–Ni, Al–Co, Al–Cr and Al–V compounds and in $MnAl_6$ shows that either no effectively localized moments occur in these alloys or the spin interactions are very strong ($\gg kT$).

§ 7. Discussion

The results of Taylor, Burger and Wucher (1959) on dilute solution of V, Cr and Mn in Al are readily explained in terms of the Friedel concept of virtual bound states. Since this treatment is applicable only when the transition-metal atoms are sufficiently dilute not to interact strongly it need occasion no surprise if it does not apply to the intermetallic compounds; in Mn_3Al_{10}, for example, certain manganese atoms are found at a distance of 2·75 Å apart (Taylor 1959).

The Lomer and Marshall (1958) scheme for the behaviour of transition-metal elements is now well known. This was based on the X-ray counts of Weiss and DeMarco (1958), the neutron diffraction results of Shull and Wilkinson (1953, 1955) and ferromagnetic saturation data on many alloy systems. Since then, however, Batterman (1959) and Batterman, Chipman and DeMarco (1960) have shown the results of Weiss and DeMarco to be incorrect. However, the empirical Lomer and Marshall scheme still provides an excellent classification of the magnetic properties of transition-metal alloys in terms of numbers of effectively localized 3d electrons. It is shown below that the magnetic behaviour of aluminium transition-metal alloys fits into this scheme.

In these intermetallic compounds no effectively localized magnetic moments exist on either the nickel or the cobalt atoms. This might be due to the conduction electrons from the aluminium atoms filling the vacancies in the 3d band: this implies absorption of approximately 0·6 and 1·7 electrons by the Al–Ni and Al–Co bands respectively. Another possibility is that the 3d states are not fully occupied, but that no localized moments occur since Hund's rule is not obeyed (as in the aluminium transition-metal dilute solutions discussed earlier in this section).

The numbers of unpaired spins on the iron and manganese atoms in the Al–Fe and Al–Mn compounds (see Table 3) are as follows:

$MnAl_6$	$MnAl_4$	Mn_3Al_{10}	Mn_4Al_{11}	Fe_4Al_{13}	Fe_2Al_5	$FeAl_2$
0	1·0	0·9	0·9	1·6	1·7	0·7

The differences of the number of spins from one in the case of the manganese compounds (with the exception of $MnAl_6$) and from two in the case of the iron compounds (with the exception of $FeAl_2$) are not considered to be significant; these differences might be caused by several factors, such as incomplete quenching of the orbital contribution to the paramagnetism, spin polarization of the conduction electrons, or the neglect of the temperature independent paramagnetism in deducing p_{eff} from the observed data. It is possible, however, that in the case of Fe_4Al_{13} and Fe_2Al_5 the moment of iron atoms in an aluminium-rich environment is slightly less than two, as was found by Nathans *et al.* (1958) in the case of Fe_3Al. Therefore, with the exception of $MnAl_6$ and $FeAl_2$, in these compounds the manganese and iron atoms retain the effectively localized 3d electron configurations of the pure metals (i.e. 1 in Mn and 2 in Fe respectively).

The crystal structures of the phases $MnAl_6$ (Nicol 1953), Mn_3Al_{10} (Taylor 1959) and Mn_4Al_{11} (Bland 1958) show many similarities (the crystal structure of the $MnAl_4$ phase is unknown). The manganese atoms in all three phases are surrounded by ten aluminium atoms in similar spatial arrays. The striking difference between $MnAl_6$ and the other two phases, however, is that in $MnAl_6$ the manganese atom is in very close contact with two aluminium atoms which are not in contact with other manganese atoms. It is suggested, therefore, that strong covalent bonding occurs between the manganese atom and the two aluminium atoms and that the one 3d electron which may be expected to be effectively localized on the manganese atom is involved in the formation of these covalent bonds, giving zero resultant localized spin on the manganese atom. Other possibilities are that the localized 3d state occurs above the Fermi surface and is therefore unoccupied, or that manganese in $MnAl_6$ behaves as manganese in dilute solution in aluminium.

The crystal structure of $FeAl_2$ is unknown (the crystal structure reported by Osawa (1932) has been shown by Forsyth (1959) to be incorrect); it is suggested that some anomalous feature exists here also which would account for the difference between the spins on the iron atoms in $FeAl_2$ and in Fe_4Al_{13} and Fe_2Al_5.

The absence of any effectively localized magnetic moments on the chromium and vanadium atoms in these compounds shows that the behaviour of chromium and vanadium atoms is approximately the same as in the pure metals: the chromium atoms appear to have lost the small moment ($0{\cdot}4\,\mu_B$) which they possess in the pure metal.

The behaviour of transition-metal atoms in compounds with aluminium is very similar to their behaviour in the ferromagnetic binary alloys discussed by Lomer and Marshall. Furthermore, the marked difference in the magnetic properties between the Al–Fe and Al–Co compounds is similar to that observed between the metals Fe and Co in many ferromagnetic binary alloys: the x-ray work of Batterman now shows that the marked change in the electronic distribution between the pure metals Co and Fe suggested by Weiss and DeMarco does not exist.

The discussion by Hume-Rothery and Coles (1954) of the variation in cohesion in alloys of Al with Ni, Co, Fe, seems to be in line with the scheme for the number of effectively localized 3d electrons suggested in this section, although melting points give only a very rough indication of bond strengths and the contributions of electrons in various states to the cohesion of a metal cannot be analysed.

Lomer and Marshall suggest that the electronic structure is not appreciably affected by the crystal structure and that the crystal structure is chosen to be the most appropriate to the electronic structure rather than vice versa. Some characteristic features of the structures of the aluminium transition-metal intermetallic compounds have been reviewed by Black (1956) who showed that size factor considerations alone could not be responsible for the observed co-ordination numbers and concluded that the co-ordination numbers are influenced by some specific characteristic of the aluminium transition-metal interaction. In the case of $MnAl_6$ the unusual magnetic behaviour may possibly be explained by a particular structural peculiarity; a similar explanation is put forward for $FeAl_2$. But in general the results of the magnetic analysis do nothing to explain the occurrence of the complex crystal structures taken up by these compounds.

§ 8. CONCLUSIONS

1. The behaviour of transition metal atoms in the aluminium transition-metal intermetallic compounds bears some resemblance to that in the pure metals and in the ferromagnetic binary alloys discussed by Lomer and Marshall (see Table 4).

Table 4. The Analogy between Binary Ferromagnetic Alloys and Aluminium Transition-metal Alloys

	Ti	V	Cr	Mn	Fe	Co	Ni
Binary ferromagnetic alloys (Lomer and Marshall)	no moments			low d		high d	
Aluminium transition-metal alloys	no moments			some low d moments		no moments	

2. The absorption hypothesis of Raynor cannot explain the magnetic behaviour of the Al–Fe, Al–Mn, Al–Cr and Al–V compounds.

3. The results of the magnetic analysis do nothing to explain the occurrence of the complex crystal structures taken up by these compounds.

ACKNOWLEDGMENTS

I wish to thank the Department of Scientific and Industrial Research for the award of a Research Studentship. This research forms part of a project supported by the Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Force, through its European Office, under Contract No. AF.61(052)–50. Some of the equipment used was purchased with the help of a generous award from the Government Grants Committee of the Royal Society.

I am greatly indebted to Professor N. F. Mott and Dr. W. H. Taylor for provision of facilities and for their help and encouragement. I should like to thank Dr. J. Crangle of the University, Sheffield, Professors G. Foëx and J. Wucher of the Laboratoire Pierre Weiss, Strasbourg, and Dr. W. E. Gardner or many valuable discussions. Aluminium Laboratories Ltd., Banbury, kindly gave the super-purity aluminium used in this work, and I am indebted to Metallisation Ltd., Dudley, who prepared the pure metal powders.

LETTERS TO THE EDITOR

On the Θ Values from the Temperature Dependence of the Laue–Bragg Scattering

The Debye temperature values occurring in the theory of the temperature dependence of the Laue–Bragg scattering can be calculated with the aid of the relation (Blackman 1955)

$$\frac{3}{\Theta^2_\infty(\text{x-ray})} = \left(\frac{k}{h}\right)^2 \frac{\int \rho(\nu)\nu^2 d\nu}{\int \rho(\nu) d\nu},$$

which is valid at moderately high temperatures. Here ν is the frequency of the normal modes of the vibration of the crystal, $\rho(\nu)$ is the normalized frequency distribution function, h and k have their usual meanings and the integrals are taken over the whole vibrational spectrum. For aluminium, using $\rho(\nu)$ calculated by Walker (1956 a), the integrals were evaluated graphically and this yielded a value of 402°K for Θ_∞(x-ray). Walker's spectrum is derived from the measurements at room temperature, for which case the theory should apply quite well.

The computed value of Θ_∞(x-ray) for aluminium falls between the scattered experimental $\Theta_{\text{D.W.}}$ values. The measurements of James, Brindley and Wood (1929) give $\Theta_{\text{D.W.}} = 410$°K at 290°K (Lonsdale 1948), whereas the experiments of Owen and Williams (1947) on powdered samples give the room temperature (293°K) value of $\Theta_{\text{D.W.}} = 395$°K. Walker (1956 b) gives 402°K as the value of $\Theta_{\text{D.W.}}$. His value is based on data taken both at low temperatures and at room temperature. As the force constants change appreciably with temperature, his measurements refer to conditions where the spectrum is not constant. The accuracy of the experiments is also limited to some extent by temperature diffuse scattering (Nilsson 1957, Warren 1953, Paskin 1958), extinctions, Compton and fluorescent scattering. Without estimates of errors due to all these factors, a comparison of Θ_∞(x-ray) with $\Theta_{\text{D.W.}}$ is not quite justified.

It is a pleasure to thank Professor K. Banerjee for his interest and the referees for helpful comments. Acknowledgments are due to the Council of Scientific and Industrial Research for financial support.

Effect of Variations in the Quantum Counting Efficiency of Detectors on the Mean Wavelength of X-ray Emission Lines

Modern X-ray diffractometers, used to define the position of an X-ray line by means of its centroid, can now be used to obtain results which are reproducible to 1 part in 10^5 or better. Sources of error which can be neglected in methods of lower precision must be taken into account in this work. One such possible source of error is the variation in the mean wavelength of the detected line profile which can be caused by the change, over the range of wavelength used, of the quantum counting efficiency of the detectors. This variation of the quantum counting efficiency with wavelength will cause the fraction of the incident intensity detected to vary with wavelength. The mean wavelength of the detected profile will differ, therefore, from the mean wavelength of the true profile and, in general, from the mean wavelength of the same line recorded by a different detector.

We shall consider first the general case of a true wavelength distribution $I(\lambda)d\lambda$ modified by a factor $f(\lambda)$. The true centroid is

$$\lambda_0 \equiv \frac{\int \lambda I(\lambda)d\lambda}{\int I(\lambda)d\lambda} \qquad \ldots\ldots (1)$$

and the modified centroid

$$\langle\lambda\rangle = \frac{\int \lambda f(\lambda)I(\lambda)d\lambda}{\int f(\lambda)I(\lambda)d\lambda}. \qquad \ldots\ldots (2)$$

Near the centroid, $f(\lambda)$ can be expanded as

$$f(\lambda) = f(\lambda_0) + (\lambda-\lambda_0)f'(\lambda_0) + \ldots \qquad \ldots\ldots (3)$$

$$= f + (\lambda-\lambda_0)f' + \ldots . \qquad \ldots\ldots (4)$$

Then

$$\langle\lambda\rangle = \frac{\lambda_0 + \int (\lambda-\lambda_0)[f + (\lambda-\lambda_0)f' + \ldots]I(\lambda)d\lambda}{\int [f + (\lambda-\lambda_0)f' + \ldots]I(\lambda)d\lambda} \qquad \ldots\ldots (5)$$

$$= \lambda_0 + \frac{Vf'}{f} + \ldots \qquad \ldots\ldots (6)$$

where V is the variance of the wavelength. The fractional change in the centroid wavelength is given to the first order by

$$\frac{\Delta\lambda}{\lambda} = \frac{Vf'}{\lambda f}. \qquad \ldots\ldots (7)$$

In the specific case of a change caused by variation in quantum counting efficiency the factor f'/f is simply the fractional rate of change of quantum counting efficiency with wavelength. The Table gives values for f'/f for the

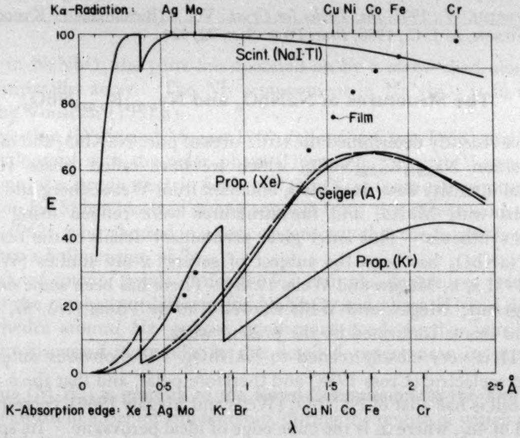
Values of f'/f (Å^{-1}) for Various Detectors at the Wavelengths of Molybdenum, Copper and Chromium Kα Radiations

(1)	(2)	(3)	(4)	(5)	(6)
Mo	+2·80	+2·62	+2·38	+2·78	0
Cu	+0·35	+0·31	+0·88	+0·82	−0·06
Cr	−0·51	−0·45	−0·14	+0·04	−0·13

(1) Radiation; (2)–(6) f'/f (Å^{-1}) for different detectors: (2) Geiger; (3) proportional (Xe); (4) proportional (Kr); (5) film; (6) scintillation.

most commonly used methods of detection, at the wavelengths of the molybdenum, copper and chromium Kα lines. These values were obtained from the Figure.

It is clear that when comparing results obtained by two different detectors the fractional change in wavelength, or in practice the fractional change in lattice spacing, can be found by substituting the difference between the respective values of f/f' in Eqn (7). For the case of copper Kα this varies from nearly zero, when comparing results from Geiger and proportional counters, to 3 parts in 10^6 when results from scintillation counters are compared with those obtained from krypton-filled proportional counters. (The variance is taken as one-third of the square of



Calculated quantum counting efficiency E as a function of wavelength λ for four counter tubes. The absorption of Eastman No-screen double-coated x-ray film is indicated by the dots.

Counter	Gas (cm Hg)	Length (cm)	Window thickness (cm)
Geiger	55 cm A	10	Mica 0·0013
Proportional	50 cm Kr	2·2	Mica 0·0013
Proportional	32 cm Xe	2·0	Mica 0·0013 +Be 0·013
Scintillation	(NaI.Tl)	0·1	Be 0·013

(Reproduced by permission of W. Parrish (1962).)

the peak separation.) Much larger differences can be found in the case of molybdenum Kα, where a comparison of results obtained by a scintillation counter with those obtained by a Geiger counter can produce differences of 2·5 parts in 10^5.

The fractional change of the peak wavelength is easily calculated to be $-f'I/\lambda fI''$, where f, I, f', I'' are the values of $f(\lambda)$, $I(\lambda)$ etc. at the peak (Wilson 1958).

Although at the moment this effect is on the fringe of detectability for normal diffractometer techniques, it may well be of importance in the field of x-ray spectroscopy. This will be especially true if, as is hoped, work is done on the line profiles of the more important x-ray emission lines. At the moment, however, this effect is yet another unknown in the determination of x-ray wavelengths.

The Structures of $NaNbO_3$ and $Na_{0\cdot975}K_{0\cdot025}NbO_3$

We have recently determined the structures of pure $NaNbO_3$ and of a material of composition $Na_{0.975}K_{0.025}NbO_3$, which we have called phase II. Three-dimensional intensity data were used, obtained from Weissenberg and oscillation photographs with MoKα, and the structures were refined using successive differential syntheses. This letter gives preliminary details of the results.

Pure $NaNbO_3$ has been the subject of several x-ray studies (Wood 1951, Vousden 1951 a, b, Megaw and Wells 1958). There has been some doubt about the space group; Megaw and Wells showed it to be Pbma (No. 57, in the *bca* setting) and this is confirmed by the present work.

Phase II is very closely related to $NaNbO_3$. The obvious differences are that it is ferroelectric (Cross 1958) and therefore polar, and that the *b* dimension of its unit cell is half that of $NaNbO_3$ (Wells and Megaw 1960), corresponding to $2a_0$ instead of $4a_c$, where a_0 is the cube edge of ideal perovskite. Its space group is $P2_1ma$ (No. 26, in the *cab* setting); it spoint group is thus 2mm, while that of $NaNbO_3$ is mmm.

Cell dimensions and atomic coordinates of the two structures are given in the Table.

Both structures are based on distortions of ideal perovskite. Individual NbO_6 octahedra are only slightly distorted, but are rotated relative to each other about the *y* axis. The Nb atom in each is displaced by about 0·15 Å along the *x* axis, towards the middle of an octahedron edge in the (010) plane; within this plane all Nb displacements are (nearly) in the same direction, and no O is approached by more than one Nb.

The principal difference between the two structures lies in the way in which successive layers of octahedra normal to [010] are arranged. In both structures there are pairs of layers related by a (010) mirror plane, with parallel Nb displacements. But, while in phase II one such pair constitutes the translation

	NaNbO$_3$			Phase II

Note: In phase II the origin is on the screw diad, at a position arbitrarily chosen to give the same *x* coordinate as in NaNbO$_3$ to the centre of gravity of the O$_3$O$_4$ square.

repeat unit, in NaNbO$_3$ the pairs are operated on by a screw diad along [010], giving an antiparallel array. The Nb arrangement in NaNbO$_3$ is in essentials that found by Vousden (1951 b).

The suggestion (Wells and Megaw 1960, following Cross 1958) that phase II is probably identical with the polar phase ('forced ferroelectric') produced by the application of a strong electric field to NaNbO$_3$ at room temperature (Cross and Nicholson 1955) has received strong support from the recent work of Wood and Miller (1962), who showed in a very elegant way that the forced ferroelectric phase also has a *b* dimension of $2a_0$.

There are, of course, points of detail—for example, departures from perfect regularity of the octahedra (different for NaNbO$_3$ and phase II) and differences in the polyhedra around Na—whose significance needs further consideration. These will be discussed more fully in the detailed report now in preparation.

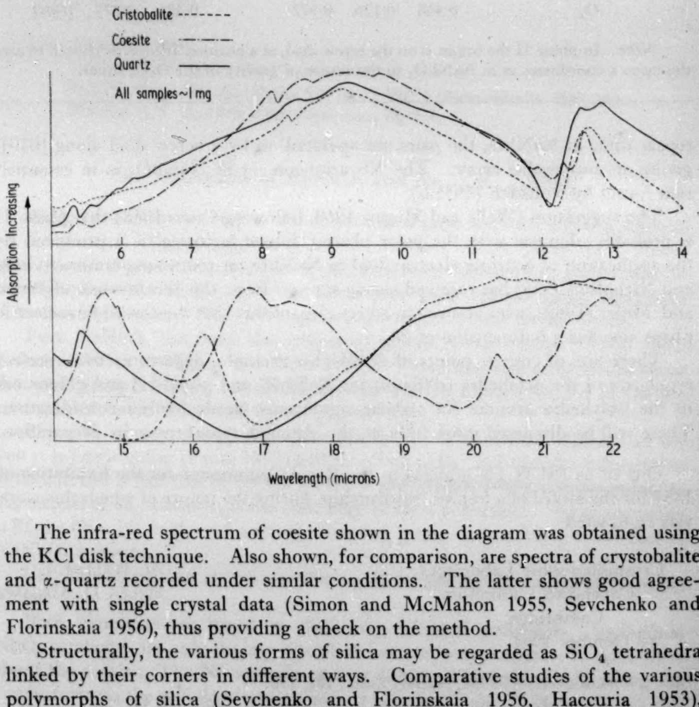
Absorption of Coesite in the Wavelength Region 5–22 Microns

The optical properties of coesite, a dense, high pressure form of silica, are less well known than those of quartz, crystobalite and tridymite, the other members of this family.

Small samples have been made at N.P.L. using a tetrahedral anvil apparatus. Following the data by Boyd and England (1960), a pressure of 42 kilobars and a temperature of 1400°c were used, with finely ground crystal quartz as the starting material. Refractive index and x-ray measurements (Boyd and England 1960) indicated a high yield ($\sim 90\%$) of coesite crystals, approximately 50 microns in diameter.



The infra-red spectrum of coesite shown in the diagram was obtained using the KCl disk technique. Also shown, for comparison, are spectra of crystobalite and α-quartz recorded under similar conditions. The latter shows good agreement with single crystal data (Simon and McMahon 1955, Sevchenko and Florinskaia 1956), thus providing a check on the method.

Structurally, the various forms of silica may be regarded as SiO_4 tetrahedra linked by their corners in different ways. Comparative studies of the various polymorphs of silica (Sevchenko and Florinskaia 1956, Haccuria 1953), silicates (Matossi 1949) and silicic esters (Weiler 1933) have shown that the bands in silica near 8·4, 9·2, 12·6 and 20–22 microns may be associated with the four fundamental vibrations of the SiO_4 group. Except for the last band, these wavelengths are relatively insensitive to the form of the lattice coupling the tetrahedra. Additional bands which appear in the region 13–18 microns are specific to each polymorph.

The spectrum of coesite is consistent with this general view. The marked differences, which occur between coesite and the other polymorphs, are in the fundamental region 20–22 microns and the region 13–18 microns.

Anisotropy in the Electric Strength of Alkali Halide Crystals

Previous investigations (Cooper, Grossart and Wallace 1957) have shown that KCl is strongly anisotropic but NaCl appears to be isotropic with respect to electric strength. No other members of the alkali halide family have been investigated but the discharge tracks from point electrodes have been extensively studied and they are preferentially directed in NaCl and other crystals. Isotropic electric strength is not easily reconciled with this fact. This work has been reviewed recently in detail (Davisson 1959).

In the previous investigation (Cooper, Grossart and Wallace 1957), apparently similar specimens of NaCl and KCl exhibited great variation in their electric strengths. The work of preparation limited the number of specimens in each group and it was not possible for statistical reasons to detect small differences in average electric strengths. The cause of this difficulty has been determined and it can be eliminated by using specimens appreciably thicker than the ones generally used in the past (Cooper and Smith 1961). Using thick specimens, we have re-investigated the electric strengths of NaCl, added to the previous work with KCl, and investigated KBr. The results obtained are stated below. The experimental method was similar to that adopted previously (Cooper and Fernandez 1958) but on this occasion a series of flat-topped impulses was applied to each specimen until it broke down. The amplitude of each impulse exceeded that of the previous one by not more than 3%. The specimens were all annealed.

The values of electric strengths quoted in Table 1 were obtained at 20°C from groups of NaCl specimens with the applied field in the directions stated. The 'equal component' specimens were cut so that the resolved component of the field was the same in a [100], a [110] and a [111] direction and it amounted to 89% of the applied field. The 25° specimens were prepared from plates obtained by cutting the parent crystals perpendicularly to the (001) planes and at 25° to the (100) planes. In Table 2 similar results are stated for KBr. The average electric strength of both materials is least in the [100] direction. The difference between this value for NaCl and the corresponding [110] value is small but application of Student's '*t*' test indicates it to be significant at the 5% level.

Table 1. Electric Strength of NaCl at 20°C

	Field direction	Electric strength (MV cm^{-1}) Max.	Av.	Min.	Variance	No.	Track
(*a*)	[100]	0·87	0·79	0·71	0·0026	24	[100]
(*b*)	[110]	0·89	0·83	0·74	0·0029	16	[110]
(*c*)	[111]	0·95	0·88	0·78	0·0032	12	[111]
(*d*)	25° to [100]	0·98	0·89	0·80	0·0027	25	[110] [100]
(*e*)	equal component	0·94	0·88	0·78	0·0023	22	[100]

Carbon electrodes; specimen thickness 0·050–0·070 cm; cavity radius 0·7 cm.

Table 2. Electric Strength of KBr at 20°C

Field direction	Electric strength (MV cm^{-1}) Max.	Av.	Min.	Variance	No.	Track
[100]	0·55	0·48	0·44	0·00142	11	[100]
[110]	0·65	0·60	0·57	0·00067	12	[110]
[111]	0·63	0·59	0·54	0·00040	11	[111]
25° to [100]	0·62	0·56	0·50	0·00027	11	[100]
35° to [100]	0·63	0·59	0·56	0·00046	10	field direction and [100]
equal component	0·59	0·55	0·51	0·0011	14	[100]

Carbon electrodes; specimen thickness 0·050–0·070 cm; cavity radius 0·7 cm.

Discharge tracks in directions other than the applied field were noted in both materials. Consideration of Table 1 and Table 2 indicates that breakdown occurred in the direction in which the resolved component of the applied field is equal to the electric strength. The behaviour of KCl is consistent with this. Previous experiments (Cooper and Fernandez 1958) have shown that the electric strength of unstrained [110] specimens is about $\sqrt{2}$ times that of similar [100] specimens and the discharge tracks in both groups were in [100] directions. In the present investigation an average electric strength of 0·73 MV cm^{-1} was obtained for thick 'equal component' specimens of KCl and 0·66 MV cm^{-1} for similar [100] specimens. Only [100] tracks were observed in both groups.

In the case of KBr, experiments were made at −190°C, −100°C, +20°C, +110°C and +170°C to determine if the preferred track direction depended on temperature. 'Equal component', uniform field specimens were used, and also specimens with embedded point electrodes of both positive and negative polarity. In these, breakdown occurred in the absence of ambient discharges. In all cases the discharge tracks were in [100] directions.

The present investigation, combined with that of Cooper, Grossart and Wallace (1957), shows that three members of the alkali halide family are anisotropic, the [100] direction being the weakest. The discharge track in a spherically symmetrical field should be in a [100] direction if it results from the primary electronic instability and not from other secondary processes resulting from this instability. This is the case in KBr and in KCl at low temperatures. Above about 150°C the conditions of breakdown in KCl may be modified by ionic migration (Cooper, Higgin and Smith 1960). The [100], [110] and [111] tracks were all observed in NaCl by Cooper, Grossart and Wallace (1957). This is attributed to the difficulty in producing a truly spherically symmetrical field in a material that is not very anisotropic.

It would be surprising if other members of the alkali halide family behaved qualitatively differently from KCl, KBr, and NaCl, and limited experiments suggest that NaF, and NaBr are respectively similar to KCl and NaCl. The evidence of isotropic behaviour usually quoted consists of experiments performed using small numbers of unannealed NaCl specimens. It is now evident that such experiments could not yield significant results.

Neither this investigation nor the previous one (Cooper, Grossart and Wallace 1957) has provided evidence of marked temperature dependent transitions in the preferred track direction (Davisson 1959). Caspari's investigation (1955) indicates that these occur when breakdown is initiated by discharges in the ambient near to the anode, a condition which did not arise in the present or previous investigation.

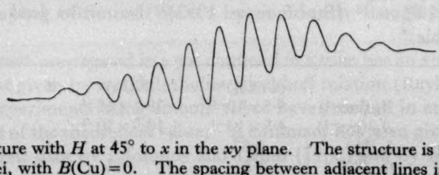
σ-bonding in $(CuCl_6)^{4-}$

Paramagnetic resonance methods have been used to investigate the electron distribution in $(CuCl_6)^{4-}$ complexes present in mixed crystals of $Cu:CdCl_2$ with $Cu:Cd \sim 1:200$. Extensive hyperfine structures from the Cl nuclei are found which indicate that there are surprisingly strong Cu–Cl σ-bonds. An example is shown in the Figure, where the Cu hyperfine structure is negligible and the Cl structure is particularly well resolved.



Hyperfine structure with H at 45° to x in the xy plane. The structure is from 4 equivalent Cl nuclei, with $B(Cu) = 0$. The spacing between adjacent lines is 14 gauss.

Previous measurements by Partridge (Orton 1959) have shown that the behaviour of the system is typical of that expected of a trigonally distorted octahedral complex of Cu^{2+} (Abragam and Pryce 1950, Bleaney, Bowers and Pryce 1955). For the present purpose the important point is that at 20°K there are, in addition to the trigonal distortion, frozen-in Jahn–Teller distortions, with the result that the Cu^{2+} ion sees a field of tetragonal symmetry with axis along a Cu–Cl bond direction. The ground state is then $d_{x^2-y^2}$ which bonds to four Cl^- ions. This is the state which has been investigated in detail at 20°K using wavelengths of 1·2 cm and 3·0 cm.

The results may be described by the spin-Hamiltonian

$$\begin{aligned}H_s=&g_{\parallel}\beta H_zS_z+g_{\perp}\beta(H_xS_x+H_yS_y)\\&+AS_zI_z+B(S_xI_x+S_yI_y)+P[I_z^2-\tfrac{1}{3}I(I+1)]\\&+A'S_xI_x^1+B'(S_yI_y^1+S_zI_z^1)+A'S_yI_y^2+B'(S_xI_x^2+S_zI_z^2)\\&+A'S_xI_x^3+B'(S_yI_y^3+S_zI_z^3)+A'S_yI_y^4+B'(S_xI_x^4+S_zI_z^4),\end{aligned}$$

where $S=\frac{1}{2}$, $I(\mathrm{Cu})=\frac{3}{2}$, $I(\mathrm{Cl})=\frac{3}{2}$, z is the distortion axis; the numbers 1, 2, 3 and 4 refer to the Cl ions on the positive and negative x and y axes respectively.

$g_{\parallel}=2{\cdot}339\pm0{\cdot}002$, $g_{\perp}=2{\cdot}070\pm0{\cdot}002$, $A=113\pm3\times10^{-4}\,\mathrm{cm}^{-1}$, $B=0{\cdot}0\pm4\times10^{-4}\,\mathrm{cm}^{-1}$, $A'=18{\cdot}5\pm1{\cdot}0\times10^{-4}\,\mathrm{cm}^{-1}$, $B'=5{\cdot}0\pm0{\cdot}5\times10^{-4}\,\mathrm{cm}^{-1}$. The limits of B were calculated assuming that the magnitude of P is approximately as found in most other Cu salts ($10\times10^{-4}\,\mathrm{cm}^{-1}$). In the Cl^- sub-Hamiltonians the dipolar interaction, the quadrupole interaction and direct effect of the field on the nucleus are omitted because they are negligibly small.

To interpret the Cl hyperfine structure it will be assumed that the distribution of the unpaired electron can be described by the antibonding molecular orbital

$$\Psi_{x^2-y^2}=N[(d_{x^2-y^2}-\alpha_s(\mathrm{s}_1-\mathrm{s}_2+\mathrm{s}_3-\mathrm{s}_4)-\alpha_{\mathrm{p}_\sigma}(-\mathrm{p}_1+\mathrm{p}_2+\mathrm{p}_3-\mathrm{p}_4)],$$

where s and p refer to chlorine 3s and $3\mathrm{p}_\sigma$ orbitals respectively; N is the normalization constant, and admixture coefficients α_s and $\alpha_{\mathrm{p}_\sigma}$ are expected to consist of an overlap term S plus a covalent bonding parameter λ, $\alpha\sim S+\lambda$ (see Freeman and Watson 1961, who also give earlier references). Overlap with other chlorine orbitals, e.g. 2s and $2\mathrm{p}_\sigma$, may also be important but will be omitted in order that a simple approximate estimate of the bond strength can be made. The chlorine hyperfine structure constants are then expected to be

$$A_s=\frac{16\pi\gamma\beta\beta_N}{3}N^2\alpha_s^2|\mathrm{s}(0)|_{3s}^2,\quad A_{\mathrm{p}_\sigma}=\frac{4\gamma\beta\beta_N}{5}\langle r_{3\mathrm{p}}^{-3}\rangle N^2\alpha_{\mathrm{p}_\sigma}^2,$$

where these are related to the experimentally observed quantities by

$$A'=A_s+2A_{\mathrm{p}_\sigma}\qquad B'=A_s-A_{\mathrm{p}_\sigma}.$$

Assuming that $|\mathrm{s}(0)|_{3s}^2=69\times10^{24}$ (Hartree and Hartree 1936) and that $\langle r_{3\mathrm{p}}^{-3}\rangle=55{\cdot}6\times10^{24}\,\mathrm{cm}^{-3}$ (Sternheimer 1953), the results lead to the values given in the Table.

	$(CuCl_6)^{4-}$	$(NiF_6)^{4-}$
A_s (cm^{-1})	$9{\cdot}5\times10^{-4}$	$39{\cdot}1\times10^{-4}$
A_p (cm^{-1})	$4{\cdot}5\times10^{-4}$	$10{\cdot}9\times10^{-4}$
f_s (%)	0·67	0·5
f_{p_σ} (%)	8·3	4·95

$f_s = N^2\alpha_s^2$ and $f_{p_\sigma} = N^2\alpha_{p_\sigma}^2$ can be regarded as the effective fraction of unpaired spin in a Cl 3s or $3p_\sigma$ orbital, subject to the approximations made above (neglect of 2s, $2p_\sigma$ etc.). The nuclear magnetic resonance results of Shulman and Knox (1960) on $(NiF_6)^{2-}$ are also given, where the σ-bonds are between $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ Ni^{2+} orbitals and 2s and $2p_\sigma F^-$ orbitals. It is seen that the two sets of results are consistent, in that the ratios of f_s/f_{p_σ} are much the same in each case, the bonding being stronger for Cl than for F, actually about twice as strong if allowance is made for the fact that in $(NiF_6)^{4-}$ $d_{3z^2-r^2}$, as well as $d_{x^2-y^2}$, can σ-bond to ligands on the x and y axes. The present results thus support these authors, Keffer *et al.* (1959) and Shulman and Sugano (1961), in suggesting that the admixtures in this type of complex are large and apparently much larger than estimates based on overlap effects alone with no covalent bonding.

The values of the parameters for the Cu^{2+} ion, A, B and g given above, also support the general picture of relatively strong bonding as can be seen by comparing the present results for $(CuCl_6)^{4-}$ with those of Bleaney, Bowers and Pryce (1955) for $Cu^{2+}(H_2O)_6$. Using the hyperfine structure theory of these authors, we find $p' = 2\gamma\beta\beta_N\langle r^{-3}\rangle N^2 = 212 \pm 15 \times 10^{-4}\,\text{cm}^{-1}$, which compares with $p' \simeq 300 \times 10^{-4}\,\text{cm}^{-1}$ for $Cu^{2+}(H_2O)_6$ and suggests that $N^2\langle r^{-3}\rangle$ is about 30% smaller in the present case. Similarly, the isotropic s electron contribution is found to be 25% smaller with value $\kappa p' = 73{\cdot}1 \times 10^{-4}\,\text{cm}^{-1}$, where $\kappa = 0{\cdot}345 \pm 0{\cdot}015$. Finally, the orbital part of the g value, $g-2$, is reduced in a manner roughly consistent with the other results, but a detailed analysis awaits optical measurements of the splittings of the d orbital levels.

Damping of Sound Waves by an Ideally Rough Surface

A sound wave propagated in a gas confined in a tube has an amplitude attenuation coefficient given by the Helmholtz–Kirchhoff relation (Rayleigh 1894). The majority of experiments using smooth tubes have resulted in attenuations about 15% in excess of the theoretical value. A summary has been given by Lee (1957) and more recent data by Edmonds and Lamb (1958) and by Smith and Wintle

(1960). When tubes with a rough surface are used the attenuation rises but no experiments have been carried out in which the change in attenuation could be compared with a numerical value for roughness.

In the present experiments a sound tube 39·1 cm long and 4·3 cm internal diameter was employed. Each end was closed by a telephone, one of which was fed from a variable-frequency oscillator at about 420 c/s. The amplitude and phase of the voltage output from the second telephone were compared with the input current using an oscilloscope. It can be shown (Zwikker and Kosten 1949) that with poor matching between telephones and gas column and with $\alpha \ll \omega/c$, the transfer impedance Z is given by

$$Z = \frac{E}{I} \propto \operatorname{cosech} ql,$$

using the notation of an earlier paper (Wintle 1960). As the frequency is increased Z executes a dumb-bell figure in the complex plane similar to that of sech $\frac{1}{2}ql$ (Wintle 1960, Fig. 2). The maximum value of Z is given by

$$\frac{1}{Z_{\max}} \propto \sinh \alpha l \simeq \alpha l,$$

while the phase angle ϕ taken with respect to the position of the maximum is given by

$$\tan\phi \simeq -\frac{2\pi(f-f_{\mathrm{n}})}{\alpha c},$$

where f_{n} is the resonance frequency.

The roughness of the sound tube was increased by gluing ball bearings 0·63 cm in diameter to its inner surface. They were placed in rows and arranged randomly along the length of the tube, the least number of rows employed being three. The increase in roughness was presumed to be proportional to the number of balls used. An approximate value for the attenuation due to a sphere placed on the surface of the tube can be calculated by comparing the forces exerted on unit area of the cylindrical surface and on the sphere when subjected to unidirectional Poiseuille flow. The force on the surface is simply $\eta(dv/dx)$, where η is the coefficient of viscosity, v the gas velocity and x the coordinate normal to the surface. The mean velocity past the sphere will be approximately $v(a)$, where a is the radius of the sphere. Since $v(0)=0$, this becomes $a(dv/dx)$ and the drag given by Stokes' relation is therefore $6\pi\eta a^2(dv/dx)$. With n spheres per unit area the total viscous force is

$$\eta(1+6\pi a^2 n)\frac{dv}{dx} = \eta\left(1+\frac{3a^2N}{rl}\right)\frac{dv}{dx},$$

where N is the number of balls in the tube, r the radius and l the length of the tube, so the viscous force should be increased in the ratio $1+3a^2N/rl$ compared with that for a perfectly smooth tube. Under oscillatory conditions an increase in attenuation of this order of magnitude must be expected. A graph of α against N should therefore be linear with a slope of about $3\alpha_{\mathrm{HK}}a^2/rl$.

The experimental plot is shown in Fig. 1. The individual values of α are correct to about 3%. The graph is linear as expected, with a slope $3{\cdot}6\times10^{-6}$ cm^{-1} per ball to be compared with the calculated value of $1{\cdot}0\times10^{-6}$ cm^{-1} per ball. The attenuation with no balls present is three times that expected for a perfectly smooth tube.

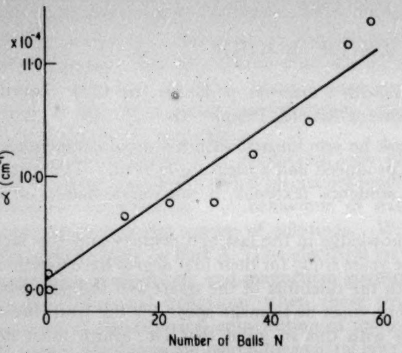

Fig. 1. Graph of attenuation against number of balls in the sound tube.

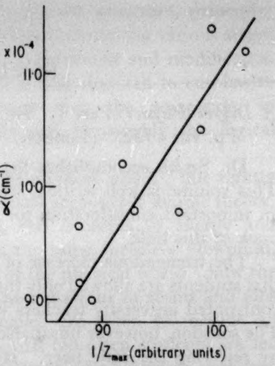

Fig. 2. Graph of attenuation against $1/Z_{\text{max}}$. The straight line passes through the origin, indicating direct proportionality.

A graph of $1/Z_{\text{max}}$ against α is shown in Fig. 2. The straight line is drawn through the mean of the experimental points and the origin and shows that within the experimental error these quantities are in direct proportion, thus establishing the satisfactory operation of the apparatus. It is therefore concluded that the attenuation of sound increases linearly with the numerical measure of the roughness of the tube, and that the magnitude of this increase agrees within a factor of four with that expected upon the basis of an extremely simple approximate theory.

REVIEWS OF BOOKS

A Degree Physics, Part I: *The General Properties of Matter*, by C. J. SMITH. Pp. viii + 732. (London: Edward Arnold, 1960.) 63*s*.

Dr. Smith accomplishes the task he sets himself with his usual competence. This volume is well written, well produced and a pleasure to read. The price, an important consideration for a students' textbook, is not unreasonable for a book of this bulk.

The tremendous increase of knowledge in the last half century and the fact that students are allowed only three years study for their first degree have together confronted university teachers with the dilemma of the quart and the pint pot. The solution, however unsatisfactory, must be to make space for the fresh brew by rejecting the stale beer. It is with this in mind that Dr. Smith must be criticized; his book fails to fill the requirements of an English university student of physics in the middle of the twentieth century. It treats in great detail many well-established topics but sadly lacks any novelty of approach.

To illustrate this criticism two examples may be chosen. The subject of surface tension is discussed in some seventy pages. Two short paragraphs ' explain ' surface tension as a result of intermolecular attraction but no description or explanation of intermolecular forces is given. Nearly two hundred pages are devoted to elasticity and the strength of materials. A description of a method of determining Poisson's ratio for a piece of tubular rubber is given but no account of the elastic properties of a single crystal.

In his preface Dr. Smith regrets that the choice of subject matter is in part fixed by university examination syllabuses. One can sympathize with him, but he alone is responsible for the presentation, and it is difficult to reconcile the above examples with the claim that " the book is written to meet the needs of those who wish to gain a thorough insight into the fundamentals of physics . . . . ."

To sum up, the book is well written and should be in university libraries as a work of reference for students. The length of the book and its selection of material make it unlikely that it will become a standard textbook. J. A. NEWTH.

Structure and Change: *An Introduction to the Science of Matter*, by G. S. CHRISTIANSEN and P. H. GARRETT. Pp. xv + 608. (San Francisco, London: Freeman, 1960.) 63*s*.

This book does not fit into any of the categories of textbooks normally published in this country, but it leaves one with the impression that the general state of scientific education here would be better if such books were less exceptional. After studying it any intelligent person with no previous training in physics or chemistry and with only the most elementary knowledge of mathematics would have a real understanding of the nature of the physical world and of how our understanding of it has been obtained. I should like to see it made compulsory reading for *all* sixth-form pupils or first-year undergraduates.

The authors have, at the outset, rejected the distinction between physics and chemistry, and the anatomization of these subjects into such moss-encrusted sections as heat, light, sound, properties of matter, and organic, physical and inorganic chemistry. They discuss in general terms the structure, principles and methods of science, pointing out the relationships between the various stages of observation, generalization, hypothesis, further experiment and modification of hypothesis. My only criticism of this section is that they fail to emphasize how greatly the physical sciences have profited from the possession, in mathematics, of a means of examining rapidly and thoroughly the logical consequences of a postulate.

Part 1 is entitled 'The mechanical view of the physical world', but rightly adds to what is normally called mechanics mechanistic accounts of atomic theory, chemical combination, the behaviour of gases, the concepts of energy and momentum and the nature of solutions. With the same inclusive viewpoint, the authors show in Part 2, 'The electrical view of the physical world', how the principles of electricity and magnetism govern the behaviour of atoms and ions in their chemical behaviour when these principles are taken to include an account of the electrical constitution of matter. All too often students are led to regard physics as the search for general laws governing the *behaviour* of things, and find later with surprise that much of the activity of physicists is concerned with finding ways of describing the *constitution* of things, whether these are nuclei, atoms, solids or stars. A common manifestation of this is a dreadful ignorance of the Periodic Table, a topic returned to several times in this book.

The last part of the book provides a simplified, but not misleading, account of modern physics, including the nature of light, quantum theory, radioactivity, and nuclear reactors, and a final chapter glances rather hastily at some of the most fundamental topics in atomic and cosmic physics. The whole book is well supplied with diagrams which are with very few exceptions clear and helpful, and each chapter is followed by questions which are by no means simply arithmetic and which should help any serious student. Some mathematical operations and some techniques of chemical book-keeping are given in appendices.

Only two criticisms seem worth mentioning. Chapters 15 and 24, The mechanical and chemical views of the earth, by their inevitable differences in approach from those preceding and following them, break the flow of the book, and would be better together at the end; and a chapter on oxidation–reduction reactions serves to introduce some rather arbitrary techniques and terminology (how, in the sense in which the term is defined earlier, does hydrogen increase its valence on being oxidized to water?) which add nothing to an understanding of the constitution or behaviour of matter.

These are minor flaws, and I can think of no better book to recommend to any arts graduate or undergraduate wishing to have a foot in both cultures.

B. R. COLES.

Fourier Transforms: *Cambridge Tracts in Mathematics and Mathematical Physics*, No. 52, by R. R. GOLDBERG. Pp. viii + 76. (London: Cambridge University Press, 1961.) 21*s*.

This monograph deals directly with mathematical rather than physical theory. Using the ideas of Lebesgue integration, Dr. Goldberg describes the theory of Fourier transforms of integrable-modulus and integrable-square functions so as to provide an introduction to the generalized theory of Fourier transforms on a locally compact group. The latter theory has applications of physical interest, but these are not discussed in the present work, and indeed the extension beyond transforms on the real line is confined to seven pages of appendix.

After a short first chapter which recalls the necessary definitions and theories on the Lebesgue integral, the second chapter, which is half the book, is devoted to the Fourier transforms of functions in L^1, that is, functions of integrable modulus. Every such function has a Fourier transform which is continuous on the real line and vanishes at $\pm\infty$. However, not all functions with these two properties are Fourier transforms, and not all Fourier transforms of functions in L^1 lie themselves in L^1. Inversion then is dealt with by using the convergence factor, $1-|x|/R$ between $-R$ and R and zero outside that range, then letting $R\rightarrow\infty$. The problem of what sort of functions are Fourier transforms is then discussed, leading up to the remarkable theorem of Wiener that, if the Fourier transform of a function in L^1 is nowhere zero, then any function of L^1 can be constructed as a linear combination of the original function with itself translated by various amounts (more precisely, L^1 is the closure of the set of translates of this function).

A shorter chapter on the transforms on L^2 is followed by a discussion of generalizations of Wiener's theorem, stopping at the point where functional analysis is needed for further progress. There is a final chapter on the Fourier–Stieltjes transform and Bochner's theorem, and a short appendix on abstract harmonic analysis on groups more general than the real line.

This book is very clearly written and makes an admirable guide through the thickets of real variable theory. It is well worth reading even if one has no immediate need to advance into abstract harmonic analysis, but intends rather to turn back from the guided path to a more detailed study of the classical theory.

GEORGE WYLLIE.

The Theory of Neutral and Ionized Gases, edited by C. DEWITT and J. F. DETOEUF. Pp. 469. (London: John Wiley, 1961.) 140*s*.

This book is based upon the lectures given at the 1959 Summer School at Les Houches. There were seven lecturers and the scope of their lectures was rather more general than the title suggests. The first article is by E. W. Montroll on modern developments in statistical mechanics, being mainly concerned with the diagrammatic expansions which have recently been applied to equilibrium and to transport problems. There is also an account of random walk problems and the Ising problem. L. van Hove's article is concerned with transport theory and the problem of relating the Pauli and Boltzmann equations to the new closed forms for transport coefficients. The current situation as described by these two articles has enormously clarified in the last few years, but this clarification has amounted to vigorously justifying results already known by other methods. The time should now be ripe for really new ground to be explored, and these articles are a very good introduction to the current situation.

The remaining articles on ionized gases fall into three classes. Those of J. L. Delcroix and A. N. Kaufman and J. F. Denisse on the microscopic properties of plasmas (in French), plasma transport theory and waves in plasmas (in French), respectively, can be regarded as concerned with ideal plasmas, i.e. those properties corresponding to simple physical situations which may be far removed from those obtained in important practical cases. The lectures of M. Kruskal are concerned with the problems of stability based on hydromagnetic equations. The final article by E. Schatzman (in French) applies plasma theory to astrophysical problems. Again these articles are an excellent introduction to the current situation in plasma theory. The book is rather expensive but it must be admitted that it is beautifully produced. S. F. EDWARDS.

The Application of Group Theory in Physics. By G. YA. LYNBARSKII. Translated from Russian by STEVAN DEDIJER. Pp. ix + 380. (London: Pergamon Press, 1960.) 63*s*.

This is a translation of a Russian textbook based on the author's lectures at Kharkov University. It commences with a general introduction to groups and their representations, followed by chapters on particular topics. For finite groups the applications are to the theory of small oscillations, second-order phase transitions, crystal properties and the absorption and Raman scattering of light. Of particular interest is the chapter on phase transitions, since apart from a brief discussion in Landau and Lifshitz's book this is not available elsewhere and here it is given in some detail. On infinite groups there are chapters on Clebsch–Gordon and Racah coefficients, on the Lorentz group, relativistic wave equations, and on the application of group theory to nuclear reactions.

The main trouble with books on group theory, and even more so with chapters on group theory in more general books, is that they do not usually go into their subject sufficiently fully for the reader to master an application, before they move on to another field. On the whole this book avoids this trouble, though the Lorentz group for example cannot be thoroughly discussed in thirty pages. Almost any theoretical physicist will find reading this book worth while and probably find some new approach or new application in it. There is however one serious drawback to it: it is quite deplorably printed. It is produced by photolithography direct from a type and handwritten manuscript. Group theoretical formulae usually involve lots of subscripts and superscripts and these are quite often illegible, and these and other symbols are sometimes completely missing. If Pergamon want to produce books this way the least they could do is to buy a decent typewriter and employ a competent proof reader. The reviewer's copy had but half an index; where the other half ought to have been was an apology from the publisher for the state of the book and its price which were excused " with a view to making the information contained in this publication speedily available ". In fact group theory cannot be regarded as hot news and one hopes that standard Russian texts will be treated better than this in future. S. F. EDWARDS.

A Bibliography of The Honourable Robert Boyle, by J. F. FULTON. Pp. 217 + xxvi. (Oxford: The Clarendon Press, 1961.) 50*s*.

This second edition of the Bibliography of Robert Boyle coincides with the Tercentenary of the Royal Society

Since the first edition of the Bibliography in 1932, a number of fresh studies of Boyle and various aspects of his life and work have become available, and discussion of these is included in the new edition.

Introduction à l'Électrodynamique Quantique, by D. KASTLER. Pp. xiii + 333. (Paris: Dunod, 1961.) 68 n fr.

One might expect a Frenchman to be as exact and elegant as possible. Professor Kastler does not disappoint on this score. His book on elementary quantum electrodynamics uses the resources of modern pure mathematics to present an exposition of its subject which is as logically precise as possible. It is his hope thereby simultaneously to clear the minds of physicists, who may be bewildered by false difficulties which arise from imprecision of statement, and also to present the subject in a form which is accessible to pure mathematicians without the need of conscious slumming. In this he succeeds, but it seems doubtful to this reviewer that many fruitful consequences will flow from it.

Quantum electrodynamics is in excellent agreement with experiment. The apparent juggling with infinities in the renormalization programme should not be taken too seriously. The difficulties here are really physical rather than mathematical for it seems reasonable to suppose that the quantities would be finite if we understood the details of the theory at short distances. In fact a renormalizable theory is simply one whose low energy behaviour can be predicted without a detailed knowledge of its high energy structure. The real formal difficulties of quantum electrodynamics are largely concerned with the proper formulation of the Lorentz condition and gauge invariance, and within its elementary limits this book gives a good account of them.

The first two chapters are devoted to mathematical preliminaries and then the theory of second quantization is developed. There are chapters dealing with the Klein–Nishina formula and Compton and Møller scattering. The book concludes with the introduction of Feynman graphs and the use of external fields. It does not deal with renormalization theory. Thus the material is as elementary as the style is advanced. J. C. POLKINGHORNE.

Proceedings of the VIIth International Conference on Low Temperature Physics, edited by G. M. GRAHAM and A. C. HOLLIS HALLETT. Pp. xviii + 725. (Toronto: University Press; Amsterdam: North Holland, 1961.) £5 14*s*.

No doubt this was a very enjoyable and profitable beano for those who enjoy and profit from such beanos. Only I cannot imagine why all those reputable scientists should want to *publish* the scraps of information which they communicated there. Either they had something new and important to say, when it should have been published (i.e. *made public*) in a standard scientific journal, available in any ordinary scientific library, or else it was old, or unimportant, and there was no need to waste print on it. It has been suggested to me that I should compliment the editors and publishers for getting it out so quickly. Certainly, by the usual standards of such publications, eight months is quite expeditious; but may I remark that any physics journal that took so long between receipt of the manuscript and publication would be considered a bit dilatory. The fact is that large expensive miscellanies of this sort are a curse to modern science. Let us all resolve never to make reference to them (it is difficult enough anyway, the title being more a dinner than a mouthful) so that no one ever looks at them, libraries will not buy them, and publishers will refuse to touch them for lack of a profit. J. M. ZIMAN.

Fundamentos Teóricos de la Física Atómica y Nuclear, by C. SÁNCHEZ DEL RIO. Pp. vi + 167. (Madrid: Servicio de Publicaciones de la J.E.N., 1960.) 175 Pesetas.

The purpose of this book is to provide a qualitative introduction to the theories of the atom, the nucleus and elementary particles. It is meant for two classes of readers: students who are just starting the study of such theories, and engineers and others who are dealing with the technical aspects of atomic energy and want to have at least some notions of current theoretical ideas.

For this second class of readers the book should succeed admirably because the exposition is always as simple as the subject allows it to be and is based on semi-classical arguments, while providing, however, substantially sound information, even on such concepts as ' isotopic spin ', ' non-conservation of parity ', or ' strangeness '. As for students, one is doubtful. It is certainly an advantage to be introduced without tears to the concepts of modern physics, but in a field in which the point of view, the methods, the approximations, the very mathematical techniques are of paramount importance and are inextricably mixed up with the physical results, an introduction which gives these results in a dogmatic way (even if the doubtful points are fairly stressed) may not lead to the right frame of mind in approaching the subject.

The titles of the eight chapters are: ' Basic ideas on atoms and nuclei ', ' Fundamental concepts of quantum theory ', ' Structure of the atom ', ' Interactions between particles and between particles and radiation ', ' Structure of the nucleus ', ' Nuclear levels ',' Nuclear reactions ', ' Elementary particles '. There are two mathematical appendices, a table of constants and a list of books for further reading. This small volume is well produced and will undoubtedly become very popular in Spanish-speaking countries. L. PINCHERLE.

Praktische Mathematik für Ingenieure und Physiker, by R. ZURMÜHL. Pp. xiv + 548. (Berlin, Göttingen, Heidelberg: Springer, 1960.) DM 29.40.

This book is an introductory reference work for those who, using desk calculators, have frequent occasion to use numerical methods to solve their problems. The inversion of a matrix, eigenvalue problems, questions of numerical integration, the significance of the χ^2-test are some of the topics treated.

The author gives in most cases a good account of the background theory (without getting lost in it), and then takes off his jacket in order to work through a few numerical examples which illustrate the procedures which he has discussed. This, together with clear diagrams and a lucid style, makes this handbook of numerical analysis very useful. It must be highly recommended as a first reference, with the aid of which one may hope to avoid recourse to a more specialized literature.

The contents include the following: (1) Methods of solving equations of third, fourth or higher order; (2) Linear equations and manipulation of matrices; (3) Interpolation and integration; (4) Statistical methods; (5) Representation of arbitrary functions, including harmonic analysis; (6) Initial and boundary value problems in differential equations. P. T. LANDSBERG.

The Principles of Nuclear Magnetism: *International Series of Monographs on Physics*, by A. ABRAGAM. Pp. xvi + 599. (London: Clarendon Press, Oxford University Press, 1961.) 84*s*.

A theoretical argument does not become acceptable to Professor Abragam until he has reproduced it in his own way. Although the subject of nuclear magnetism is a fairly new one, there exists, scattered through the literature, a considerable amount of theory. This has all been brought together in the present volume and presented in a clear, comprehensive and thoughtful way, so that throughout one feels guided by an author who not only has the whole subject at his fingertips but who has also gone to immense trouble to present the arguments in the most instructive ways. Mathematics is not avoided, but it is not indulged in for its own sake, and it is continually reinforced by physical arguments and well-chosen experimental results.

The result is a lengthy but invaluable account of the whole field of nuclear resonance and the associated phenomena of nuclear magnetism, and a book of which the author and publishers can well be proud. Your reviewer is very impressed by the high standard of scholarship maintained throughout, and although one might hesitate to recommend the book as a first introduction to nuclear magnetism, it is obviously a text to which all serious workers in this field will refer repeatedly. As for its contents it is sufficient to say that all the theory is there, even including topics such as cross-relaxation, which can hardly have been discovered when the manuscript first went to press.

A Direct Measurement of the Proton Total Reaction Cross Section for Copper at 9·3 MeV

By G. W. GREENLEES and O. N. JARVIS†

Department of Physics, University of Birmingham

MS. received 31*st May* 1961

Abstract. A value of 930 ± 70 mbn has been obtained for the proton total reaction cross section for copper at 9·3 ± 0·3 MeV by a poor geometry transmission method not involving counter coincidence techniques. This result, which is in good agreement with values obtained by indirect methods, is appreciably higher than values predicted by published optical model analyses using a volume absorption term. Differential elastic cross sections are presented for the angular range 30°–155° (centre of mass). These were obtained using the same target as in the reaction cross section measurement. Good agreement with both the differential cross sections and the reaction cross section can be obtained using an optical model potential with an absorptive term peaked at the nuclear surface.

§ 1. Introduction

During the past few years the measurements of proton–nucleus elastic scattering angular distributions has received considerable attention in the low and intermediate energy regions and considerable success has been achieved in describing the results in terms of the optical model (Glassgold *et al.* 1957, 1958, Melkanoff *et al.* 1957). This model has also been found capable of reproducing the general features of such polarization measurements as have been made (Rosen and Brolley 1958) but, unfortunately, it has been found to be incapable of fitting the available data uniquely, this failure giving rise to the familiar V–R ambiguity relating the possible sets of parameters judged to represent equivalent fits to the data. This ambiguity should be resolvable, at least in part, by a comparison of accurate total reaction cross section measurements with the predictions made by the model for each of the different sets of parameters. As yet, few total reaction cross section measurements have been made in the proton energy range below 100 MeV owing to the experimental difficulties involved.

For proton and deuteron energies of only a few MeV, the total reaction cross section can be determined as a sum of all the various partial reaction cross sections that are significant. Thus Slaus and Alford (1958) have measured the total reaction cross section for 4 MeV deuterons on ^{63}Cu as the sum of the cross sections for the (d, d′), (d, n), (d, p), (d, α) and (d, pn) reactions. This procedure is particularly simple when one type of reaction makes the dominant contribution. At higher energies this method becomes less satisfactory owing to the increasing number of reactions that are energetically possible. Recently, however, measurements at 9·85 MeV have been reported by Meyer and Hintz (1960) of the proton total reaction cross sections for copper and zinc. These determinations were made by measuring the total charged particle reaction cross sections and combining the results with existing measurements of the (p, n) cross sections. The results of the work, which are in good agreement with the present determination, will be discussed in some detail in a later section. Finally, Fulmer (1959) has obtained determinations of the proton total reaction cross sections for the uranium isotopes at 23 MeV; this is a special case since the fission cross sections make an 80–90% contribution.

---

† Now at Atomic Energy Research Establishment, Harwell.

Total proton reaction cross sections have been measured by direct transmission methods at several energies above 200 MeV, at 134 MeV (Cassels and Lawson 1954) and, more recently at 61 and 34 MeV (Meyer, Eisberg and Carlson 1960, Gooding 1959). These experiments involve the use of counter coincidence techniques to determine the attenuation of the proton beam on placing the absorber between a set of 'passing' counters and the final detector. At high energies such experiments are not greatly troubled by the energy loss due to ionization in the passing counters and the absorber, but at lower energies the specific ionization increases rapidly and at 10 MeV constitutes the dominating feature of this type of measurement.

Because of the short range of protons at 10 MeV, the present experiment was designed to use no 'passing' counters to define the beam but to rely on the beam intensity remaining constant over a short time interval whilst the counting rate was determined with and without the absorber in position. The experiment is only practicable using an accelerator providing a continuous beam; in the present work, the Birmingham 60 in. cyclotron was used. The statistics of the experiment are those appropriate to a Poisson distribution so that at least 10^{10} protons must be recorded in order to obtain a 5% result with a copper absorber 0·6 MeV thick, since such an absorber gives an attenuation due to non-elastic processes of only 0·02%. Copper was chosen for the present measurement because this element has been the subject of detailed optical model analyses and both angular distribution (Hintz 1957, Greenlees, Kuo and Petravic 1957) and polarization (Rosen and Brolley 1958) data are available; also it is an element for which the optical model is expected to apply using 10 MeV protons.

§ 2. EXPERIMENTAL METHOD

As mentioned above, advantage is taken of the fact that the fixed frequency cyclotron is not a pulsed machine and that the beam intensity can be held reasonably constant over short time intervals. With a beam of sufficiently constant intensity it would be possible to measure the total reaction cross section simply by making counting rate determinations with and without the copper absorber in position. In practice, however, the measurements were repeated cyclically with a fairly rapid repetition rate (nearly twice per second) so that any fluctuations in the intensity of the beam averaged out over a sufficient number of cycles. The requirement of a constant intensity was further relaxed by the use of a monitor counter which sampled the beam entering the experimental area. In principle, using a monitor, constancy of beam intensity is no longer important; it does, however, enable higher mean counting rates to be used and this is essential from a practical viewpoint.

The measurement of the beam intensity was made in poor-geometry using a large, accurately defined, acceptance angle subtending a cone of half-angle

θ (~ 50)° at the absorber. A separate experiment was performed to determine the magnitude of the correction term required to allow for the elastic scattering of protons through angles greater than θ. A large acceptance angle was used to reduce the error introduced into the elastic scattering corrections by the uncertainty in this angle. A second correction term was also required to give a measure of those inelastic events occurring in the absorber which give rise to charged particles entering the detector with energies sufficient to overcome the set detector bias (E_{min}). This term was necessary since it was not possible to bias the detector just below the pulse height corresponding to elastically scattered protons because of the rather poor resolution given by the plastic scintillator used as a detector and because, at the counting rate used throughout the experiment (about 3×10^5 pulses per second), fluctuations in the gain of the electronics must be expected. The bias was set to 50% of the peak height. The magnitude of this non-elastic scattering correction was small and could be estimated from the results of Meyer and Hintz (1960).

Owing to the possibility of the incident protons undergoing nuclear interaction in the scintillation material, as well as in the copper absorber, it was necessary to ensure that the beam energy at the detector be the same for the two counting rate determinations. A comparison absorber of gold, which was chosen so as to give an energy degradation equal to that of the copper, was therefore placed in the beam during the 'no-absorber' measurements. The total reaction cross section for copper was determined from the measurement of the counting rate ratio $R(\theta)$, which gives the relative counting rates with the copper and gold absorbers in the path of the beam. The necessity for introducing this comparison absorber had the unfortunate consequence that the appropriate elastic scattering correction was large, being several times the magnitude of that for the copper absorber. It was therefore necessary to determine this correction accurately. The choice of gold for the comparison absorber was indicated by the small total reaction cross section for 10 MeV protons, this being less than 10% of that for copper owing to the relatively high Coulomb barrier. Since the thickness of the gold absorber (measured in terms of number of nuclei per cm^2) required for the energy compensation was less than one half of that for the copper absorber, it is seen that the total reaction cross section for gold makes only a 4% contribution to the result of the experiment; a rough estimate of its magnitude was therefore sufficient. This was obtained for published optical model predictions based on the results of Hintz (1957) at 9·8 MeV.

The total reaction cross section for copper may be expressed in terms of the measured ratio $R(\theta)$ and the various correction terms mentioned above in the following form

$$\sigma_{\mathrm{R}}(\mathrm{Cu}) = \frac{N_{\mathrm{Au}}}{N_{\mathrm{Cu}}}\left[\int_{\theta}^{\pi}\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{el,Au}} d\Omega + \sigma_{\mathrm{R}}(\mathrm{Au})\right] - \int_{0}^{\pi}\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{el,Cu}} d\Omega$$

$$+ \int_{0}^{\theta}\int_{E_{\text{min}}}^{E_{\text{max}}}\left(\frac{\partial^2\sigma}{\partial\Omega\,\partial E}\right)_{\text{non el,Cu}} d\Omega\, dE - \frac{1}{N_{\mathrm{Cu}}}\left[R(\theta) - 1\right]$$

where N_{Au}, N_{Cu} are the surface densities (number of nuclei per cm^2) for the two absorbers.

§ 3. Apparatus and Procedure

3.1. *The Absorption Measurement*

A diagram of the apparatus is shown in Fig. 1. This consisted essentially of a vacuum chamber in which the counting rate determinations were made, and a counting rate monitoring unit which recorded protons elastically scattered from a thin gold foil placed in the path of the collimated beam. The vacuum chamber contained a rotating wheel which placed alternately the copper and the gold absorbers in the path of the beam before the main detector unit. Two sets of scaling units were coupled to each of the two particle detectors and these were gated on and off in synchronism with the rotation of the wheel such that one set was operative when the copper absorber was in the beam and the other set when the gold absorber was in the beam. The gates were opened by pulses from two photomultipliers (not shown in the diagram) attached to the chamber upon which light was allowed to fall each time the wheel passed through two positions; the gates were closed precisely 0·16 sec later by a delayed signal derived from a 1 Mc/s crystal oscillator and a bank of scaling units. In this manner the gate-open periods for the two absorbers were made equal to better than one part in a million.

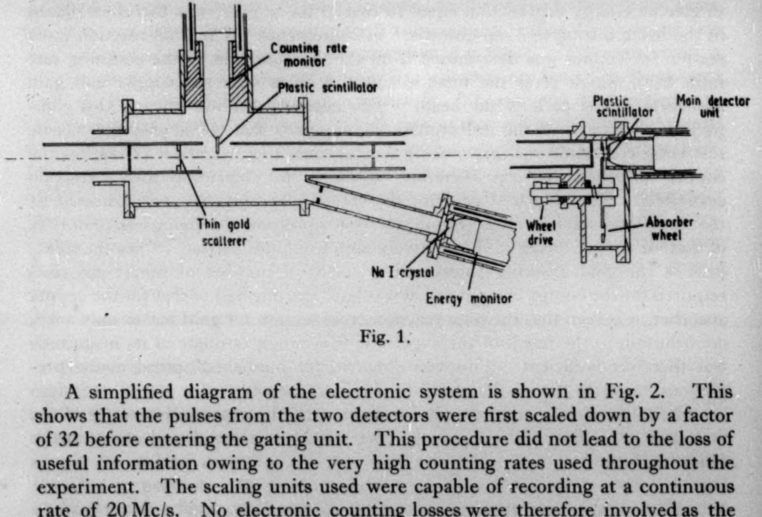

Fig. 1.

A simplified diagram of the electronic system is shown in Fig. 2. This shows that the pulses from the two detectors were first scaled down by a factor of 32 before entering the gating unit. This procedure did not lead to the loss of useful information owing to the very high counting rates used throughout the experiment. The scaling units used were capable of recording at a continuous rate of 20 Mc/s. No electronic counting losses were therefore involved as the cyclotron radio frequency is only 10 Mc/s. The acceleration is such that if two or more protons are accelerated together during the same radio-frequency period the time spread between them will be less than 20 nsec; the scaling units were set so that they would not record such protons separately. Thus, the counting rate correction for the experiment was dependent only on the cyclotron beam intensity and the radio-frequency acceleration period. A pulse sampling system was constructed which accepted a small fraction of those pulses recorded by the input circuit and displayed them on a 100-channel pulse height analyser. This gave a visual display of the bias level setting and also of the fraction of the spectra which comprised two or more protons simultaneously accelerated and recorded; the counting rate correction was therefore given uniquely by this system. The possibility of electronic gain drifts in the various units was unimportant owing to the rapidity with which the comparative counting rate determinations were made and the fact that those units in which the drift could affect the result were common to both counting channels.

Fig. 2.

The Birmingham 60 in. cyclotron was originally designed for the acceleration of H_2^+ ions but, by reducing the magnetic field to half, and with the aid of current shims on the magnet pole faces to shape the field, free protons can be accelerated (Fremlin, Hardy and Shaylor 1959). It was this 'half-field' beam which was used in the present experiment. A difficulty in using the beam arose when it was found that a range of energies could be obtained under different machine conditions for the low circulating currents used. To overcome this difficulty a beam energy monitor was included in the apparatus to give a continuous check on the energy and to relate the energy at which the absorption measurement was made to that at which the elastic scattering corrections were determined. This monitor unit consisted of a scintillation counter set to receive protons elastically scattered through 15° by the thin (80 kev) gold foil placed in the path of the beam (Fig. 1). Half of the acceptance window of this counter was covered by a 100 mg cm^{-2} aluminium foil, with the result that the recorded pulse spectra showed two sharp peaks, the relative positions of which could be related directly to the beam energy. Energy changes of the order of 30 kev could be detected with this system.

3.2. *Elastic Scattering Corrections*

The elastic scattering corrections were determined with a separate scattering chamber. Only a brief description of this chamber will be given here since a more detailed description may be found in a previous paper (Greenlees, Kuo and

Petravic 1957). After collimation the beam passed through the target; the scattered beam was detected in a scintillation counter and the unscattered beam was collected in a Faraday cup. The scintillation counter, which was also used as the energy monitor in the absorption measurement, was mounted on the lid of the chamber so that the line joining the centre of the target to the detector made an angle of 15° with the horizontal plane containing the incident beam; as a result of this geometry, scattering angles between 15° and 165° could be studied. Pulses from the detector were displayed on a 100-channel pulse height analyser gated to record until a specific charge had been collected by the Faraday cup. Absolute cross sections could be measured with an accuracy to ±1% using this apparatus.

In order to determine the correct elastic scattering corrections it was considered desirable to perform this part of the experiment using targets which presented the same surface density to the beam as those used in the absorption measurement. Consequently, two targets were used for each angular distribution; the first, being set normal to the beam direction, was used for scattering angles θ in the range $30° < \theta < 75°$ and $105° < \theta < 165°$, the second being set at 45° to the beam direction, was used for $75° < \theta < 105°$. The beam energy at which these angular distributions were obtained was determined from the range of protons as measured in a nuclear emulsion (Ilford C2) using the range–energy data of Shapiro (1958). The value so obtained was found to compare well with that obtained from the constants of the scattering chamber and of the Faraday cup beam integrator unit on the assumption that the scattering from gold follows the Rutherford formula exactly for forward scattering angles.

The differential elastic scattering cross sections for gold were found to follow the Rutherford formula closely for scattering angles below 70° and to fall off gradually with increasing angle above this value. The maximum (extrapolated) deviation from the Rutherford formula was only 10% at 180°. The results for copper are given in Table 1; these measurements are in close agreement with earlier results obtained in this laboratory at a comparable energy (Greenlees, Kuo and Petravic 1957). In order to obtain the elastic scattering correction, the cross section data was integrated numerically over the relevant angular ranges and the energy E was adjusted according to the Rutherford $1/E^2$ relationship so as to be appropriate to the absorption measurements.

§ 4. RESULTS

The absorption apparatus was first tested without the absorbers in position to ensure that there was no asymmetry between the two counting channels. No evidence for such an effect was obtained. A measurement was next undertaken, with the absorbers in position, to discover whether the observed result depended on the bias level of the input circuitry. Bias settings of 25% and 40% of the peak pulse height gave counting rate ratios $R(\theta)$ which differed from unity by $(33 \pm 2) \times 10^{-5}$ and $(32 \pm 2) \times 10^{-5}$ respectively. These results set an upper limit on the magnitude of any bias dependent effects which might have been present. Unfortunately, the energy monitor was not used in this first experiment and the beam energy was uncertain to ± 150 kev so that an absolute uncertainty of ± 9% exists in the resultant value for σ_R(Cu). This large error for an uncertainty in energy of ± 150 kev is due to the large Coulomb scattering from the gold (see Table 2).

Table 2. A Typical Set of Results

Element	Surface density	Energy equiv. at 9·7 Mev
Au	34·8 mg cm^{-2}	0·630 ± 0·006 Mev
Cu	22·6 mg cm^{-2}	0·638 ± 0·006 Mev

Proton energy (lab)	9·30 ± 0·05 Mev
$R\ (\theta = 48^\circ\ 30')$	1·000328 ± 0·000016
$\frac{1}{N_{\mathrm{Cu}}}(R(\theta)-1)$	−1530 ± 70 mbn
$\frac{N_{\mathrm{Au}}}{N_{\mathrm{Cu}}}\int_{\theta}^{\pi}\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{el,Au}} d\Omega$	+2840 ± 70 mbn
$-\int_{\theta}^{\pi}\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{el,Cu}} d\Omega$	−420 ± 10 mbn
$\int_{0}^{\theta}\int_{E_{\mathrm{min}}}^{E_{\mathrm{max}}}\left(\frac{d^2\sigma}{d\Omega dE}\right)_{\mathrm{non\ el,Cu}} d\Omega dE$	+29 ± 6 mbn
$\frac{N_{\mathrm{Au}}}{N_{\mathrm{Cu}}}\sigma_{\mathrm{R}}(\mathrm{Au})$	+40 ± 7 mbn
Energy balance correction	+6 ± 4 mbn
Correction for finite beam pencil	+15 ± 3 mbn
Correction for scintillator response variation	−50 ± 25 mbn

Final value for σ_R(Cu) averaged over three runs = 930 ± 70 mbn.

Note. Probable errors are quoted in this table.

A second experiment was performed (with a different pair of absorbers) during which the beam energy was monitored using the system described previously; a result was obtained with a similar statistical uncertainty to that of the previous measurements. After being suitably weighted the several results were combined to give a single cross section. Before a final value for the total reaction cross section for copper can be obtained several corrections must be included. Apart from terms already mentioned, corrections are required for the lack of energy balance between the two absorbers, for the fact that a finite area of the absorbers is illuminated by the proton beam and also for the non-uniformity of response of the scintillator over its surface. The magnitudes of these terms are quoted in Table 2, which is only representative of the three sets of results obtained. The total reaction cross section for copper was found from the weighted mean of three runs to be 930 ± 70 mbn at 9·30 ±0·30 Mev. The total length of machine time required for this measurement was about 100 hours.

§ 5. Discussion

5.1. *Proton Total Reaction Cross Section Data near* 10 *Mev*

It has already been mentioned that Meyer and Hintz (1960) have obtained values from the proton total reaction cross section for several elements at 9·85 Mev by the addition of the partial cross sections involved. Their cross sections do not include values for the (p, γ) reaction but this is expected to be small ($\sim$1–2 mbn). The value quoted by these authors for natural copper is $\sigma_R = 910 \pm 60$ mbn, this result being obtained as a suitable average over the two isotopes. This result is clearly in good agreement with the present measurement of 930 ± 70 mbn at 9·30 Mev. The value for σ_R at 9·30 Mev would in fact be expected to be less than that at 9·85 Mev (by about 30 mbn) owing to the reduced penetrability of the Coulomb barrier, but this could easily be masked by the experimental errors.

The values of the (p, n) reaction cross sections for ^{63}Cu and ^{65}Cu used by Meyer and Hintz were 480^{+90}_{-65} mbn and 819 ± 75 mbn, respectively (the errors represent the spread in the existing measurements). Albert and Hansen (1961) have recently published new measurements for σ (p, n) at 9·85 Mev. These new values combined with Meyer and Hintz's measurements yield $\sigma_R = 865 \pm 60$ mbn. Benveniste (private communication) has made measurements of the charged particle reaction cross sections for Cu at several energies. These values together with Albert and Hansen's σ(p, n) results yield $\sigma_R = 921 \pm 45$ mbn. Combining the several measurements of all the partial cross sections without preference to any particular data we find $\sigma_R = 900 \pm 56$ mbn at 9·85 Mev.

Before the experimental values can be compared directly with predictions from optical model analyses, it is necessary to add the contribution to the total reaction cross section appropriate to compound elastic events. The compound elastic cross section for copper is expected to be small on theoretical grounds. Experimentally, the existence of compound elastic scattering is generally assumed (Wall and Waldorf 1957) when the optical model angular distributions fall below the experimental values for large scattering angles where the Coulomb and shape elastic scattering is least and the compound elastic scattering of comparable magnitude. For the even A isotopes of nickel it is indicated that the compound elastic cross section is about 50 mbn (Greenlees and Rolph 1960), but no such effect is found for copper. The presence of compound elastic scattering would, of course, increase the experimental values of σ_R.

5.2. *Optical Model Analyses*

The elastic scattering angular distribution for copper at 9·75 MeV due to Hintz (1957), was first analysed by Glassgold *et al.* (1957) using an optical model potential for which both the real and imaginary parts were described by the Saxon–Woods form factor (Saxon and Woods 1954). The angular distribution was found to be fitted equally well with several sets of parameters, the values for the total reaction cross section lying in the range 660–790 mbn. In this analysis polarization effects were not considered. Nodvik and Saxon (1960) have repeated the analysis using a potential which includes a spin–orbit term to describe the polarization data of Rosen and Brolley (1958). They found that the inclusion of the spin–orbit term gave rise to only second-order effects in σ_R, the range of values predicted being unaltered. Definite preferred sets of parameters were obtained, however, the set giving the best fit to the data being associated with a value for $\sigma_R = 720$ mbn.

Now that experimental values for σ_R have become available it is clear that the predicted values are too low. In order to obtain values of σ_R from the optical model, which are as much as 200 mbn above the best fit of Nodvik and Saxon, it seems necessary to make some alteration in the form of the potential. There is some theoretical justification for the use of a surface absorption term rather than the volume absorption of the Saxon–Woods form-factor and also for extending the radius of the absorptive part of the potential beyond that for the real part (Shaw 1959, Gomes 1959).

The need for a surface absorption is indicated by the analysis of neutron scattering work by Bjorkland and Fernbach (1958) who found that, in order to obtain a set of optical model parameters which do not change greatly between heavy and light nuclei, it was necessary to use a form-factor for the imaginary part of the potential well which is strongly peaked at the nuclear surface. That this has not so far been necessary in proton scattering is probably due to the influence of the Coulomb potential. It has been indicated on theoretical grounds (Kikuchi 1959) that whereas a surface absorption is probably necessary below 20 MeV its presence above this energy is not very realistic. This is interesting since the reaction cross section measurements for protons at 34 MeV (Gooding 1959) and 61 MeV (Meyer, Eisberg and Carlson 1960) are in reasonable agreement with predictions from optical potentials using only a volume absorption term.

Optical model analyses have recently been carried out by Easlea (1961) using an imaginary potential which combines both volume and surface absorption terms. The effect of varying the relative contributions of these terms was investigated, as was also the effect of increasing the radius for the imaginary part of the potential well relative to that of the real part. The results of this work are published in an accompanying paper and will not be discussed in detail here. The main difficulty in arriving at a unique conclusion was due to discrepancies in the experimental data. Whilst, as discussed earlier in this paper, the reaction cross section measurements available for Cu agree within the experimental errors around 10 MeV, there are significant differences in the differential cross section data. Nevertheless, in order to obtain the required reaction cross section and simultaneously obtain a good fit to any of the differential cross section and polarization data, it is necessary to use an imaginary potential with a peaking in the nuclear surface. To obtain a fit it is not necessary to increase the radius of the imaginary potential. Since different radii for the real and imaginary potentials introduces an additional parameter it is a step to be avoided unless essential.

Considering only the results (σ_R and differential cross sections) presented in this paper, Easlea was able to obtain an excellent fit to the differential cross section and predict a value of $\sigma_R \sim 900$ mbn using two sets of parameters; one set involved a purely surface imaginary potential of $-8{\cdot}2$ MeV and gave $\sigma_R = 920$ mbn and the other an imaginary potential with a central value of $-2{\cdot}9$ MeV and a surface value of $-5{\cdot}8$ MeV, gave $\sigma_R = 915$ mbn. These are both in good agreement with the present value of 930 ± 70 mbn. Both these sets of parameter give a good fit to Rosen's polarization data (Rosen and Brolley 1958).

In conclusion, the total reaction cross section for Cu obtained in the present work by a direct method, agrees with values obtained by an addition of the partial cross section involved, within the accuracy of the experiments; if such values, which fit the differential cross section data, are to be obtained from an optical model analysis it is necessary to use a surface peaking in the imaginary part of the potential used in the model.

ACKNOWLEDGMENTS

The authors wish to thank members of the Cyclotron Scattering Group for help at various stages of the work and also Mr. B. R. Easlea for providing his results in advance of publication. One of us (O. N. J.) thanks the Department of Scientific and Industrial Research for financial support.

Proton Scattering by Copper at 10 MeV

By B. R. EASLEA†

Institute for Theoretical Physics, University of Copenhagen, Denmark

Communicated by G. E. Brown; *MS. received* 31*st May* 1961

Abstract. An optical model analysis is given of the experimental data of Hintz at 9·75 MeV and of Greenlees *et al.* at 9·30 and 9·47 MeV on the scattering of protons by natural copper. A sufficiently general form factor for the imaginary part W of the optical potential is used such that W can have a maximum value lying in any desired region of the nucleus. It is found that the absorption must be peaked at the surface of the nucleus in order to fit not only the polarization and differential elastic cross section, but at the same time to give the correct magnitude of the total reaction cross section. The available experimental data do not at present allow the determination of how much absorption occurs at the centre of the nucleus or whether the maximum of W should lie slightly beyond the half-way radius of the real part of the optical potential.

---

§ 1. Introduction

Several calculations (Verlet and Gavoret 1958, Oda and Harada 1959, Shaw 1959, Gomes 1959) have been carried out to determine the magnitude and radial dependence of the imaginary part W of the optical potential. These calculations have predicted W to have a smaller value at the centre of the nucleus than determined empirically by optical model analyses which use only a volume absorption, i.e. a radial dependence for W given by the Saxon–Woods form factor

$$f(r)=\frac{1}{1+\exp[(r-R)/a]}. \qquad \ldots\ldots(1)$$

On the other hand none of the theoretical predictions agrees with such a radial distribution. Their prediction is rather that in the surface region W first rises to a maximum value some two or three times greater than its value at the centre of the nucleus before finally falling to zero far enough outside the surface. The calculations assume a nucleon density distribution given by $f(r)$ and predict the peaking of W to take place at, or slightly beyond, the half-way radius R.

Now although one or two of the simplifying approximations made for the surface region in the calculations cannot be justified (Gomes 1959, Weisskopf 1959), nevertheless it is usually assumed that they ought at least to give some guide to the radial dependence of W and accordingly we have chosen a form factor for W in our phenomenological investigations which allows W to follow, if necessary, such a radial dependence.

---

† The greater part of this work was done while the author was a research student in the Department of Physics, University College London.

We may note here that Björklund *et al.* (Björklund and Fernbach 1958, Björklund, Fernbach and Sherman 1956) have carried out an analysis of elastic scattering and polarization data over a wide range of E and A using either pure volume absorption or pure surface (Gaussian form factor). Their conclusion was that surface absorption seems to fit the available data slightly better up to energies as high as 100 MeV. Now a suitable optical model potential must at the same time fit the total inelastic scattering and, with the measurement of such reaction cross sections, it becomes possible to decide quite definitely between the two kinds of radial distribution.

With this consideration in mind we have attempted to fit the available experimental data on proton scattering by natural copper in the energy range 9–10 MeV, choosing this particular nucleus and energy region for several reasons. Firstly, the copper nucleus is heavy enough so that compound elastic scattering should be small and the (p, n) thresholds for ^{63}Cu and ^{65}Cu, 4·21 and 2·16 MeV respectively (Marion and Fowler 1960), are both well below the energy region of 9–10 MeV. Hence one of the main decay channels of the compound nucleus is not blocked. (The author has found that the elastic scattering of protons by ^{58}Ni at approximately 9·5 MeV has too much scattering at backward angles to be fitted by the optical model. This is undoubtedly caused by compound elastic scattering since the incident proton energy is only just on the isotope's (p, n) threshold of 9·46 MeV. On the other hand, the evidence is that scattering by ^{60}Ni at this energy, (p, n) threshold 7·03 MeV, can be fitted much better by the optical model.†) Secondly, the copper nucleus is not deformed so that one can deal with spherical potentials. Finally, its Coulomb barrier is not so high as to prevent protons of low angular momentum from getting into the nucleus at the energies we consider, but is sufficiently high so that, together with the centrifugal barrier, it prevents those of high angular momentum from penetrating. Thus the scattering is very sensitive to the details of the nuclear surface and particularly to the amount of absorption at the surface.

§ 2. THE OPTICAL POTENTIAL AND ITS USE

The optical potential we have used may be written as

$$\mathcal{V}(r) = -Vf_1(r) - iW\left\{kf_2(r) - n\frac{df_2(r)}{dr}\right\}$$
$$+\begin{bmatrix} l \\ -(l+1) \end{bmatrix} a_0^2 \frac{1}{r}\left\{v\frac{df_1(r)}{dr} + iw\frac{df_2(r)}{dr}\right\}, \quad a_0 \equiv 1 \text{ fermi}, \quad \ldots\ldots(2)$$

where $f_1(r)$ and $f_2(r)$ may contain different parameters, i.e. $R_1 \neq R_2$ and $a_1 \neq a_2$. The Coulomb potential is obtained by solving Poisson's equation assuming a charge density proportional to $f_1(r)$. V, W, v and w are the absolute magnitudes of the potentials such that $-V$ is an attractive potential, $-iW$ an absorptive one, while the spin up potential ($J = L + \frac{1}{2}$, upper half of square brackets) is attractive and the spin down ($J = L - \frac{1}{2}$, lower half) is repulsive. For w the same sign convention is maintained and thus w effectively accounts for any difference in the density of $J = L + \frac{1}{2}$ and $L - \frac{1}{2}$ levels. At the energies considered w has been found to be very small or zero.

---

† Optical model analyses on new data for ^{58}Ni and ^{60}Ni confirm these suggestions (G. W. Greenlees, private communication, Brown 1961, Greenlees and Rolph 1960).

We write the form factor for $W(r)$ as

$$g_W(r) = kf_2(r) - n\frac{df_2(r)}{dr}. \qquad \ldots\ldots(3)$$

There are three cases of interest. (i) If $n=0$ then $g_W(r)$ has the radial dependence we refer to as volume absorption. (ii) If $k=0$ then $g_W(r)$ is symmetrical about R_2. We refer to this as surface absorption. (iii) If k is taken as unity and $n \neq 0$ ($n > a_2$) then W is finite at $r=0$ and rises to a maximum at a value of r slightly less than R_2. This corresponds to the radial dependence of W calculated theoretically. Fig. 1 shows $g_W(r)$ plotted for the three different combinations of k and n. They are

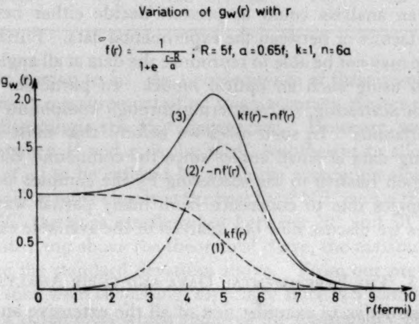

Fig. 1. Curves illustrating the three different radial distributions used for W. Curve (1) shows pure volume absorption, (2) pure surface absorption, and (3) combined volume and surface absorption.

$$(1)\ k=1,\ n=0; \quad (2)\ k=0,\ n=6a_2; \quad (3)\ k=1,\ n=6a_2.$$

The third case corresponds to a maximum of W just over twice the value at the centre of the nucleus and lying about $\frac{1}{4}$ fermi inside R_2.

If we define $W(0) \equiv W_c$, $W(R_2) \equiv W_s$, and $W(r_{\max}) \equiv W_{\max}$ and remember that $R = r_0A^{1/3}$, we see that $\mathcal{V}(r)$ may be completely specified by either

$$a_1a_2r_{01}r_{02}\ (\text{fermi})\ VW_cW_svw(\text{MeV}) \qquad \ldots\ldots(1)$$

or

$$a_1a_2r_{01}r_{\max}\ (\text{fermi})\ VW_cW_{\max}vw(\text{MeV}). \qquad \ldots\ldots(2)$$

If $a_1 = a_2$ and/or $R_1 = R_2$ or $r_{\max}$, as will usually be the case, then the suffices will be dropped and only one parameter quoted.

The form factor $g_W(r)$ introduces the possibility of using three extra parameters compared with the usual single parameter of pure volume or pure surface absorptive potentials, which is simply the magnitude of W. In general we can have $a_2 \neq a_1$, and we must choose the ratio of W_s/W_c or $W_{\max}/W_c$ as well as the value of R_2 or $r_{\max}$. However, the advantage of the optical model is that it is able to follow the broad trends of the elastic and polarization data over a wide range of E and A with only regular systematic changes of its, up to now, six parameters (or seven with Gaussian surface absorption). To fit also the reaction cross section σ_R, both at a particular energy and to follow its energy variation, we do not of course wish to introduce more parameters than seems absolutely necessary. Hence we shall concentrate on keeping $a_2=a_1$ and R_2 or $r_{\max}$ the same as R_1. We shall be chiefly interested then in altering the ratio of surface to volume absorption and examining its effect on the elastic scattering and reaction cross section. We have not carried out time-consuming least squares analyses but rather investigated the more general behaviour of the optical model curves. As we shall show, the experimental data are not entirely consistent and while it is possible to draw certain conclusions without a least squares analysis we do not feel that such an analysis could at present decide either between particular choices of form factors or between the experimental data. Furthermore we must suppose that one may not be able to reproduce the data at all angles or the detailed energy variation using such an optical model. In particular the presence of compound elastic scattering, i.e. scattering through compound states, may give rapid energy variations. In such cases we believe that most attention should be paid to fitting data at small angles since the compound elastic scattering is small in this region relative to the scattering by the complex potential which is large at small angles due to coherence from many partial waves. With such theoretical biases we discuss now our analysis of the available experimental data.

§ 3. THE EXPERIMENTAL DATA AND THEIR ANALYSIS

It will be instructive to examine first of all the extensive analysis of Hintz's 9·75 MeV elastic scattering data (Hintz 1957) already performed by Nodvik and Saxon (1960, to be referred to as NS) but with a volume absorption only. Fig. 2 shows both the experimental data (plotted against $\theta_{\text{c.m.}}$ as the ratio to the Coulomb or Rutherford cross section) and the best fit reported by NS using a radius of $r_0=1{\cdot}26$ fermi. (This curve has been obtained from the author's programme

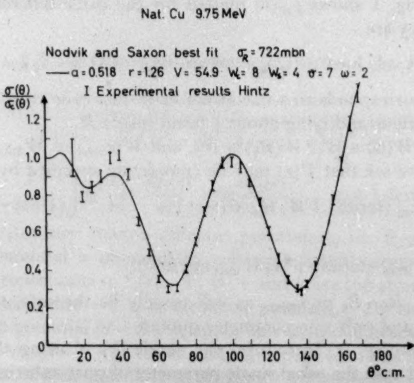

Fig. 2. Curve showing the best fit of Nodvik and Saxon to the elastic scattering data of Hintz.

using the parameters given by NS. The sole difference between the two potentials is due to our use of a Saxon form factor for the charge density distribution.) Nodvik and Saxon noted that, within a range $1{\cdot}20 \lesssim r_0 \lesssim 1{\cdot}30$ fermi, almost identical fits to the elastic data could be obtained by making use of the $Vr_0{}^n$ degeneracy ($n \sim 2{\cdot}35$) and in Table 1 we reproduce their values relating the total reaction cross section to r_0. As a consequence of these results Nodvik and Saxon declared that a measurement of σ_R to an accuracy greater than 5% would be necessary to disentangle the $Vr_0{}^n$ degeneracy. However, we shall see that this ambiguity between V and r_0 is, by itself, insufficient to allow the recently measured values of σ_R to be reached by a volume absorption alone.

Table 1.

r_0 (fermi)	1·20	1·23	1·26	1·28	1·30
σ_R (mbn)	671	702	725	746	762

In addition, looking more closely at the best fit of NS, we see that for all angles greater than $\theta = 50°$ the fit is excellent but between 20° and 50° there are four experimental points lying above the theoretical curve, the maximum point at 40° being nearly twice the standard deviation above. From our previous considerations this seems somewhat surprising, especially since NS found that there was no combination of parameters which removes the discrepancy between 20° and 50° and at the same time preserves the fit for angles greater than 50°. However, a reasonable fit to the newer *elastic* data of Greenlees and Jarvis (1961) is possible in this region with only a volume absorptive potential. Hence the discrepancy referred to by NS may not be as serious as at first appears. The main point to note from the analysis of NS is that their reaction cross section was 762 mbn with $r_0 = 1{\cdot}30$ fermi and, since the fit to $\sigma(\theta)$ deteriorated using a larger radius, a value of about 780 mbn effectively represents their maximum reaction cross section. It is this upper bound of 780 mbn to σ_R which is far more worrying.

Values for σ_R have recently been given by Hintz and Meyer (1960) at 9·85 MeV, by Albert and Hansen (1961) at the same energy, and by Greenlees and Jarvis at 9·30 MeV. Hintz and Meyer measured the cross sections for all reactions in which a charged particle is emitted. When this sum is added to the total (p, n) cross section a lower limit is obtained for σ_R. To this lower limit should be added the values of $\sigma(p, \gamma)$ and $\sigma_{c.e.}$, but Hintz and Meyer claim the former to be of the order of only 1 or 2 mbn and the compound elastic scattering is probably very little greater for the reasons mentioned. (The good optical model fit at backward angles is also an indication of very little compound elastic scattering.) Basing their estimate on rather conflicting measurements for the (p, n) cross sections of ^{63}Cu and ^{65}Cu Hintz and Meyer gave the value of σ_R as 910 ± 60 mbn. Albert and Hansen remeasured these (p, n) cross sections to give σ_R for ^{63}Cu as 875 ± 60 mbn and for ^{65}Cu as 855 ± 60 mbn. A mean value between these isotope cross sections gives the lower bound of σ_R for natural copper as 865 ± 60 mbn.

Greenlees and Jarvis measured σ_R by a somewhat more direct attenuation measurement at the slightly lower energy of 9·30 MeV. Essentially they measured the number of protons absorbed by the copper target by taking the difference in counts between the direct beam with no target absorber present and then with the absorber in place. Their final value for natural copper was $\sigma_R = 930 \pm 70$ mbn. Thus the two measurements of Greenlees and Jarvis and Hintz *et al.* agree within the errors quoted although one might expect σ_R to rise as E increases since the protons are better able to penetrate the Coulomb barrier.

These two values for σ_R of 865 mbn at 9·85 Mev and 930 mbn at 9·30 Mev show the theoretical upper bound of 780 mbn for σ_R using only volume absorption to be low. For the moment we take the lower value of 865 mbn in analysing Hintz's data and see what can be done to improve matters.

In Fig. 3 we again show the best fit of NS (curve I) as well as one attempt, still using only volume absorption, to fit the forward data better (curve II).

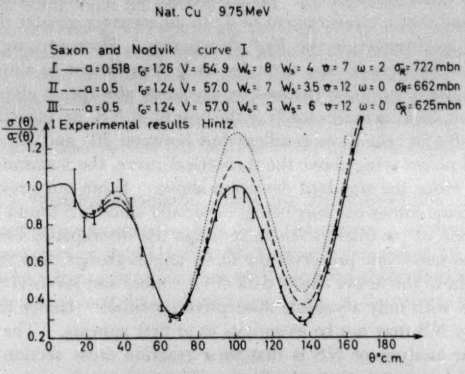

Fig. 3. Curves illustrating the effect of introducing surface absorption on the elastic scattering and reaction cross sections.

However the fit at other angles is destroyed and a decrease in σ_R results. It does not seem possible to increase σ_R for the value of r_0 taken by using pure volume absorption and at the same time to maintain or improve the fit to the elastic data. Hence we introduce a surface absorption (curve III) given by $W_c = 3$, $W_s = 6$ Mev; all other parameters are the same as for curve II. The effect is striking. With the sole exception of the minimum at 70° the elastic scattering is everywhere enhanced, and in particular the maximum at 40° rises to within the experimental limits. But corresponding to the increase in $\sigma(\theta)$ is a large decrease in σ_R from 662 to 625 mbn. At first sight the situation does not look encouraging. We have achieved a fit at forward angles only to lose it elsewhere and we have decreased σ_R when a large effect in the opposite direction is desired. However, since the increase in $\sigma(\theta)$ and the decrease in σ_R are caused solely by putting the absorption at the surface we see that this procedure alone is equivalent to increasing the reflectivity of the absorptive surface. To compensate for this we ought to increase the diffuseness of both real and imaginary surfaces ($a_1 = a_2$) both to increase σ_R and to restore the elastic fit at backward angles. Fig 4 (curve I) shows that a large increase from $a = 0{\cdot}5$ to 0·6 fermi is necessary and the magnitude of V has to be decreased from 57 to 54 MeV to compensate for the increased range of the potential.

This interplay between the diffuseness and the distribution of W brings about welcome improvements. Curve I shows that the fit to $\sigma(\theta)$ is now everywhere very good (note the forward angle fit between 20° and 50°) and, even better, the value of σ_R has increased from 625 to 785 mbn, a value some 70 mbn over an inferior fit to $\sigma(\theta)$ obtainable with only volume absorption. Curve II shows the effect of putting all the absorption at the surface. Both the elastic fit and the value of σ_R are comparable to those of curve I. Provided then that the absorption is peaked at the surface it is evident that the fit to both $\sigma(\theta)$ and σ_R can be improved.

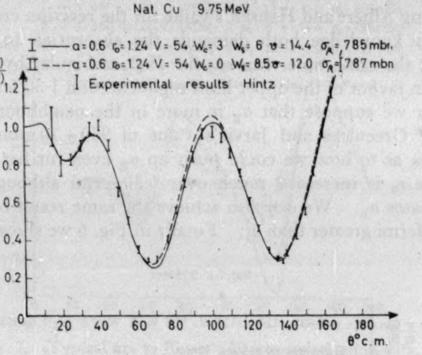

Fig. 4. Two fits to Hintz's elastic data with the absorption peaked at the nuclear surface. Note the increase in σ_R.

However, while a least squares analysis could now be used to improve even further the fit to $\sigma(\theta)$ we must note that σ_R is still some 80 mbn or so short of the

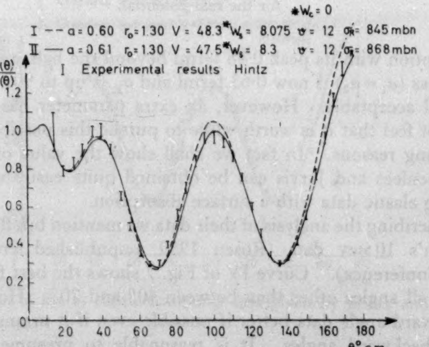

Fig. 5. **Two fits to Hintz's elastic data with pure surface absorption and a radius of $r_0 = 1{\cdot}30$ fermi. The value of σ_R is now experimentally acceptable.**

value given by Albert and Hansen. The only means we have left to push up the value of σ_R is to use the Vr_0^n degeneracy which we achieve by increasing r_0 to 1·30 fermi. This is shown in Fig. 5 with only surface absorption. The fit to $\sigma(\theta)$ remains very good and σ_R has increased from 785 to around 865 mbn. Curve II, with $\sigma_R = 868$ mbn, is perhaps the best overall fit to both $\sigma(\theta)$ and σ_R.

Thus, taking Albert and Hansen's value for the reaction cross section, we see that this extra knowledge both demands the absorption to be peaked at the surface and at the same time removes the Vr_0^n ambiguity by rejecting a radius of 1·24 fermi in favour of the upper limit region around 1·30 fermi.

If however we suppose that σ_R is more in the neighbourhood of 900 mbn (remembering Greenlees and Jarvis's value of 930 ± 70 mbn at 9·30 Mev) the question arises as to how we could push up σ_R even further. The fit to $\sigma(\theta)$ deteriorates as r_0 is increased much over 1·30 fermi although this procedure certainly increases σ_R. We can also achieve the same result by increasing a_2 to be about 0·05 fermi greater than a_1. Finally in Fig. 6 we show the effect of pure surface absorption with its peak 0·48 fermi beyond the half-way radius R_1 of V. The diffuseness ($a_1 = a_2$) is now 0·63 fermi and σ_R is up to 902 mbn while the fit to $\sigma(\theta)$ is still acceptable. However, an extra parameter has been introduced and we do not feel that it is worth while to pursue this possibility further until there are strong reasons. In fact we shall show the value of 930 mbn for σ_R given by Greenlees and Jarvis can be obtained quite easily when fitting their corresponding elastic data with a surface absorption.

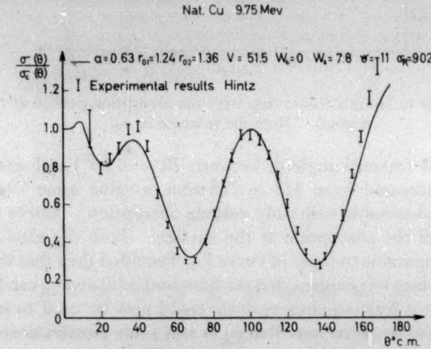

Fig. 6. Effect of extending pure surface absorption beyond the half-way radius used for the real potential.

Before describing the analysis of their data we mention briefly our polarization fits to Rosen's 10 Mev data (Rosen 1959, unpublished Proceedings of the Tallahassee Conference). Curve IV of Fig. 7 shows the best fit of NS which is acceptable at all angles other than between 40° and 70°. However, we prefer to fit this forward angle data better if possible even if it means producing more structure at backward angles. It is reasonable to presume theoretical predictions to show more structure than experimental values especially since the latter quantities are liable to inelastic contamination at backward angles. Thus we feel curve I probably gives the best all round fit to the data†. It turns out that fits to $\sigma(\theta)$ are not very sensitive to such changes in the value of v.

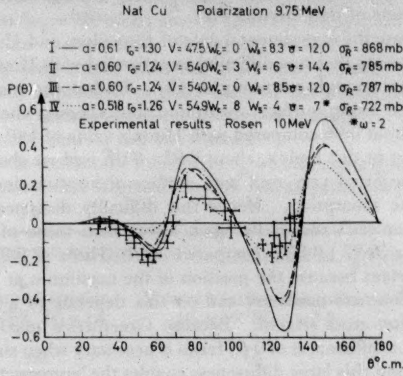

Fig. 7. Typical fits to Rosen's 10 MeV polarization data.

In Fig. 8 we have plotted the 9·75 MeV elastic scattering data of Hintz together with those of Greenlees, Kuo and Petravic (1957) at 9·37 MeV and of Greenlees and Jarvis at 9·47 MeV. The two sets of data by Greenlees, Kuo and Petravic and Greenlees and Jarvis agree extremely well with each other between 30 and 120° although there is a rather large difference in the backward angle scattering

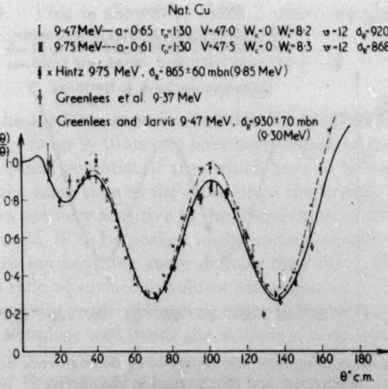

Fig. 8. Comparison of fits to elastic scattering data given by Hintz and by Greenlees, Jarvis *et al.*

---

† Large polarization at backward angles has been found by Robbins, Grotowski and Greenlees (1961). In fact the polarization predicted using the parameters of curve I, Fig. 8, with $v = 12$ MeV is in excellent agreement with their data.

beyond 120°. However, as explained earlier, our preference in such cases is to fit the smaller angle scattering and we shall concentrate on the available data between 30° and 120°. As it turns out good fits in this region are about half-way between the two sets of data beyond 120°.

We now compare the experimental data of Greenlees and Hintz between 30° and 120° remembering that one difficulty experienced with Hintz's data was our inability to achieve enough scattering at 40°. In fact the maximum value of $\sigma(\theta)/\sigma_C(\theta)$ obtained using surface absorption and keeping the good elastic fit elsewhere lay at about 0·96 compared with Hintz's value of $1{\cdot}01 \pm 0{\cdot}03$. Greenlees' data are lower in this region, about $0{\cdot}92 \pm 0{\cdot}02$, and we shall show that this region can now be fitted very well with surface absorption and almost as well using only volume absorption. Hence this difficulty disappears. Also, however, at 100° Greenlees's results lie again lower than those of Hintz (at 100° Greenlees obtains $0{\cdot}87 \pm 0{\cdot}025$ compared with Hintz's $0{\cdot}97 \pm 0{\cdot}03$). This difference is important because the position of the maximum at 100° determines the amount of diffuseness necessary and on this depends to a large extent the value of the reaction cross section. Because Greenlees's maximum lies lower than that of Hintz, a diffuseness of 0·65 fermi is necessary when surface absorption is used (curve I), and this large diffuseness enables the large reaction cross section of 920 mbn to be reached so easily, combined with an excellent fit to the 9·47 MeV elastic data for all angles up to 120°. At the same time the fit to Hintz's 9·75 MeV data is likewise good except around 40° (although the theoretical curve is never more than one standard deviation away from the experimental results) and Hintz's value for σ_R of 865 mbn is also fitted well with surface absorption and a diffuseness of 0·61 fermi.

Looking now only at the 9·47 MeV data of Greenlees we show in Fig. 9 that volume absorption is completely unacceptable even though the fit to the elastic data is about as good as with surface absorption. This is because σ_R is only 813 mbn which is certainly not high enough for the value of 930 ± 70 mbn by Greenlees and Jarvis. Even if we take the value of 865 ± 60 mbn by Albert and Hansen it is still only just over the lower limit of a lower bound for σ_R. Curve

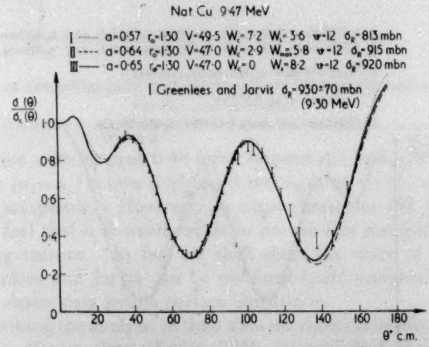

Fig. 9. Three curves illustrating how knowledge of σ_R distinguishes between pure volume absorption and that peaked at the surface.

II shows another good fit to the elastic data using a ratio of surface to volume absorption of 2 : 1. The maximum of W lies at R_1 and is twice the value of W(2·9 MeV) at $r=0$. In this case σ_R is 915 mbn. Curve III is the fit with all surface absorption ($\sigma_R = 920$ mbn) shown again for comparison. Hence, we see once again that one cannot easily distinguish between a volume and surface absorption fitting only elastic data but that, once reaction cross sections are known, it becomes imperative to place most of the absorption at the surface. Provided the ratio of surface to volume absorption is about 2 : 1 or greater, equally good fits to both $\sigma(\theta)$ and σ_R can be obtained.

It is of interest to see that the increase in σ_R which results from the combination of surface absorption and large diffuseness comes principally from the partial waves $l=3$ and 4. This is shown in Table 2 where we give the partial wave contributions to σ_R for the three curves of Fig. 9.

Table 2. Partial Wave Contributions to $\sigma_R(l)$(mbn)

	Volume absorption $W_c=7{\cdot}2,\ W_s=3{\cdot}6$	Volume + surface absorption $W_c=2{\cdot}9\ \ W_{max}=5{\cdot}8$	Surface absorption $W_c=0,\ W_s=8{\cdot}2$
$l=0$	66	66	65
$l=1$	159	153	149
$l=2$	273	284	276
$l=3$	217	255	267
$l=4$	75	117	119
$l=5$	22	35	38
$l=6$	1	4	5
$l\geqslant 7$	0	1	1
σ_R (total)	813	915	920

§ 4. CONCLUSION

In analysing the available experimental data for protons scattered by natural copper in the energy range 9–10 MeV we have been interested mainly in the changes necessary in the optical potential, if any, which have to be made when fits to σ_R are attempted at the same time as the more usual fits to $\sigma(\theta)$. We found in fact that fits to $\sigma(\theta)$ are not very sensitive to the distribution of W in the nucleus but that fits to σ_R demand W to be peaked in the surface region.

It is difficult to say anything more definite than this. Fits to both σ_R and $\sigma(\theta)$ with either a ratio of surface to volume absorption of 2 : 1 or with all surface absorption seem equally good. However, since we know theoretically that some absorption does take place well inside the nucleus it is reasonable to assume that the former radial dependence is the more appropriate one. This then agrees with the distribution of W predicted theoretically in the surface region.

The disagreement between the elastic data of Hintz and Greenlees *et al.* seems too great to be due to an energy difference of about 0·3 MeV. Preliminary data by Meyer and Beneviste (private communications) in this energy range also appear to be somewhat conflicting in the heights of the two maxima at 4° and 100°. For a more thorough analysis it would be desirable for the elastic data to agree and for the experimental errors in σ_R to be reduced if possible. For example, consider a possible fit to both Hintz's elastic data and the upper limit of approximately 1000 mbn for σ_R given by Greenlees and Jarvis. Then the difficulty experienced in reaching a value for σ_R as high as 900 mbn makes such a fit appear extremely improbable even with all surface absorption extended beyond the half-way radius of V (Fig. 6). On the other hand if we take the lower limit of 800 mbn as given by Albert and Hansen and try to fit Greenlees' elastic data, then in fact we could do so using only volume absorption. While neither of these extreme cases seems likely the possibility indicates how welcome further experimental clarification would be. If however we take σ_R to lie between 850 and 950 mbn and the elastic data to lie somewhere between those of Hintz and Greenlees *et al.* then the conclusion is unavoidable that W must be concentrated at the surface of the copper nucleus.

ACKNOWLEDGMENTS

It is a pleasure to thank Professor G. E. Brown for suggesting this investigation and for his continual interest and guidance. My thanks are due also to Professor Sir Harrie Massey, Dr. G. W. Greenlees, Mr. L. Castillejo, and Professor N. M. Hintz for interesting conversations, to the staff of the University of London Computer Unit for the many facilities provided and to Mr. M. W. Hansen for drawing the figures. Finally I am grateful to the Department of Scientific and Industrial Research for the award of a Research Studentship and to the Institute for Theoretical Physics, Copenhagen, for hospitality during the time in which this paper was written.

On the Reaction Pt(n, α)Os†

By M. W. CRESSWELL and R. R. ROY

Laboratories of Nuclear Physics, College of Chemistry and Physics,
Pennsylvania State University, University Park, Pennsylvania

MS. received 20*th March* 1961, *in revised form* 14*th July* 1961

Abstract. The reaction Pt(*n*, α)Os has been investigated by a nuclear emulsion technique, using the thermal neutron flux of the Pennsylvania State University reactor. A semi-empirical range–energy relationship has been developed for α-particles in platinum and has been used for the evaluation of data. Two groups of alpha particles have been observed with certainty, corresponding to *Q*-values $6{\cdot}9 \pm 0{\cdot}3$ MeV, and $8{\cdot}5 \pm 0{\cdot}3$ MeV and have been identified with reactions ^{194}Pt(n, α)^{191}Os and ^{195}Pt(n, α)^{192}Os respectively. A probable group of alpha particles corresponding to *Q*-value $12{\cdot}1 \pm 0{\cdot}3$ has been associated with the reaction ^{193}Pt(n, α)^{190}Os.

§ 1. INTRODUCTION

The aim of the present investigations was to establish the existence of (n, α) reactions for five isotopes occuring in natural platinum by the bombardment with thermal neutrons. The available mass data (Wapstra 1958) for platinum and osmium indicate positive *Q*-values for (n, α) reactions.

§ 2. EXPERIMENTAL DETAILS

The Pennsylvania State University reactor provided the thermal neutron flux. The natural platinum targets used in the experiment consisted of foils sandwiched between 400 μ Ilford G5 electron sensitive emulsions. The electron sensitive plates were used in order to detect any beta particles originating from the same point as an alpha particle in the emulsion and would thereby aid in establishing a reaction. In the interests of resolution of the different *Q*-values, the platinum foil was chosen as thin as possible. However, consideration of the Coulomb barrier indicated a relatively low reaction cross section, and a compromise had to be reached as regards the minimum number of observable events acceptable for measurement. This number was limited by the fact that gamma radiation which blackens the plates was also present in the thermal neutron flux. Consideration of these factors and preliminary trial exposures indicating that a foil thickness of 2·54 μ was about the optimum under the existing conditions. The plates were placed inside a lead container and exposed for one minute in front of the thermal column, the reactor operating at a power level of 1 kw.

§ 3. MEASUREMENTS AND CALCULATIONS

The plates were examined after development with Leitz Ortholux microscoper, By calibrating the microscopes and determining the emulsion shrinkage factos. the ranges *R* corresponding to energies E_1 (see Fig. 1), of over 1300 alpha particle

---

† Work supported by U.S. Atomic Energy Commission.

tracks were measured. Only those tracks which entered the emulsion from the surface were taken to be originating in platinum and were considered for measurements. The angles which each track made with the surface of the emulsion were similarly determined.

With this information, the energy E_2 which each particle had or would have had at the centre of the foil, on the trajectory defined by the microscope measurements, was calculated. It was intended to determine the different Q-values by taking the values of E_2 at which peaks in the E_2 spectrum occurred. Particles with E_2 values near to one of these peaks would in general correspond to their being produced in the immediate vicinity of the centre of the foil.

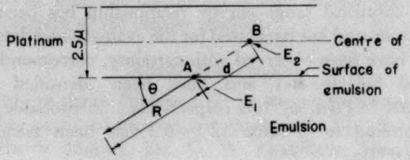

Fig. 1. Schematic representation of the path of an alpha particle.

To determine the energy E_2 it was necessary to develop a range–energy relation for alpha particles in platinum. The passage of a heavy particle through matter is described by the well known relation (Evans 1955):

$$-\frac{dE}{ds}=\frac{4\pi e^4 z^2}{m_0 v^2} NZ \log\left(\frac{2m_0 v^2}{I}\right) \qquad \ldots\ldots(1)$$

where m_0 and e are the electronic mass and charge, ze the charge of the particle, Z the atomic number of the absorber, N the number of atoms per unit volume of the absorber, and I the average excitation potential. The above expression is valid for $2zZ/137\beta \ll 1$ and $\beta \gg Z/137$. By integrating and substituting the parameter values appropriate to the description of the passage of an alpha particle through platinum, Eqn (1) becomes

$$R=1{\cdot}084\,\mathrm{Ei}\,(\log 0{\cdot}470E^2) \qquad \ldots\ldots(2)$$

where R microns is the range of an α-particle of energy E MeV in platinum and $\mathrm{Ei}(x)$ is the exponential integral

$$\mathrm{Ei}(x)=\int_{-\infty}^{x}\frac{\mathrm{e}^u}{u}\,du$$

whose values are known (National Bureau of Standards, 1940).

Although the conditions mentioned above are not satisfied for alpha particles of about 10 MeV in platinum, an equation similar to (2) was derived for lead, and the theoretical range values so calculated for α-particles compared favourably with the values given by previous workers (Aron, Hoffman and Williams 1953, Whaling 1958). For this reason, Eqn (2) was taken to be valid for α-particles in platinum.

To determine E_2 a function $K(R)$ was defined by

$$K(R)=\frac{R_{E+1}-R_{E-1}}{R'_{E+1}-R'_{E-1}}$$

where $R_{E\pm1}$ and $R'_{E\pm1}$ are the ranges in microns of α-particles of energy $(E\pm1)$ MeV in emulsion and platinum respectively. The former can be obtained from the data of Rotblat (1951) and the latter from Eqn (2). The function K was constructed empirically in order that once the distance $AB=d$ was determined from the miscroscope measurements, the equivalent distance Kd, which would represent the distance travelled in the emulsion by an alpha particle between the same two energy limits, E_2 and E_1, could be obtained. It was found that the function K could approximately be represented by the form $K=0{\cdot}0112R+2{\cdot}72$ within the limits of R, the range in microns in emulsion of a particle of energy E MeV, which were going to be used. An approach of this type is justified because it is used to determine $E_2-E_1=\Delta E$ which is only a small fraction of the energy E_2.

Accordingly E_2 MeV is the energy of a particle describing a path of length R_2 microns in emulsion where, since K varies only very slowly with R, R_2 is given by

$$R_2 \simeq R+(0{\cdot}0112R+2{\cdot}72)d. \qquad \ldots\ldots (3)$$

The calculation indicated in Eqn (3) was performed for some 1300 tracks measured and the R_2 spectrum obtained.

§ 4. Results and Discussion

The number of α-particle tracks has been plotted as a function of the corrected range, R_2, for a total of over 1300 events as shown in Fig. 2.

It can be noted from the figure that there are two maxima of different intensities corresponding to $R_2=34{\cdot}1\,\mu$ and $43{\cdot}9\,\mu$. A probable third group of much smaller intensity is observed at $R_2=77{\cdot}8\,\mu$. The Q-values derived from the values of R_2 at the maxima are given in the Table together with the values obtained from mass data.

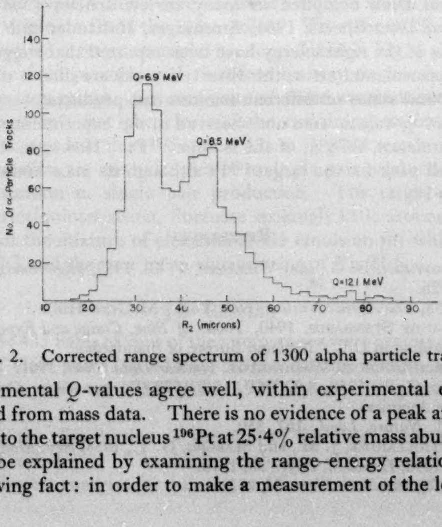

Fig. 2. Corrected range spectrum of 1300 alpha particle tracks.

The experimental Q-values agree well, within experimental error, with the values obtained from mass data. There is no evidence of a peak around 5·24 MeV corresponding to the target nucleus ^{196}Pt at 25·4% relative mass abundance. This, however, can be explained by examining the range–energy relation (2) together with the following fact: in order to make a measurement of the length R of any

Q-values obtained from Experiments and from Mass Data

Reaction	Mass data Q-value (MeV)	Observed Q-value (MeV)	Relative mass abundance of target
^{192}Pt(n, α)^{189}Os	9·40	no evidence	0·78%
^{193}Pt(n, α)^{190}Os	12·12	$12{\cdot}1 \pm 0{\cdot}3$	0·1%
^{194}Pt(n, α)^{191}Os	7·02	$6{\cdot}9 \pm 0{\cdot}3$	32·8%
^{195}Pt(n, α)^{192}Os	8·39	$8{\cdot}5 \pm 0{\cdot}3$	33·7%
^{196}Pt(n, α)^{193}Os	5·24	no evidence	25·4%

track in the emulsion with tolerable error, the minimum range acceptable for measurement was about 20 μ. According to the relation (2), a 5·24 MeV particle can travel through no more than 0·95μ of platinum before entering the emulsion with sufficient energy to describe a track at least 20 μ long and qualify for measurement. This means that a very small number of these tracks would actually be observed in the experiments. Furthermore, those that were counted would originate from a region close to the emulsion surface of the foil and would consequently be overcorrected for their energy loss. Thus, their E_2 values are not truly representative of the actual Q-value.

Additional confirmation of the identification of the 6·9 MeV peak with the reaction ^{194}Pt(n, α)^{191}Os was obtained from the fact that the ^{191}Os nucleus is not stable but decays by the emission of a 0·143 MeV electron (Rey and Baro 1958). In some fifty cases, beta particle tracks of about this energy were observed originating from the same point as alpha particle tracks. The R_2 spectrum of these particular α-particle tracks indicated fairly well that particles concerned were associated with the experimental Q-value of 6·9 MeV.

The decay of excited states of medium and heavy elements has been well studied and has been compiled in many review articles (National Research Council Nuclear Data Sheets, 1961, Stroninger, Hollander and Seaborg 1958). No gamma rays of the right energy have been reported that suggest that, within the limits of experimental error, the observed peaks are due to transitions other than to the ground states of different osmium end-products.

The 9·39 MeV Q-values were not observed in the experiment which might be due to low abundance, 0·78%, of the isotope ^{192}Pt. However, there is an indication of a small peak for the target ^{193}Pt although its mass abundance is of the order of only 0·1%.

Multiplet Production by X-rays

By R. R. ROY, C. H. BLANCHARD, E. H. WEBB, H. S. SANDHU
and R. C. MOHANTY

Nuclear Physics Laboratory, Pennsylvania State University, University Park, Pennsylvania

MS. received 23rd June 1961

Abstract. Ilford G5, 400μ thick nuclear emulsion plates were bombarded by a hardened X-ray beam of energy 5–90 MeV. Altogether 54 433 fields of view were examined, the volume of each field of view being $120\mu \times 150\mu \times 220\mu$. A total of 21 887 pairs, 1935 triplets, 106 quartets, 10 quintets and one sextet have been observed. Frequency of occurrence of multiplets, (quartets, quintet and sextet), together with the energy distribution of the small energy partners of the multiplets have been presented. Possible explanations of the origin of multiplets have been discussed.

---

§ 1. Introduction

A study of the electron–positron pair and triplet production in nuclear emulsion is being completed at this laboratory. Ilford G5 nuclear emulsion, 400μ thick, was exposed to a hardened X-ray beam from the National Bureau of Standards electron synchrotron. The incident photon spectrum extended from 5 to 90 MeV. While these plates were being scanned in search of pairs and triplets, there were observed events in which four, five and six electron tracks originate from the same point. We refer to these many-track events as 'multiplets'. Some examples are reproduced in Fig. 1 (Plate). There was no magnetic field present, and therefore no way to discriminate between positron and electron tracks. In every one of these events most of the energy is shared between two fast particles and the remaining tracks correspond to electrons with energy less than 0·5 MeV. There is good reason to believe that the events in question are not examples of multiple pair production, but consist of multiple ionization in single pair production. The ratios of production; pair/triplet/quartet/quintet/sextet, fluctuate strikingly little around a mean value of about 12·5, for the mixture of elements in G5 emulsion for which the average value of Z is 13·3 and the root mean square value of Z is 21·5.

§ 2. Results

Altogether 54 433 fields of view of the microscopes were examined; the volume of each field of view was $120\mu \times 150\mu \times 220\mu$. In the volume of emulsion examined there were observed 21 887 pairs, 1935 triplets, 106 quartets, 10 quintets and 1 sextet.

Fig. 2 gives the distribution of the *sum* of the kinetic energies of the *low* energy tracks of each event. The abscissa is the sum of the two lowest energies for quartets, three lowest energies for quintets and four lowest energies for the sextet.

The ordinate is the number of events in each total-low-energy bin. No distinction is made between different multiplicities or between different photon energies in this figure.

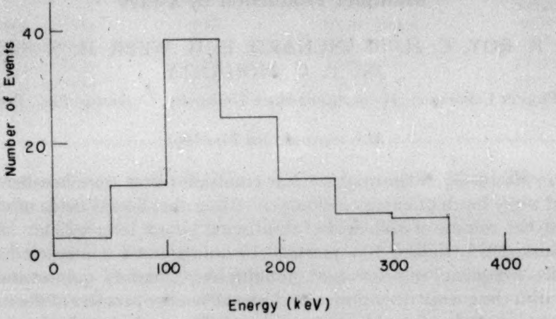

Fig. 2. The ordinate gives the number of events whereas the abscissa represents the sum of the kinetic energies of the small energy partners of multiplets.

§ 3. Discussion

It is necessary to show that the multiplets are not due to the chance occurrence of two or more small energy background electron tracks born at the origin of a pair or of a triplet. Two independent studies were made to estimate such a chance occurrence. The first method consisted of scanning about 900 fields of view from different plates. The aim of this experiment was to determine the number of small energy electrons, pairs and triplets born per field of view of the emulsion and to calculate the probability of a false multiplet due to the chance occurrence of two or more small energy electrons at the origin of a pair or of a triplet. The average number of small energy electrons, pairs and triplets observed per field of view were respectively 31·20, 0·26 and 0·02. With these data it can be shown that the probability of small energy electrons born within $0{\cdot}4\mu$ (average grain size) of a pair or a triplet thereby giving a false multiplet is indeed very small.

The second method of estimating the chance occurrence of a false multiplet consisted in counting the number of small energy electron tracks ending at the origin of a pair or of a triplet. This number will then give the actual false multiplet, since the probability of a small energy track's ending at the origin of a pair or of a triplet is the same as the probability of its being born at the origin. Some 500 pairs and 100 triplets were specially studied in search of false multiplets. None was observed.

It was therefore concluded that the multiplets observed in the experiment represented the real events.

It seems unlikely that the events under discussion involve multiple pair production, because the ratio of the double pair production cross section to that for single pair production is expected[†] to be of the order of $(e^2/\hbar c)^2 \simeq (19\,000)^{-1}$.

[†] W. Heitler (*The Quantum Theory of Radiation*, 3rd edition; Oxford, 1954) gives an estimate on p. 228 which differs from that quoted above. Heitler's incorrect estimate seems to result from an invalid extrapolation (originally suggested by J. E. Hooper and D. T. King, *Phil. Mag.*, **41**, 1194, 1950) of the 'substitution law' to multiple events. Multiple pair production is expected to be even rarer than emphasized by Heitler.

On this estimate we should have seen only about $22\,000/19\,000 \simeq 1$ quartet, whereas we have 106 quartets, an excess of two orders of magnitude. One can perhaps get some feeling for the nature of the effects involved here as follows. Suppose that a pair production takes place in the field of one of the atomic electrons in the K shell, and that the atomic electron thereby acquires a recoil momentum q. The electron will have left the K shell, with a kinetic energy of the order of $E_1 = q^2/2m$, in a time of the order of $T = (a_{\mathrm{Bohr}}/Z)/(q/m)$. Its removal will constitute a pulse of electromagnetic field containing frequencies up to $\omega = 1/T$, and may thus transfer energies as high as $E_2 = (Zq\hbar)/(ma_{\mathrm{Bohr}})$ to the other K electron. For $q \simeq mc$ we have $E_1 \simeq \frac{1}{2}mc^2$ and $E_2 \simeq (Z/137)mc^2$. For the highest Z in emulsion, these energies are seen to be comparable with the observed quartet recoil energies. (This argument is evidently very rough, neglecting relativistic corrections and binding energies, and is intended only as an order-of-magnitude interpretation.)

ACKNOWLEDGMENTS

The authors are indebted to H. W. Koch and J. M. Wyckoff for giving facilities of exposure of the plates with the National Bureau of Standards electron synchrotron and for their help and advice during the exposure. We wish to thank the microscopists, Dorothy Groner, Sylvia Levenson, Judith Loftin, Marie Ventrice and Beverly Wilson for their help in scanning the plates.

Isotope Shift in the CdI Resonance Line λ 2288 Å

By F. M. KELLY and E. TOMCHUK
Department of Physics, University of Manitoba, Winnipeg, Canada

MS. received 19*th June* 1961

Abstract. The isotope shifts in the singlet resonance line of CdI have been observed. The line was excited by electron bombardment of an atomic beam and the high resolution was obtained with a Fabry–Pérot interferometer. The shifts measured in this line (λ2288 Å) are compared with those previously measured in the intercombination resonance line (λ3261) to show that the specific mass effect is small. Comparisons are made with similar measurements in magnesium, zinc, and strontium.

---

§ 1. Introduction

There are two causes of isotope shift in atomic spectra, the mass effect and the field or volume effect. In the light elements the observed shifts can be accounted for by the mass effect while in the heaviest elements the shifts are attributed to the field effect. The mass effect can conveniently be separated into the normal mass effect and the specific mass effect (Hughes and Eckart 1930, Bartlett and Gibbons 1933, Vinti 1939, 1940). The normal mass effect is easily determined from a simple reduced mass calculation and thus can be taken into account in all atomic energy levels. The specific mass effect, on the other hand, requires the computation of a number of integrals involving the products of radial wave functions of the atomic levels, and, except in the case of helium, has achieved only moderate success. Both mass effects decrease with increasing atomic number but it is not certain where the specific mass effect can be neglected. It is possible, however, to make an experimental estimate of the specific effect by comparing the shifts in a pair of lines. Such a pair is the singlet and intercombination resonance lines of cadmium.

The singlet resonance line λ2288($5s^2\ ^1S_0$–$5s5p\ ^1P_1$) and the intercombination resonance line λ3261($5s^2\ ^1S_0$–$5s5p\ ^3P_1$) have a common lower level. The upper levels arise from the same (5s5p) electronic configuration. The field effect shift of either a $p_{1/2}$ or a $p_{3/2}$ electron is small compared to the shift due to an s electron so that the shift arising from the field effect should be the same in both these lines. The specific mass effect, however, predicts that the shifts of these two lines should differ by an amount depending only on $K(5s, 5p)$, one of the specific mass integrals in the notation of Bartlett and Gibbons (1933).

Isotope shifts in λ3261 have already been reported (Kelly and Tomchuk 1959). The shifts observed in λ2288 are reported here, and are compared with the shifts in λ3261. Similar comparisons in lighter elements have been made for zinc (Crawford *et al.* 1950), magnesium (Kelly 1957) and strontium (Hughes 1957).

§ 2. EXPERIMENTAL ARRANGEMENTS

The singlet resonance line was excited in the atomic beam source used for the study of λ3261. The collimation of the beam was such that the calculated source line width was 0·002 cm^{-1}. The line was isolated with a Hilger medium quartz spectrograph and the high resolution was supplied with a quartz Fabry–Pérot interferometer mounted externally to the spectrograph. A 10 cm spacer was used. The reflectivity of the aluminium films at λ2288 Å was estimated to be 80% from the measured transmission coefficient in the blue and the curves of Burridge, Kuhn and Pery (1953). The patterns were recorded on Ilford QI and QII plates with exposure times up to two hours.

§ 3. RESULTS

The line λ2288 was resolved into three closely spaced components. Twenty-five exposures with structure in two to five orders were measured five times by each of two observers. Microphotometer measurements were not satisfactory due to the curvature of the fringes. The three components are designated A, B and C with A having the highest frequency. The measured separations are

$$\Delta\nu(\mathrm{A, B}) = 16{\cdot}8 \pm 0{\cdot}3 \times 10^{-3}\,\mathrm{cm}^{-1}$$
$$\Delta\nu(\mathrm{B, C}) = 12{\cdot}5 \pm 0{\cdot}5 \times 10^{-3}\,\mathrm{cm}^{-1}.$$

The errors quoted are the average deviations from the mean multiplied by 0·68.

The assignment of component A to a blend of components due to isotopes 110 and 111, component B to a blend of components due to isotopes 112 and 113 and C to isotope 114 is consistent with visually estimated relative intensities.

The unresolved separations of the isotope pairs (110–111) and (112–113) were assumed to be in the ratio found in λ3261, and, by Kuhn and Ramsden (1956), in λ4416. Then, if we use the relative abundance as a weight factor the separations between even isotopes can be calculated. These calculations give

$$\Delta\nu(110\text{–}112) = -17{\cdot}0 \pm 0{\cdot}6 \times 10^{-3}\,\mathrm{cm}^{-1}$$
$$\Delta\nu(112\text{–}114) = -13{\cdot}2 \pm 1{\cdot}0 \times 10^{-3}\,\mathrm{cm}^{-1}.$$

In this the error has been doubled to allow for the extra uncertainties introduced. We also assumed that the magnetic hyperfine structure in the $^1P_1$ level is negligible. The negative sign means the lighter isotope has the higher frequency.

A plot of theoretical curves shows that the influence of isotope 116 on the position of isotope 114 is much less than the experimental error.

§ 4. DISCUSSION

The isotope shifts between even isotopes in the singlet (λ2288) and the intercombination (λ3261) resonance lines may be analysed in a manner similar to that used for the Zn I resonance lines (Crawford *et al.* 1950).

Table 1. Isotope Shift in Cd I (in 10^{-3} cm^{-1})

	2288		3261	
	110–112	112–114	110–112	112–114
Observed shift	−17·0	−13·2	−16·3	−13·5
Normal shift	+ 3·4	+ 3·7	+ 2·7	+ 2·6
Residual shift (Δν)	−20·9	−16·9	−19·0	−16·1
3261–2288 (δ(Δν))	+ 1·9	+ 0·8		

The residual shift ($\Delta\nu$) is the observed shift minus the normal mass shift. The differences between the residual shifts are $+1{\cdot}9\pm1{\cdot}1$ for (110–112) and $+0{\cdot}8\pm1{\cdot}4$ for (112–114). These two values agree within experimental error and the average is $+1{\cdot}3\pm1{\cdot}3$.

The difference between the isotope shifts in the triplet and the singlet resonance lines according to the specific mass theory (Bartlett and Gibbons 1933) is

$$\delta(\Delta\nu)\ (\text{triplet–singlet}) = -4Rm\left\{\frac{1}{M_1}-\frac{1}{M_2}\right\}K(n\text{s},\, n\text{p})$$

where R is the Rydberg constant (cm^{-1}), m the electron mass, M_1, M_2 the nuclear masses ($M_2 > M_1$), and K the specific mass integral which is intrinsically negative. The data for Mg (Kelly 1957), Zn (Crawford *et al.* 1950, Hately and Littlefield 1958), Sr (Hughes 1957) and Cd for the shifts arising from isotopes differing by two neutrons are summarized in Table 2.

Table 2

	n	$\delta(\Delta\nu)$ Triplet–singlet ($\times 10^{-3}$ cm^{-1})	$K(n\text{s}, n\text{p})$
Mg	3	$+57{\cdot}9\pm1{\cdot}6$	$-0{\cdot}076\pm0{\cdot}002$
Zn	4	$+10\ \ \pm1{\cdot}5$	$-0{\cdot}091\pm0{\cdot}014$
Sr	5	$+5{\cdot}6\ \pm1{\cdot}8$	$-0{\cdot}033\pm0{\cdot}024$
Cd	5	$+1{\cdot}3\ \pm1{\cdot}3$	$-0{\cdot}03\ \pm0{\cdot}03$

The value of the specific mass integral $K(n\text{s}, n\text{p})$ is not very sensitive to the value of the principal quantum number n, and for $n=5$ appears to be decreasing. The factor $\Delta M/M_1M_2$ in the heavy elements will reduce the resulting specific mass shifts to small values. Consequently in the heavy elements one can expect to obtain specifically nuclear data from the observed isotope shifts.

Rotational Analysis of the E–X System of Silicon Monosulphide

By R. F. BARROW†, J. L. DEUTSCH†, A. LAGERQVIST‡
and B. WESTERLUND‡

† Physical Chemistry Laboratory, Oxford University
‡ Institute of Physics, University of Stockholm

MS. received 7th July 1961

Abstract. The rotational analysis of twenty bands of the E–X system of SiS has been carried out. The system arises from a transition $^1\Sigma^+$–$^1\Sigma^+$, and, unexpectedly, no perturbations have been detected in $\mathrm{E}^1\Sigma^+$. Constants (in cm^{-1}) for the state $\mathrm{E}^1\Sigma^+$, valid for $0 \leqslant v \leqslant 7$ are as follows:

$$T_0 = 41743{\cdot}8_6,\ G_v = 406{\cdot}8_3\,(v+\tfrac{1}{2}) - 1{\cdot}95_2\,(v+\tfrac{1}{2})^2,$$

$$B_v = 0{\cdot}2213_7 - 0{\cdot}0013_9\,(v+\tfrac{1}{2}) - 1{\cdot}_{75}\times 10^{-5}\,(v+\tfrac{1}{2})^2.$$

It seems probable that the state E is the $^1\Sigma^+$ state arising from the configuration ......$\pi^3\sigma^2\pi^*$, analogous to the state $\mathrm{B}^1\Sigma^+{}_u$ of the isoelectronic molecule P_2.

---

§ 1. Introduction

PRESENT information about the lower lying electronic states of CO and of similar molecules, such as CS, SiO and SiS, indicates that they arise from the three configurations

$$\ldots\ldots\quad \pi^4\sigma^2\text{–}\mathrm{X}^1\Sigma^+ \qquad\ldots\ldots(1)$$

$$\ldots\ldots\quad \pi^4\sigma\pi^*\text{–}{}^3\Pi_r,\ {}^1\Pi \qquad\ldots\ldots(2)$$

$$\ldots\ldots\quad \pi^3\sigma^2\pi^*\text{–}{}^1\Sigma^+,\ {}^1\Sigma^-,\ {}^3\Sigma^+,\ {}^3\Sigma^-,\ {}^1\Delta,\ {}^3\Delta. \qquad\ldots\ldots(3)$$

The absorption systems allowed in Hund's cases *a* and *b* are $^1\Pi \leftarrow \mathrm{X}^1\Sigma^+$ and $^1\Sigma^+ \leftarrow \mathrm{X}^1\Sigma^+$. Rotational analyses of the well-known longest wavelength absorption systems of SiO and SiS have shown that they arise from transitions $^1\Pi \leftarrow {}^1\Sigma^+$ (Lagerqvist and Uhler 1953, Barrow 1946), and studies of perturbations in the $^1\Pi$ states (Lagerqvist, Nilheden and Barrow 1952, Nilheden 1955) have provided information about some of the other states which arise from configuration (3).

It was therefore of interest to examine the rotational structure of the second ultra-violet system E–X. For SiO this lies in the Schumann region (Barrow and Rowlinson 1954), but in the case of SiS the most readily observed bands lie between about 2200 and 2500 Å (Vago and Barrow 1946). The present paper is concerned with the rotational analysis of bands of the E–X system of SiS.

Experimental details have already been given. Measurements and analyses were carried out independently in Stockholm and in Oxford.

§ 2. Analysis and Discussion

All the bands show a simple structure of single R and P branches. Rather surprisingly, by comparison with the $\mathrm{D}^1\Pi$ state, no perturbations were detected.

The analyses were straightforward since values of the ground state combination differences $\Delta_2F''(J)$ were available from earlier work. Constants for the $\mathrm{E}^1\Sigma^+$ state were calculated from those of the ground state, using the relation

$$\mathrm{R}(J-1)+\mathrm{P}(J)=2\nu_0+2\Delta BJ(J+1)-2\Delta DJ^2(J^2+1).$$

The results are given in Table 1.

The constants derived in this way for the state $\mathrm{E}^1\Sigma^+$ fit well with those obtained for other states believed to arise from the configuration ...... $\sigma^2\pi^3\pi^*$, as may be

Table 1. Constants for Bands of the E–X System of SiS

† See references given by Lagerqvist, Nilheden and Barrow (1952).
‡ Herzberg and Hugo (1955).
§ Mulliken (1958).

seen from the values given in Table 2. It is probable too that the state E of SiS is analogous to the well-known state $B^1\Sigma_u^+$ of the isoelectronic molecule P_2 (see Table 3).

Table 3.

Molecule	State	T_e	$\omega_e/\omega_e(x)$	$B_e/B_e(x)$
SiS	$E\ ^1\Sigma^+$	41915	0·54	0·73
P_2†	$B\ ^1\Sigma_u^+$	46943	0·61	0·80
SiS	$D\ ^1\Pi$	35027	0·68	0·88
P_2†	$A\ ^1\Pi_g$	34515	0·79	0·91

† The data for P_2 are from Douglas and Rao (1958).

At this point some evidence is available for six of the nine electronic states arising from the configurations (1), (2) and (3). Analysis of the visible emission bands of SiS may provide further information, and it might be that a study of the absorption spectrum in the visible region with long paths would reveal the forbidden $^3\Pi$–$x^1\Sigma^+$ system. Apart from the fact that no state of CO analogous to state E of SiS is yet known, there is no evidence yet to suggest that the lower excited states of SiS are other than similar to those of CO.

On Perturbation Calculations for the π-Electrons and their Application to Bond Length Reconsiderations in Aromatic Hydrocarbons

BY C. A. COULSON AND A. GOŁĘBIEWSKI†
Mathematical Institute, Oxford

MS. received 15*th June* 1961

Abstract. An alternative method for calculating the atom–atom, atom–bond, bond–bond and other polarizabilities in π-electron molecules, originally due to R. D. Brown, is extended to deal with orbital degeneracy. It is then applied to a new discussion of the bond lengths in certain aromatic hydrocarbons. A simple and partly self-consistent method of calculation is developed, which yields results in satisfactory agreement with recent accurate experimental measurements.

§ 1. INTRODUCTION

ONE of the simplest and relatively powerful methods in quantum chemistry is the LCAO MO theory of π-electrons in planar aromatic hydrocarbons. This method is particularly simple in the Hückel approximation (Hückel 1931, 1932), and all our subsequent theoretical analysis will be in terms of it. Since this standard method is discussed both in papers (e.g. Hückel 1931, 1932, Coulson and Longuet-Higgins 1947 a, b) and in books (e.g. Daudel, Lefebvre and Moser 1959, Coulson 1961) there is no need to do more than recapitulate the notation and a few of the basic equations. Our present paper is concerned with the development of a simple form of perturbation theory within this framework, and its application to the calculation of bond lengths.

The normalized molecular orbital ψ_k of a particular π-electron is approximated, in Hückel's theory, by a linear combination of atomic 2pπ orbitals ϕ_r:

$$\psi_k = \sum_{r=1}^{n} c_{kr}\phi_r = \mathbf{C}_k{}^{\dagger}\boldsymbol{\varphi}. \qquad \ldots\ldots(1)$$

In (1) $\mathbf{C}_k$ is a column vector with elements $c_{k1}, c_{k2}, \ldots c_{kn}$; $\mathbf{C}_k{}^{\dagger}$ is the transpose of $\mathbf{C}_k$, and $\boldsymbol{\varphi}$ is a column vector with elements $\phi_1, \phi_2, \ldots \phi_n$. The index k enumerates the MO ψ_k, whose energy is ϵ_k. An important concept in this theory is the Hamiltonian matrix $\mathbf{H}$; its elements are given by

$$H_{rr} = \int \phi_r{}^* H \phi_r d\tau = \alpha_r \qquad \ldots\ldots(2)$$

$$H_{rs} = \int \phi_r{}^* H \phi_s d\tau = \beta_{rs},\ r \neq s. \qquad \ldots\ldots(3)$$

It is most frequently assumed in this theory that when dealing with hydrocarbons we may put all Coulomb integrals α_r equal ($\alpha_r = \alpha$ for all r), and all resonance integrals β_{rs} for neighbour carbon atoms equal ($\beta_{rs} = \beta$ for all neighbour

---

† Now at The Department of Theoretical Chemistry, Jagellonian University, Krakow, Poland.

r, s). The remaining β_{rs} are put equal to zero. We usually take α as the zero of energy and β as the unit in which it is measured.

Let us denote by ξ any perturbation parameter. In a particular case ξ may be a change of one or more Coulomb integrals, or one or more resonance integrals, explicitly or implicitly. Whatever the precise meaning of ξ we have essentially to solve the eigenvalue problem

$$[\mathbf{H}(\xi)-\epsilon_k(\xi)\mathbf{1}]\mathbf{C}_k(\xi)=0 \qquad \ldots\ldots(4)$$

where

$$\epsilon_k(\xi)=\mathbf{C}_k{}^{\dagger}(\xi)\,.\,\mathbf{H}(\xi)\,.\,\mathbf{C}_k(\xi) \qquad \ldots\ldots(5)$$

$$\mathbf{C}_s{}^{\dagger}(\xi)\,.\,\mathbf{C}_k(\xi)=\delta_{sk}. \qquad \ldots\ldots(6)$$

Eqns (4)–(6) are particularly simple for the unperturbed problem, when $\xi=0$. Eqn (6) expresses the orthonormality of the MO's.

There are two important situations where the case of $\xi=0$ has been solved. These are the effect of introducing some heteroatom, such as nitrogen, instead of one of the carbon atoms, and the effect of changing the β_{rs}'s, as in a kind of self-consistent LCAO MO calculation (Coulson, Daudel and Robertson 1951, Pople 1953, Md. Asgar Ali 1960). Both situations could be discussed either *ab initio* or with the use of a perturbation theory (Coulson and Longuet-Higgins 1947 a, b), provided that the perturbation calculations are simple enough. In this paper we shall consider only perturbation calculations, but with a particular regard to their simplicity.

Hitherto perturbation calculations in the LCAO MO theory have usually been based on the concept of atom–atom, atom–bond and bond polarizabilities, introduced by Coulson and Longuet-Higgins (1947 a, b). But unfortunately the calculation of all the polarizabilities needed for any particular problem is usually a tedious task. However Brown and Bassett (1958), independently of the present authors, have pointed out that a more convenient method exists, without depending explicitly on these polarizabilities. In the following section we shall re-discuss this method and remove some of the difficulties which Brown and Bassett found for degenerate levels. Subsequently we shall apply the method to an approximate SCF LCAO MO treatment of conjugated molecules. The object of this application is to reconsider theoretical predictions of bond lengths in butadiene, naphthalene and anthracene. Such reconsideration is desirable in view of new experimental results of high accuracy for these latter two molecules (Unpublished work by Almenningen, Bastiansen and Dyvik, reported in references 6, 7 of Bastiansen and Skancke 1961, Cruickshank and Sparks 1960).

§ 2. GENERAL FORMULATION OF PERTURBATION PROCEDURE

We shall express our analysis in a form that is suitable for calculating the first-order perturbation of any finite Hermitian matrix. The method, therefore, is much more general than the specific use that we shall later make of it. It is necessary, however, to distinguish between degenerate and non-degenerate levels. We deal with them separately.

2.1. *Non-degenerate Levels*

Equations (4)–(6) are obviously valid for all values of ξ, and its seems reasonable to assume continuity of $\mathbf{C}_k(\xi)$, $\epsilon_k(\xi)$, $H_{rs}(\xi)$ and their first derivatives in the neighbourhood of $\xi=0$. Differentiating (4)–(6) and letting $\xi\rightarrow 0$, we obtain

$$[\mathbf{H}(0)-\epsilon_k(0).\mathbf{1}]\,\mathbf{dC}_k(0)=[d\epsilon_k.\mathbf{1}-\mathbf{dH}]\mathbf{C}_k(0) \qquad \ldots\ldots(7)$$

where

$$d\epsilon_k=\mathbf{C}_k{}^{\dagger}(0).\mathbf{dH}.\mathbf{C}_k(0) \qquad \ldots\ldots(8)$$

$$(dH)_{rs}=d(H_{rs})$$

$$\mathbf{C}_k{}^{\dagger}(0).\mathbf{dC}_k(0)=0. \qquad \ldots\ldots(9)$$

Eqns (7)–(9) are effectively the same as those given by Brown and Bassett (1958, to be referred to as BB). According to them it is convenient to look for a solution

$$\mathbf{dC}_k=\mathbf{a}_k+\lambda_k\mathbf{C}_k(0) \qquad \ldots\ldots(10)$$

where $\mathbf{a}_k$ is any particular solution of (7) and where, from (9) and (10),

$$\lambda_k=-\mathbf{C}_k{}^{\dagger}(0).\mathbf{a}_k. \qquad \ldots\ldots(11)$$

The set of equations (7) is easy to solve (in order to get $\mathbf{a}_k$) because on account of (8) there is no eigenvalue condition, and (7) is therefore a set of simultaneous linear equations.

Having found $\mathbf{dC}_k$ for all occupied orbitals, we can easily obtain the new formal charges $q_u(\xi)$ and the new π-bond orders $p_{uv}(\xi)$. For, if n_k is the occupation number of the MO ψ_k,

$$q_u(\xi)=q_u(0)+\left(\frac{\partial q_u}{\partial\xi}\right)_0 d\xi\equiv q_u(0)+2\sum_k n_k c_{ku}dc_{ku} \qquad \ldots\ldots(12)$$

$$p_{uv}(\xi)=p_{uv}(0)+\left(\frac{\partial p_{uv}}{\partial\xi}\right)_0 d\xi=p_{uv}(0)+\sum_k n_k(c_{ku}dc_{kv}+c_{kv}dc_{ku}). \qquad \ldots\ldots(13)$$

Eqns (7)–(13) show that this type of perturbation calculation is simpler than the repeated solution of the new eigenvalue problem for each $\xi(\neq 0)$. For there is now no eigenvalue condition and, further, the solution of (7) for $\mathbf{dC}_k$ is much simpler than that of the analogous equation for $\mathbf{C}_k(\xi)$. It would, of course, be perfectly possible to express $q_u(\xi)$ and $p_{uv}(\xi)$ of (12) and (13) in terms of the Coulson–Longuet-Higgins polarizability coefficients. But, as BB pointed out, and as we shall see later in in our detailed application, the large number of these mutual polarizabilities ($\frac{1}{2}n(n+1)$ for the atom–atom polarizabilities in a molecule containing n carbon atoms) makes the older method less convenient than the new ones.

2.1. *Degenerate Levels*

So far we have assumed that none of the occupied MO's is degenerate. For degenerate states the method of Brown and Bassett needs special care. This is particularly true if the presence of the perturbation ξ changes the symmetry properties of the molecule. Since our approach for these degenerate levels differs considerably from that of BB, we shall first describe our own method. Then certain differences and contradictions between the two treatments will have to be discussed.

Let us assume that $\epsilon_k(0)$ has a g-fold degeneracy, and $\mathbf{C}_{k1}(0),\ldots,\mathbf{C}_{kg}(0)$ are the appropriate eigenvectors, which we assume to be orthonormal. We also suppose that all occupation numbers are the same (usually two, corresponding to a closed-shell molecule). We now have

$$[\mathbf{H}(\xi)-\epsilon_{ki}(\xi).\mathbf{1}]\mathbf{C}_{ki}(\xi)=0 \qquad \ldots\ldots(14)$$

$$\mathbf{C}_{ki}{}^{\dagger}.(\xi)\mathbf{C}_{kj}(\xi)=\delta_{ij} \text{ with } i,j=1,2,\ldots g. \qquad \ldots\ldots(15)$$

In general $\epsilon_{ki}(\xi) \neq \epsilon_{kj}(\xi)$ if $i \neq j$, but of course $\epsilon_{ki}(0)=\epsilon_{kj}(0)$ ($=\epsilon_k$ for short). Then by differentiation of (14)–(15) and going to the limit as $\xi \to 0$:

$$[\mathbf{H}(0)-\epsilon_k\mathbf{1}]\mathbf{dC}_{ki}(0)=[d\epsilon_{ki}.\mathbf{1}-\mathbf{dH}]\mathbf{C}_{ki}(0) \qquad \ldots\ldots(16)$$

$$\mathbf{C}_{ki}^{\dagger}(0).\mathbf{dC}_{kj}(0)+\mathbf{C}_{kj}^{\dagger}(0).\mathbf{dC}_{ki}(0)=0 \qquad \ldots\ldots(17)$$

where

$$\mathbf{C}_{ki}(0)=\lim_{\xi\to 0}\mathbf{C}_{ki}(\xi). \qquad \ldots\ldots(18)$$

Equations (7)–(9) are now replaced by (16)–(18). But certain important differences must be noticed between the two sets of equations. Thus, according to (18), we must start with properly chosen eigenvectors $\mathbf{C}_{ki}(0)$ of the unperturbed problem, and in addition $\mathbf{dC}_{ki}(0)$ is no longer necessarily orthogonal to $\mathbf{C}_{kj}(0)$. However the following theorems simplify the solution of (16)–(18). Their proofs are given in the Appendix.

Theorem 1. If the occupation numbers of all g degenerate levels are equal, so that $n_{k1}=n_{k2}=\ldots=n_{kg}$, then without loss of generality it may be assumed that in the calculation of $q_u(\xi)$, $p_{uv}(\xi)$ and $\epsilon_{ki}(\xi)$

$$\mathbf{C}_{ki}^{\dagger}(0).\mathbf{dC}_{kj}(0)=0 \quad \text{for all } i, j. \qquad \ldots\ldots(19)$$

Theorem 2. To avoid inconsistency in the linear set (16) the vectors $\mathbf{C}_{ki}(0)$ must be properly chosen. The necessary and sufficient condition for this proper choice of the zero-order eigenvectors is that

$$\mathbf{C}_{ki}^{\dagger}(0).\mathbf{dH}.\mathbf{C}_{kj}(0)=0 \quad \text{for all } i\neq j. \qquad \ldots\ldots(20)$$

This theorem is proved (see later) on the assumption that the degenerate eigenvectors are orthonormal:

$$\mathbf{C}_{ki}^{\dagger}(0).\mathbf{C}_{kj}(0)=\delta_{ij}. \qquad \ldots\ldots(21)$$

Theorem 3. In practice the degeneracy is seldom greater than two. Let us put $g=2$, and take X_{k1} and X_{k2} to be any orthonormal eigenvectors of the unperturbed molecule for the degenerate eigenvalue ϵ_k. Then it follows from theorem 2 that the properly chosen zero-order eigenvectors for the perturbed molecule are given by the following explicit formula.

$$\mathbf{C}_{ki}(0)=\lim_{\xi\to 0}\mathbf{C}_{ki}(\xi)=aX_{k1}+bX_{k2} \qquad \ldots\ldots(22)$$

where

(i) if $dH_{12}(\xi)$ vanishes in the neighbourhood of $\xi=0$, then

$$a=1,\ b=0 \text{ or alternatively } a=0,\ b=1, \qquad \ldots\ldots(23)$$

(ii) if $dH_{12}(\xi)$ does not vanish in the neighbourhood of $\xi=0$, then

$$b/a=-Q\pm(1+Q^2)^{1/2} \qquad \ldots\ldots(24)$$

with

$$Q=\tfrac{1}{2}\lim_{\xi\to 0}\left\{\frac{dH_{11}-dH_{22}}{dH_{12}}\right\}. \qquad \ldots\ldots(25)$$

Theorem 4. When the proper zero-order eigenvectors have been chosen (according to theorems 2 or 3), and when all the occupation numbers are equal (with the consequences of theorem 1), then the solution of the linear equations (16) can be obtained in a similar way to that in the case of non-degenerate levels:

$$\mathbf{dC}_{ki}=\mathbf{a}_{ki}+\sum_{\text{all}}\lambda_{ij}^{(k)}\mathbf{C}_{kj}(0), \quad i=1,2,\ldots g \qquad \ldots\ldots(26)$$

where $\mathbf{a}_{ki}$ is any particular solution of (16) and

$$\lambda_{ij}^{(k)} = -\mathbf{C}_{kj}^{\dagger}(0) \cdot \mathbf{a}_{ki}. \qquad \ldots\ldots(27)$$

This rather involved discussion of the situation in degenerate levels is essential if we are to deal effectively with molecules such as benzene, where different perturbations affect the molecular symmetry in different ways, as for example, in Jahn–Teller distortions in aromatic ions.

Theorems 1 and 4 are different from those given by BB; theorems 2 and 3 are new. The reason for our differences in theorems 1 and 4 lies in BB's claim that with degenerate states a direct solution of (16) in terms of a_{ki}, $\mathbf{C}_{k1}(0), \ldots \mathbf{C}_{kg}(0)$ is not in general possible, when the perturbation $\mathbf{dH}$ arises from changes in the bond-resonance integrals β. BB say that this arises from an error, usually repeated from Schrödinger, that the vectors $\mathbf{dC}_{kj}$ and $\mathbf{dC}_{ki}$ must be orthogonal for each i and j. But from the proof of our theorem 1 it follows that although such an orthogonality is not really necessary, it can nevertheless be assumed without any lack of generality in calculations of $q_u(\xi)$, $p_{uv}(\xi)$ and $\epsilon_{ki}(\xi)$ if, as is usually the case, the occupation numbers of all the degenerate eigenvectors considered are the same. BB's failure to find the proper solution of (16) may be due either to not having insisted on the proper choice of zero-order functions $\mathbf{C}_{ki}(0)$, $i=1, 2 \ldots g$, or to having looked for a solution of the form

$$\mathbf{a}_i + \lambda_1 \mathbf{C}_i^{(1)} + \lambda_2 \mathbf{C}_i^{(2)} + \ldots + \lambda_g \mathbf{C}_i^{(g)}, \qquad \ldots\ldots(28)$$

which does not have a sufficient number of indices, as (26) shows.

Our discussion is independent of the kind of degeneracy. This can be either essential (in the case of a high symmetry) or accidental (as in the case of many large polynuclear hydrocarbons).

§ 3. APPLICATION TO HYDROCARBON MOLECULES

We shall now apply this perturbation analysis to develop a simple self-consistent theory for the π-molecular orbitals of an aromatic or condensed hydrocarbon. In the simplest theory (Hückel 1931, 1932) the MO's are only self-consistent with respect to the Coulomb terms α_r (Eqn (2)). For the secular equations are based on the assumption that all β_{rs} (Eqn (3)) are equal. Yet it is then concluded that the π-bond orders p_{rs} are unequal, and hence that the bond lengths are unequal. This should, of course, also imply that the β_{rs} are unequal. Ideally we should now start the cycle of calculations again, using the β's inferred from the first cycle; and we chould continue this iterative procedure till consistency is obtained in the β's. (Fortunately this process does not spoil the consistency in the α's.) But we can show that our perturbation analysis enables a satisfactory calculation of almost-consistent bond lengths to be made without any further solution of the secular equations. For this we use the same outlook as Coulson, Daudel and Robertson (1951), though the particular representations (29) and (30) are taken from the successful analysis of bond length alternations in conjugated chain molecules by Longuet-Higgins and Salem (1959) and later papers).

We therefore make the following assumptions concerning the relations between bond lengths R_{rs}, π-bond order p_{rs} and resonance integral β_{rs}:

(1) $\beta_{rs} = \beta_0 \exp(-\alpha R_{rs})$ for neighbours ……(29)

(2) $\beta_{rs} = 0$ for non-neighbours

(3) $\alpha_r = \text{constant } (\alpha)$ for all r

(4) $R_{rs} = b - c p_{rs}$ ......(30)

(5) all overlap integrals are zero.

We differ a little from Longuet-Higgins and Salem in our choice of parameters a, b, c. The parameters b and c were fitted by use of the following bond lengths: ethylene 1·337 Å, benzene 1·397 Å, graphite 1·421 Å. (Longuet-Higgins and Salem used 1·350 Å for ethylene. Our value of 1·337 Å is the mean of three recent very accurate measurements: Bartell and Bonham (1957) 1·334 Å, Allen and Plyler (1958) 1·337 Å, Dowling and Stoicheff (1959) 1·339 Å). So we take

$$R_{rs} = 1{\cdot}517 - 0{\cdot}180 p_{rs}$$

$$\text{i.e.} \quad p_{rs} = \frac{2}{3} - \frac{50}{9}(R_{rs} - 1{\cdot}397). \qquad \text{......(31)}$$

If this relation were valid down to $p_{rs} = 0$, it would predict that a pure single bond between sp^2 trigonal carbon atoms would have a length 1·517 Å. This is a little longer than is sometimes believed, but not impossibly so. Our change in b and c necessitates changes in a and β_0. We find

$$\beta_{rs} = \beta_0 \exp(-2{\cdot}683 R_{rs}) \qquad \text{......(32)}$$

where R_{rs} is in Å. The precise value of β_0 is not needed in these calculations.

We have used these relations in a reconsideration of the theoretical bond lengths in butadiene, naphthalene and anthracene, for all of which new accurate experimental results have recently been obtained (Coulson, Daudel and Robertson 1951, Almenningen, Bastiansen and Traetteberg 1958, Bastiansen and Skancke 1961, Cruickshank and Sparks 1960). Our procedure is as follows. Let r_{rs} be the deviation of the final bond length from the benzene value 1·397 Å. Then we have two different approximate relations between p_{rs} and r_{rs}. These are given in (13) and (31). If both are satisfied, we have a self-consistent set of bond orders and lengths. By elimination of p_{rs} we obtain

$$\frac{2}{3} - \frac{50}{9} r_{rs} = p_{rs}(0) + \sum \left(\frac{\partial p_{rs}}{\partial r_{uv}}\right)_0 r_{uv} \qquad \text{......(33)}$$

where $p_{rs}(0)$ denotes the value of p_{rs} calculated with all β_{rs} equal. For different bonds rs this gives a set of linear simultaneous equations whose solution leads at once to the required bond lengths r_{rs}. For large molecules this solution is conveniently obtained by an iterative procedure in which, when finding the nth iterative to r_{rs} we use the $(n-1)$th iteratives on the right-hand side of (33). A very few iterations are sufficient to give the required values. The numerical values of the various $(\partial p_{rs}/\partial r_{uv})$ can easily be obtained from (13), using the perturbation theory to give each dc_{ku} etc.

§ 4. NUMERICAL VALUES

Accurate comparison of theoretical and experimental bond length has always been beset by one great difficulty—further refinements have frequently made considerable changes in the 'observed' values. Thus the comparison for naphthalene and anthracene which was first made by Coulson, Daudel and Robertson (1951) had to be re-made by Pritchard and Sumner (1955). More recently still, some new different experimental values have been reported by Cruickshank and Sparks (1960) using x-ray methods, and by Almenningen, Bastiansen and Dyrik. (see Bastiansen and Skancke 1961) using electron-diffraction methods. These latest observed values differ considerably from the earlier observed values, and inspire us to reconsider the theory. It is true that Cruickshank and Sparks have already made some such reconsideration. But they used only X-ray values and did not include the most recent electron diffraction values, nor of course could they include our present calculations. In addition they used for their criterion the root mean square of all bond length deviations. This particular criterion, though probably the most important single one, is disadvantageous to the LCAO method. For it is well known that this method leads to a value for the shortest bond which is usually too great. The Pauling superposition method, on the other hand, generally gives a good value for this bond. Thus in the r.m.s. procedure using LCAO values the bond is weighted highly, so that it is possible to mask a good agreement with other bonds by a poor agreement for this one.

Our results for butadiene, naphthalene and anthracene are given in Tables 1–3. In these tables:

(i) Pauling's superposition method refers to the semi-empirical correlation between bond length and double-bond character, as discussed in the latest edition of Pauling's book (1960).

(ii) Spin states method refers to the use of Slater determinants discussed for example by Daudel, Lefebvre and Moser (1959, pp. 130–134), but using the new experimental values for ethylene, benzene and graphite instead of Table V.10 of their book.

(iii) The LCAO MO method is the original simple Hückel method, using an order–length curve but constant β_{rs}, as described by Coulson (1951).

(iv) The approximate SCF MO method is the result of solving the Eqns (33) of this present paper.

According to Cruickshank and Sparks three independent X-ray estimations of the bond lengths in anthracene gave very close results, but with naphthalene two independent estimates did not agree well. This leads us to trust the anthracene average values more than the naphthalene average values. Fortunately with electron diffraction the situation is reversed. For as Bastiansen and Skancke showed, two different zero-order models for naphthalene gave very close agreement, but not for anthracene. The X-ray and electron-diffraction average values are shown in the Tables. For the purposes of our comparison of theory and experiment, we have used the average of the X-ray and electron-diffraction measurements as the experimental lengths. Since the estimated errors of the two methods are closely similar this is at present the best that can be done.

Table 1. Comparison of Bond Lengths for Naphthalene in (Å)

Method	Bonds				Mean errors		
	1–2	2–3	1–9	9–10	X-ray	e.d.	average
1. Pauling's superposition	1·371	1·422	1·422	1·422	0·005	0·003	0·004
2. Spin states	1·389	1·397	1·417	1·438	0·017	0·014	0·016
3. LCAO MO	1·387	1·408	1·417	1·424	0·010	0·007	0·009
4. Appr. SCF (this paper)	1·382	1·414	1·420	1·419	0·005	0·004	0·004
5. X-ray	1·364	1·415	1·421	1·418	—	0·003	—
6. El. diffr.	1·371	1·412	1·422	1·420	0·003	—	—
7. Exp. average	1·368	1·414	1·422	1·419			

Finally the mean error columns in Tables 1–3 require some comment. We have calculated these values as the arithmetic mean of the absolute deviation, but only considering non-equivalent bonds. In this way we hope not to exaggerate the influence of the errors for the shortest bond, already referred to. (It is only for the 1–2 bond of naphthalene that this error is at all serious.)

Table 2. Comparison of Bond Lengths for Anthracene (in Å)

Methods	Bonds					Mean errors		
	1–2	1–11	2–3	9–11	11–12	x-ray	e.d.	average
1. Pauling's superposition	1·361	1·439	1·439	1·394	1·439	0·009	0·019	0·014
2. Spin states	1·389	1·417	1·397	1·408	1·438	0·016	0·009	0·012
3. LCAO MO	1·389	1·421	1·412	1·408	1·430	0·011	0·004	0·007
4. Appr. SCF (this paper)	1·377	1·427	1·420	1·405	1·428	0·005	0·005	0·002
5. X-ray	1·368	1·436	1·419	1·399	1·428	—	0·009	—
6. El. diffr.	1·390	1·420	1·419	1·404	1·425	0·009	—	—
7. Exp. average	1·379	1·428	1·419	1·402	1·427			

Table 3. Comparison of Bond Lengths for Butadiene (in Å)

Methods	Bonds		Mean errors		
	1–2	2–3	x-ray	e.d.	average
1. Pauling's superposition	1·337	1·507	0·03	0·012	0·023
2. Spin States	1·362	1·431	0·02	0·038	0·028
3. LCAO MO	1·356	1·436	0·015	0·033	0·023
4. Appr. SCF (this paper)	1·346	1·465	0·005	0·013	0·003
5. X-ray	1·35	1·46	—	0·018	
6. El. diffr.	1·337	1·483	0·018	—	
7. Exp. average	1·345	1·470			

The following conclusions follow from these three tables.

(1) The poorest agreement with experiment is associated with the approximate spin-states method (which is, however, the simplest).

(2) On average, the Pauling superposition method is about as reliable as the LCAO MO method. It is better by 0·005 Å for naphthalene, but worse by 0·007 Å for anthracene. Cruickshank and Sparks have already drawn attention to the surprising reliability of this simple method.

(3) Our approximate SCF method gives the best results with a mean error for the three molecules of only 0·003 Å. The inclusion of approximate self-consistence reduces the mean error for naphthalene by a factor of two, and for anthracene by a factor of three. Where the X-ray and electron-diffraction data are the same, they are also practically the same as the SCF results, the difference being usually less than 0·003 Å (which is approximately the same as the experimental accuracy of measurement). Where the X-ray and electron-diffraction differ appreciably, our predicted SCF results lie near the average (with the exception of the shortest bond in naphthalene, where the error is 0·014 Å). In all cases the predicted sequence of increasing bond lengths is identical with the experimental average.

It would be interesting to make similar comparison for other aromatic molecules. But this must be done with great care, since the experimental results are usually not known with sufficient acccuracy. Thus in coronene, which has often been used in comparison of theory and experiment, the new electron-diffraction data (as in Bastiansen and Skancke 1961, references 6 and 7) differ from the older x-ray data (Robertson and White 1945) by as much as 0·05, 0·03, 0·023, and 0·008 Å for the various distinct bonds. Until these discrepancies have been elucidated there is no point in attempting a serious comparison with theory.

§ 5. SOME OTHER REFINEMENTS

Pritchard and Sumner (1955) have discussed the influence of some other refinements in the prediction of bond lengths in aromatic molecules:

(1) Pople's SCF method,

(2) modified Pople method, with inclusion of compression or extension energy for σ-electrons,

(3) simple Hückel method with variation of Coulomb integrals,

(4) SCF MO method with variation of Coulomb integrals,

(5) as in (4), but with inclusion of compression energy.

Of these only (2) and (4) appear (see also Cruickshank and Sparks 1960) to give significant improvement. We have therefore though it worth while to compare these two approximations with our own, and with the experimental averages previously described. Tables 4 and 5 show our results.

Table 4. Errors for Bond Lengths in Naphthalene (Å)

	Bonds 1–2	2–3	1–9	9–10	Average error

Simple LCAO MO	0·010	−0·007	−0·007	0·006	0·003	0·007
Approx. SCF (this paper)	−0·002	−0·001	0·001	0·003	0·001	0·002
Approx. (2)	0·002	0·003	0·003	0·004	−0·003	0·003
Approx. (4)	0·000	0·009	0·011	0·009	0·011	0·008

In the last two lines of these tables we have used the same bond length changes in approximations (2) and (4) as were calculated by Pritchard and Sumner. It would appear from these values that, when the experimental values are taken to be those which we have adopted in this paper, approximation (2) is better than (4), and about equal to our approximate SCF method. But the approximate SCF method is the simpler. In both these two methods the average error is of the same order as the best experimental accuracy that may yet be claimed.

ACKNOWLEDGMENT

We should like to thank Mr. P. N. Skancke for the benefit of valuable discussion, and one of us (A. G.) would like to acknowledge the award of a Rockefeller Fellowship, which has made this work possible.

APPENDIX

Proof of theorem 1. We can obviously expand $\mathbf{dC}_{ki}$ of (16) in the form

$$\mathbf{dC}_{ki}=\sum_{\text{all } m,n} b_{ki,mn}\mathbf{C}_{mn}(0) \qquad \ldots\ldots(\text{A1})$$

where the $b_{ki,mn}$ are at present undetermined. Here, and in (A2) and (A4), the index n enumerates the degenerate orbitals associated with the eigenvalue index m (or k). Inserting (A1) in (16) we find that

$$\mathbf{dC}_{ki}=\sum_{m\neq k,n}\left\{\frac{\mathbf{C}_{ki}{}^{\dagger}(0)\,.\,\mathbf{dH}\,.\,\mathbf{C}_{mn}(0)}{\epsilon_k-\epsilon_m}\right\}\mathbf{C}_{mn}(0)$$
$$+\sum_{n} b_{ki,kn}\mathbf{C}_{kn}(0). \qquad \ldots\ldots(\text{A2})$$

Now from (A1) and (17) it follows that

$$b_{ki,kj}=-b_{kj,ki};\quad b_{ki,ki}=0. \qquad \ldots\ldots(\text{A3})$$

So the coefficients $b_{ki,kj}$ are antisymmetric in i, j. On the other hand the charges q_u and bond orders p_{uv} and related quantities such as the energy, are symmetric in i, j. This follows from (12) and (13). Thus the second summation in (A2) can at least formally be neglected. Therefore, if all occupation numbers of the degenerate orbitals are equal $(n_{k1}=n_{k2}=\ldots=n_{kg})$, in all calculations of q_u, p_{uv}, etc. it is sufficient to take

$$\mathbf{dC}_{ki}=\sum_{m\neq k,n}\left\{\frac{\mathbf{C}_{ki}\,(0)\,.\,\mathbf{dH}\,.\,\mathbf{C}_{mn}(0)}{\epsilon_k-\epsilon_m}\right\}\mathbf{C}_{mn}(0). \qquad \ldots\ldots(\text{A4})$$

Theorem 1 follows immediately from (A4) and the orthogonality of $\mathbf{C}_{mn}$ and $\mathbf{C}_{kj}$ for $m\neq k$.

Proof of theorem 2. This is really the familiar theorem concerning the correct zero-order functions in degenerate first-order perturbation theory. To prove the necessity of (20) we take the product of (16) with $\mathbf{C}_{kj}{}^{\dagger}(0)$. The left-hand side vanishes and so also does the first part of the right-hand side. The rest is (20) with i and j interchanged. Also, if (20) holds, then $\mathbf{dH}\,.\,\mathbf{C}_{ki}(0)$ must be some multiple of $\mathbf{C}_{ki}$. There is then no difficulty in solving (16) without the possibility of any inconsistency. Condition (20) is therefore both necessary and sufficient.

Proof of theorem 3. This is a simple application of theorem 2 Eqn (20), when i and j can only take the values 1 and 2.

Proof of theorem 4. When theorems 1–3 are satisfied, (A4) does in fact give the solution for $\mathbf{dC}_{ki}$. Alternatively, if we can find one particular solution $\mathbf{dC}_{ki}=\mathbf{a}_{ki}$, then the linearity of (16) shows that the full solution must be

$$\mathbf{dC}_{ki}=\mathbf{a}_{ki}+\sum_{\text{all } j}\lambda_{ij}{}^{(k)}\mathbf{C}_{kj}(0)$$

where, to preserve the orthogonality condition (19), the λ_{ij} must satisfy (27) Eqn (A4) shows that this solution is unique.

The Band Structure of Body-centred Cubic Transition Metals

By C. A. BATES and K. W. H. STEVENS
Department of Physics, University of Nottingham

MS. received 19th April 1961

Abstract. The theory of the magnetic properties of iron put forward by Mott and Stevens made a number of assumptions about the band structures of the body-centred cubic 3d transition metals. The purpose of the present paper is to give an account of a theoretical study which has been made to see what could reasonably be expected on fairly general grounds about the band structures. It then becomes possible to see more clearly what innovations are required for the Mott and Stevens theory. The method used is essentially a tight binding method, with the feature that the functions used are not located at lattice sites but are on the links joining nearest neighbour lattice points. It leads to an 8×8 matrix for the lattice potential for each value of $\mathbf{K}$. A discussion of the diagonalization of this 8×8 matrix is given for a number of symmetry points and directions in $\mathbf{K}$-space, and it is shown that a good deal of valuable information can be obtained from relatively simple ideas. It is also shown that the band structure so obtained is incomplete because two of the d-functions are omitted, and these are then included by perturbation methods. The Mott and Stevens model of iron is shown to follow from assumptions about the results of this perturbation treatment. A discussion is given of the ground state determinantal functions for vanadium, chromium and iron which it is hoped will be of use in interpreting the physical properties of these elements. Apart from the value the theory may have in its application to the above metals, the algebraic treatment provides an elegant example of the effects of symmetry on band structures, previously thoroughly discussed in terms of groups by Bouckaert, Smoluchowski and Wigner.

§ 1. INTRODUCTION

THE study of the properties of transition metals and alloys has proved to be of considerable experimental interest, and theoreticians have long been under pressure to produce theories which can be used to interpret the observations. As it is not possible to give complete theoretical treatments of the enormously complicated many-body problems involved, approximations are always made. It is not our purpose to review the types of approximations which have been made (see Herring 1960) but it seems worth emphasizing that it is highly desirable that all such approximations should be recognized as such and subjected to close examination.

In an earlier paper one of the present authors, in collaboration with Professor Mott, put forward a theory of the above sort to account for the magnetic properties of iron (Mott and Stevens 1957). This theory has been subjected to a close examination by a number of workers (Marshall and Weiss 1959, Slater, unpublished†, Slater and Wood unpublished‡) as well as by ourselves, and it has been criticized quite strongly, mainly on theoretical grounds. In order to have as clear a picture as possible of what may be happening in iron, and also to understand the criticisms in detail, we have been examining, from a general point of view, the band structure which might be expected for a body-centred transition metal. To this we have added special assumptions which lead to the Mott and Stevens model.

§ 2. NON-MATHEMATICAL DESCRIPTION OF MODEL

A body-centred cubic lattice can be regarded as composed of two interpenetrant simple cubic lattices. Although all the atoms in the lattice are identical, it is convenient to refer to them as A or B atoms according to the simple cubic sublattice A or B on which they lie (see Fig. 1). Suppose now that the crystal is regarded as a large covalently bonded molecule in which each A (or B) atom is linked by a bond to each of its eight neighbouring B (or A) atoms. Such a bond will be said to lie on a link, a link being the line joining two nearest neighbour atoms. To construct such bonds we may proceed as follows. At each A (or B) atom eight orbitals, formed by hybridizing suitable atomic orbitals, are constructed, so that each one is, in turn, directed principally towards a nearest neighbour B (or A) atom. Then consider a typical AB link. Along it there will be an orbital ϕ_A located at the A atom and directed towards the B atom, and at the B atom there will be a similarly shaped orbital ϕ_B directed towards the A atom. The two orbitals may then be combined symmetrically and antisymmetrically, thus:

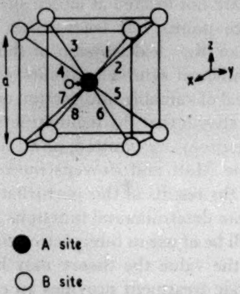

Fig. 1. Body-centred cubic lattice showing the labelling of the links joining an (A site) atom at 0 to its eight nearest neighbours (B site) atoms.

$$\psi_s = \frac{\phi_A + \phi_B}{\{2(1+S)\}^{1/2}}, \quad \psi_a = \frac{\phi_A - \phi_B}{\{2(1-S)\}^{1/2}} \qquad \ldots\ldots (1)$$

where S is the overlap integral. S will probably not be negligible. ψ_s and ψ_a are orbitals which encompass both atoms and, in the language of theoretical chemistry, ψ_s may be called a bonding orbital and ψ_a an antibonding orbital. This nomenclature arises because although they are both constructed from ϕ_A

and ϕ_B, ψ_a vanishes on the plane which bisects the link at right angles. Thus if they were both eigenstates a higher energy would normally be associated with ψ_a, and the probability of its occupation would be less than that of ψ_s. This is because the charge density associated with ψ_s is less localized than that associated with ψ_a (both charge densities are normalized to unity) since that of ψ_a certainly vanishes on a plane.

Having constructed pairs of such orbitals on each link of the crystal the method of construction is now largely forgotten, for we proceed as if the ψ_s and ψ_a are the basic orbitals. The general principles of band theory require the one-electron wave functions to be orthogonal to one another, and although bonding and antibonding orbitals on the same link are orthogonal, pairs on different links are not, in general, orthogonal. To move in the direction of obtaining fully orthogonal functions it is necessary to pass from the localized bonding and antibonding orbitals to non-localized Bloch functions. This is readily accomplished by following the usual prescription (Bloch 1928). Each Bloch function is characterized by a propagation vector $\mathbf{k}$ and two such functions with differing $\mathbf{k}$ are automatically orthogonal. Further, any single particle operator which has the same periodicity as the lattice has zero matrix elements between Bloch functions of differing $\mathbf{k}$'s. Thus as well as obtaining orthogonal functions progress is made towards diagonalizing the approximate Hamiltonian. As eight links end on each atom and on each link there are two localized orbitals, sixteen Bloch functions can be formed for each value of $\mathbf{k}$ (assuming the A atoms are different from the B atoms, so that the lattice symmetry is that of a simple cube). Actually the A and B atoms are identical and in the detailed theory it will be shown that the sixteen can be decomposed into two groups of eight.

In a complete treatment one would have to use an infinite number of Bloch functions for each $\mathbf{k}$, and one would then have to find linear combinations of them to diagonalize the Hamiltonian. Once the Hamiltonian is diagonalized the linear combinations are automatically orthogonal. The approximation we make is that of selecting sixteen functions of each $\mathbf{k}$, and diagonalizing the associated 16×16 sub-matrix of the Hamiltonian, the assumption being that matrix elements from these sixteen to the rest of the infinite set are negligible. In fact, for a given value of $\mathbf{k}$ it is usually not possible to diagonalize the 16×16 matrix unless the lattice potential is given explicitly, though it is always possible to reduce the problem to that of diagonalizing two 8×8 matrices. However a good deal of progress can be made with a general Hamiltonian for special values of $\mathbf{k}$, and it is with these values that we shall mostly be concerned.

The method we use appears to be similar to that described by Hall (1958) and used for the diamond lattice. It appears to differ from that used by Hall (1952, 1953 a, b) for a body-centred cubic lattice (though see Slater and Koster 1954).

§ 3. CONSTRUCTION OF THE ORBITALS

At each lattice point eight equivalent orthogonal directed orbitals are to be set up, each directed towards a different nearest neighbour atom. A simple application of group theory shows that this can be achieved by hybridizing functions which transform according to the Γ_1, Γ_{15}, Γ_{25}' and Γ_2' irreducible representations of the cubic group (the notation of Bouckaert, Smoluchowski and Wigner (1936), to be referred to as B.S.W. will be used throughout). The specification need be no more detailed than this, but in order to be on familiar ground we may suppose that the Γ_1 function is similar to the normalized 4s orbit of the free atom, Γ_{15} to $4p_x$, $4p_y$ and $4p_z$, Γ_{25}' to $3d_{xy}$, $3d_{yz}$ and $3d_{zx}$, and Γ_2' to $4f_{xyz}$, where Ox, Oy and Oz are taken parallel to the cube edges (Fig. 1). The hybridized function which is directed primarily along the (1, 1, 1) direction, or link 1 in Fig. 1, is similar to

$$\phi_A = \frac{1}{\sqrt{8}}\{4s + 4p_x + 4p_y + 4p_z + 3d_{xy} + 3d_{yz} + 3d_{zx} + 4f_{xyz}\}.$$

The others may be obtained from this by suitable rotations of axes and, for example, the function directed along the (1, −1, 1) direction is similar to

$$\frac{1}{\sqrt{8}}\{s + p_x - p_y + p_z - d_{xy} - d_{yz} + d_{zx} - f_{xyz}\}$$

where the principal quantum numbers have been omitted. It is not possible to demonstrate the degree of directivity achieved without making assumptions about the radial parts of the atomic wave functions. If however we assume that at some value of the radius all the radial functions are equal, then the values of ϕ_A in the (1, 1, 1), (1, 0, 0), (−1, −1, −1), (−1, 1, 1) and (1, 1, 0) directions are proportional to 9·85, 2·73, −0·10, −1·26 and 5·39 respectively. The next step is to construct the bonding and antibonding orbitals as described by Eqns (1), to obtain new functions which are strongly concentrated on the links.

§ 4. THE BLOCH FUNCTIONS

The eight links which meet on an A atom are labelled from 1 to 8 as shown in Fig. 1. Any link orbital can then be specified by a number which describes the link to which it is parallel and similarly directed, a letter a or b according to whether it is antibonding or bonding and the coordinate of the midpoint of the link on which it is situated. Thus $|1, b, \mathbf{r}_n\rangle$ is the normalized bonding orbital which parallel to link 1 and centred at $\mathbf{r}_n$. $|1, a, \mathbf{r}_n\rangle$ is the corresponding antibonding orbital. Sixteen nearly normalized Bloch functions are then formed, thus:

$$|s, b\rangle = \frac{1}{\sqrt{N}}\sum_{\mathbf{r}_n} \exp(i\mathbf{k}.\mathbf{r}_n)|s, b, \mathbf{r}_n\rangle \qquad \ldots\ldots(2)$$

$$|s, a\rangle = \frac{1}{\sqrt{N}}\sum_{\mathbf{r}_n} \exp(i\mathbf{k}.\mathbf{r}_n)|s, a, \mathbf{r}_n\rangle \qquad \ldots\ldots(3)$$

where s takes values from 1 to 8, N is the number of A atoms in the lattice, $\mathbf{r}_n$ depends on s, and $\mathbf{k}$ is a vector of the first Brillouin zone of the simple cubic lattice. In practice little confusion arises if the $\mathbf{k}$ dependence is not always given explicitly, and this has been anticipated on the left-hand sides of Eqns (2) and (3) where the $\mathbf{k}$ dependence has been omitted.

We now recognize that the A and B atoms are identical, so that the full symmetry is body-centred cubic, not simple cubic. Then the orbitals which, for example, have been labelled as 1 and 8 are seen to be identical in shape and orientation, but differently placed in the lattice. Suppose then we consider the linear combinations of Bloch functions:

$$\frac{1}{\sqrt{2}}\{|1, b\rangle + |8, b\rangle\} \qquad \ldots\ldots(4A)$$

and

$$\frac{1}{\sqrt{2}}\{|1, b\rangle - |8, b\rangle\}. \qquad \ldots\ldots(4B)$$

The first can be written as

$$\frac{1}{\sqrt{(2N)}}\left\{\sum_{\mathbf{r}_{n_1}} \exp(i\mathbf{k}\,.\,\mathbf{r}_{n_1})|1,\, b,\, \mathbf{r}_{n_1}\rangle + \sum_{\mathbf{r}_{n_8}} \exp(i\mathbf{k}\,.\,\mathbf{r}_{n_8})|8,\, b,\, \mathbf{r}_{n_8}\rangle\right\}$$

or as

$$\frac{1}{\sqrt{(2N)}}\sum_{\mathbf{R}_n} \exp(i\mathbf{k}\,.\,\mathbf{R}_n)|18,\, b,\, \mathbf{R}_n\rangle$$

where the summation of $\mathbf{R}_n$ refers to both 1 and 8 orbitals. To write the second expression (4B) in a similar form it is necessary to introduce a new vector $\mathbf{K}$ such that

$$\exp(i\mathbf{k}\,.\,\mathbf{r}_{n_1}) = \exp(i\mathbf{K}\,.\,\mathbf{r}_{n_1})$$

but $$\exp(i\mathbf{k}\,.\,\mathbf{r}_{n_8}) = -\exp(i\mathbf{K}\,.\,\mathbf{r}_{n_8}).$$

Then (4B) becomes

$$|\beta, 1\rangle = \frac{1}{\sqrt{(2N)}}\sum_{\mathbf{R}_n} \exp(i\mathbf{K}\,.\,\mathbf{R}_n)|18,\, b,\, \mathbf{R}_n\rangle. \qquad \ldots\ldots(5)$$

The simplest form for $\mathbf{K}$ is $\mathbf{K}=\mathbf{k}+\mathbf{k}_j$, where $\mathbf{k}_j$ is one of $(\pi/a)(\pm 1, \pm 1, 0)$ or $(2\pi/a)(\pm 1, 0, 0)$. Then as $\mathbf{k}$ ranges over the first Brillouin zone of the simple cubic lattice, $\mathbf{K}$ ranges over the volume external to this but internal to the first Brillouin zone of the body-centred cubic lattice. This point is illustrated in Fig. 2, in which the first Brillouin zone of the simple cubic lattice has been shaded. If now $\mathbf{K}$ is allowed to range over the whole of the inside of the first Brillouin zone of the body-centred cubic lattice the expression (5) for $|\beta, 1\rangle$ includes both linear combinations (4A) and (4B). A similar argument can be given for the other link directions and for the antibonding orbitals, though for the latter it may be noted that it is the antisymmetric combination,

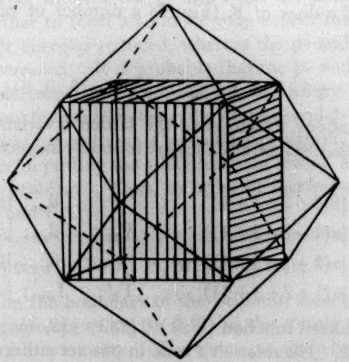

Fig. 2. Brillouin zone of a body-centred cubic lattice showing the inscribed cube corresponding to the Brillouin zone of the simple cubic lattice.

$$|\alpha, 1\rangle = \frac{1}{\sqrt{2}}\{|1, a\rangle - |8, a\rangle\}$$

which corresponds to $\mathbf{K}$ inside the first Brillouin zone of the simple cubic lattice. For each value of $\mathbf{K}$ there are now eight Bloch functions. The approximate

Hamiltonian which is used in band theory has the lattice periodicity, body-centred cubic, and it will have no matrix elements between Bloch functions of differing **K**'s. For general values of **K** no further progress seems possible unless the approximate Hamiltonian and the orbitals are given in much greater detail. For special values of **K** (Fig. 3) a number of valuable results can be obtained.

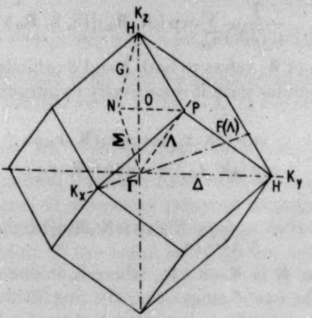

Fig. 3. Brillouin zone of a body-centred cubic lattice showing the axes and points of symmetry as used in the text.

§ 5. The Point Γ, or **K**=(0, 0, 0).

With **K**=0 rotations which leave the lattice invariant permute the Bloch functions amongst themselves, and they are found by inspection to group naturally as follows:

$$\begin{array}{llll}
\Gamma_1; & \mathrm{s}\ ;\ |\beta(1+2+3+4)\rangle & & \left\{\begin{array}{l} \mathrm{d}_{yz};\ |\beta(1+2-3-4)\rangle \\ \mathrm{d}_{zx};\ |\beta(1-2-3+4)\rangle \\ \mathrm{d}_{xy};\ |\beta(1-2+3-4)\rangle \end{array}\right. \\
\Gamma_{15}; & \left\{\begin{array}{l} \mathrm{p}_x;\ |\alpha(1-2-3+4)\rangle \\ \mathrm{p}_y;\ |\alpha(1+2-3-4)\rangle \\ \mathrm{p}_z;\ |\alpha(1+2+3+4)\rangle \end{array}\right. & \Gamma_{25}'; & \\
 & & \Gamma_2'; & \mathrm{f}_{xyz};\ |\alpha(1-2+3-4)\rangle
\end{array}$$

where the un-normalized function $[|\beta, 1\rangle \pm |\beta, 2\rangle \pm |\beta, 3\rangle \pm |\beta, 4\rangle]$ is denoted by $|\beta(1 \pm 2 \pm 3 \pm 4)\rangle$ etc. On rotation a state in one set either turns into a multiple of itself or into another state in the same set. Thus they can be used as bases for irreducible representations of the cubic group, as specified by the Γ's. The s, p_x, p_y etc. denote atomic orbitals which transform in the same ways. As no irreducible representations occur more than once the Hamiltonian has no matrix elements between the sets, as indeed is readily seen by considering the effects of suitable rotations and reflections. Also the states in a given set have the same energies, so we see that at Γ there are two triplets and two singlets.

It is now of interest to consider the physical characteristics of these states. Consider the state denoted by Γ_1. It is formed entirely from bonding orbitals, and in the neighbourhood of any nucleus it has local Γ_1 symmetry. The s atomic orbitals also have this symmetry, as does one of the g atomic orbitals. However as 5g is likely to have a much higher energy than 4s it seems likely that near any nucleus Γ_1 will be dominantly s-like, with possibly a small amount of g-like symmetry. (One might imagine it as mainly spherical with extensions in the directions of nearest neighbours.) As $\mathbf{K}=0$ this local symmetry is repeated at each nucleus, as shown schematically in Fig. 4. Similarly the states in Γ_{15} will locally be predominantly p-like, the states in Γ_{25}' will be locally like d_{yz}, d_{zx} and d_{xy}, and the state Γ_2' will be locally like f_{xyz}. If we now wish to infer something about the relative energies of these states we note first that the s- and d-like states are of the bonding type, whereas the p- and f-like are antibonding. Thus as the atoms come together to form a solid we may expect that the s- and d-like orbitals will have their energies reduced, whereas the p- and f-like orbitals will have their energies increased. It is probable that the p- and f-like orbitals will not be occupied by electrons, so we are unlikely to be very interested in them. It is, however, important to decide on the order of the s- and d-like orbitals. This cannot, strictly, be decided without a detailed calculation. However all calculations seem to agree in putting the s-like function lowest, and we shall assume that this is so in our problem. Thus, in order of increasing energy the levels occur as Γ_1, Γ_{25}', Γ_{15} and Γ_2'.

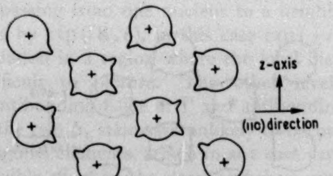

Fig. 4. Schematic diagram showing the local character in the plane containing the 1, 3, 6 and 8 links at the point Γ in the Brillouin zone for the state having Γ_1-type symmetry. (Allowance for possible g-type orbit has been made by distortions which point towards nearest neighbours, superimposed on a spherical s-type orbit).

§ 6. THE POINT H, OR $\mathbf{K}=(0, 2\pi/a, 0)$

The point H lies on the boundary of the Brillouin zone of the body-centred cubic lattice, but corresponds to $\mathbf{k}=(0, 0, 0)$ in the simple cubic zone scheme. Thus H has the full cubic symmetry. The states can again be grouped according to the irreducible representations of the cubic group, thus:

$$\begin{array}{ll}
H_1:\quad s\ :\ |\alpha(1+2-3-4)\rangle & H_{25}': \begin{cases} d_{yz}: & |\alpha(1+2+3+4)\rangle \\ d_{zx}: & |\alpha(1-2+3-4)\rangle \\ d_{xy}: & |\alpha(1-2-3+4)\rangle \end{cases} \\
H_{15}: \begin{cases} p_x: & |\beta(1-2+3-4)\rangle \\ p_y: & |\beta(1+2+3+4)\rangle \\ p_z: & |\beta(1+2-3-4)\rangle \end{cases} & H_2':\quad f_{xyz}: \ |\beta(1-2-3+4)\rangle
\end{array}$$

It may seem strange that a state such as $|\beta(1+2+3+4)\rangle$ appears as a singlet at the point Γ but belongs to a triplet at H. The reason is that the various orbitals in the Bloch functions are centred at different places, so that, if one considers, for example, the contribution near a given nucleus from $|1, b\rangle$ and $|8, b\rangle$ they add when $\mathbf{K}=(0, 0, 0)$ but subtract when $\mathbf{K}=(0, 2\pi/a, 0)$. Again no irreducible representation occurs more than once, so the Hamiltonian is diagonal. The state denoted by H_1 has the same local symmetry as the state denoted by Γ_1. However, on moving from the vicinity of one nucleus to that of a neighbouring nucleus the same function is obtained only with its sign reversed. This is indicated in Fig. 5, from which it is also clear that H does have full cubic symmetry. Similarly H_{15} is locally p-like, with a reversal in sign on passing to a neighbouring nucleus, H_{25}' is locally like d_{yz}, d_{zx} and d_{xy}, and H_2' is like f_{xyz}. In considering the energies it is now the locally s- and d-like states which are antibonding and the p- and f-like states which are bonding. There is thus the possibility that the antibonding d-like states will be above the bonding p-like states, and at one time we thought that such an arrangement might help to reduce the amount of d-character in the electronic distribution, as seemed to be required. However, it now seems that the d-character is not greatly different from that of the free atom and in any case such an ordering did not reduce the d-character as much as was apparently needed. There is thus no experimental requirement that H_{15} be below H_{25}', and a number of theoretical calculations predict the reverse order. We therefore assume that the levels, in order of increasing energy are H_{25}', H_{15}, H_1 and H_2'. It is possible that the order of H_1 and H_2' is wrong, but this is of no importance since these levels are not occupied by electrons.

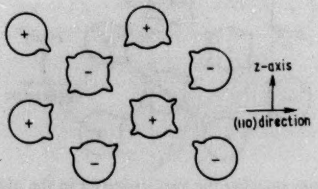

Fig. 5. Schematic diagram showing, for the [1, 3, 6, 8] plane, the local characters of the H_1-type state at the point H $(0, 2\pi/a, 0)$. The local character is shown to be mainly of s-type modified by a small amount of a g-type orbit. Note the alteration in sign in the y direction.

§ 7. THE LINE JOINING Γ and H

Any point on the line Δ which joins Γ and H has $\mathbf{K}=(0, K, 0)$. Except at the points Γ and H, the only rotations of the lattice which permute the Bloch functions are rotations which leave $\mathbf{K}$ unaltered. These are rotations through multiples of $\pi/2$ about the line having direction cosines (0, 1, 0). Reflections in symmetry planes through (0, 1, 0) also permute the Bloch functions. The states can now be conveniently grouped thus:

$$\begin{array}{llll} \Delta_1: & |\beta(1+2+3+4)\rangle & \multirow{2}{*}{$\Delta_5:$} & \left\{\begin{array}{l}|\alpha(1-2-3+4)\rangle \\ |\alpha(1+2+3+4)\rangle\end{array}\right. \\ \Delta_1: & |\alpha(1+2-3-4)\rangle & & \\ \Delta_5: & \left\{\begin{array}{l}|\beta(1-2+3-4)\rangle \\ |\beta(1+2-3-4)\rangle\end{array}\right. & \begin{array}{l}\Delta_2': \\ \Delta_2':\end{array} & \begin{array}{l}|\beta(1-2-3+4)\rangle \\ |\alpha(1-2+3-4)\rangle\end{array} \end{array}$$

where the Δ_1, Δ_5 etc. denote the irreducible representations in this smaller group of rotations and reflections. Δ_1, Δ_5 and Δ_2' each occur twice, so the Hamiltonian is not completely diagonalized by this choice. However, forgetting for the moment off-diagonal elements, it is instructive to follow the state $|\beta(1+2+3+4)\rangle$ as **K** moves along Δ from Γ to H. At Γ this state is the same as Γ_1, and is s-like locally and bonding. At H it belongs to H_{15} and is locally p_y-like, but still bonding. For some intermediate value of **K** the local function is, symbolically,

$$\cos(\tfrac{1}{2}aK)\{s\}+i\sin(\tfrac{1}{2}aK)\{p_y\}$$

and its square modulus, the local charge distribution, gradually becomes more and more elongated in the $\pm y$ direction as K increases. From this it is to be expected that the energy will increase as K increases. However, it must also be remembered that on passing from one nucleus to a neighbouring nucleus, the local function changes by $\exp(i\mathbf{K}.\mathbf{r})$, in this case $\exp(\pm iKa/2)$ for all neighbours. Thus the situation in a region where the local distributions overlap is complicated and difficult to picture. The other level of Δ_1 symmetry, $|\alpha(1+2-3-4)\rangle$, is antibonding f-like at Γ and antibonding s-like at H. The diagonal elements of the two Δ_1 states are unlikely to become equal, so we may expect that the off-diagonal elements, which in any case vanish at Γ and H, will generally have a negligible effect on the states and their energies. Similar considerations hold for all the other states, and the results so far may be summed up diagrammatically as in Fig. 6. Various comments can be made. There is no level of s-like local symmetry throughout which overlaps the other bands, although one frequently reads that in the transition metals there is a broad s-band overlapping the d-band. The broad overlapping band, which does exist, is s-like at Γ, but p-like at H. There are no energy gaps below H_1. The d_{yz}, d_{zx} and d_{xy}-like states at Γ go into similar states at H, which is consistent with three narrow bands having local d-like symmetry throughout.

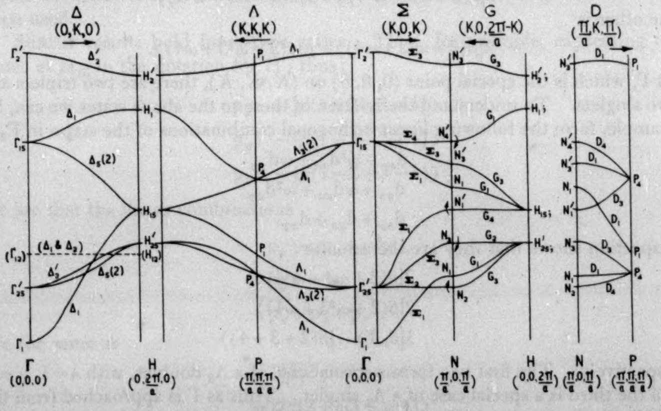

Fig. 6. The predicted energy band structure for a typical body-centred cubic transition metal for various directions in **K** space. The doublet e_g band has been inserted only in the Δ direction for clarity and states of the same symmetry have been allowed to cross. Provided that a cross-over does not occur at the Fermi level this approximation has no effect on the ground state determinantal wave-function.

§ 8. The Point P and the Lines joining it to Γ and H

Suppose we now choose **K** to lie on the line which joins Γ to P, the point $(\pi/a, \pi/a, \pi/a)$. Then $\mathbf{K}=(K, K, K)$. The **K** vector is unaltered by rotations about the (1, 1, 1) direction, but the lattice symmetry requires that such rotations be restricted to multiples of $2\pi/3$. Consider that rotation which takes 2 into 4, 4 into 6 and 6 into 2 in Fig. 1. Then $|\beta, 2\rangle$ goes into $|\beta, 4\rangle$, $|\beta, 4\rangle$ into $|\beta, 3\rangle$ and $|\beta, 3\rangle$ into $|\beta, 2\rangle$. There is a slight difference for the α-type states, for $|\alpha, 3\rangle$ and $|\alpha, 4\rangle$ go into $-|\alpha, 2\rangle$ and $-|\alpha, 3\rangle$ respectively, while $|\alpha, 2\rangle$ goes into $|\alpha, 4\rangle$. It is therefore natural to group the states as

$$\begin{array}{ll} \Lambda_1: & |\beta, 1\rangle \\ \Lambda_1: & |\alpha, 1\rangle \\ \Lambda_1: & |\beta(2+3+4)\rangle \\ \Lambda_1: & |\alpha(2-3+4)\rangle \end{array} \qquad \begin{array}{l} \Lambda_3: \begin{cases} |\beta(2+\omega 3+\omega^2 4)\rangle \\ |\beta(2+\omega^2 3+\omega 4)\rangle \end{cases} \\ \Lambda_3: \begin{cases} |\alpha(2-\omega 3+\omega^2 4)\rangle \\ |\alpha(2-\omega^2 3+\omega 4)\rangle \end{cases} \end{array}$$

where $\omega=\exp(2\pi i/3)$.

They do not completely diagonalize the Hamiltonian, but show that it gives rise to four singlet and two doublet levels. The singlets are linear combinations of $|\beta, 1\rangle$, $|\alpha, 1\rangle$, $|\beta, 2+3+4\rangle$ and $|\alpha(2-3+4)\rangle$ and if one of the states in a doublet is

$$\lambda|\beta(2+\omega 3+\omega^2 4)\rangle+\mu|\alpha(2-\omega 3+\omega^2 4)\rangle$$

the other is

$$\lambda|\beta(2+\omega^2 3+\omega 4)\rangle+\mu|\alpha(2-\omega^2 3+\omega 4)\rangle.$$

At Γ, which is the special point (0, 0, 0) on (K, K, K), there are two triplets and two singlets. To understand the relation of these to the above states we can, for example, form the following linear orthogonal combinations of the states in $\Gamma_{25}{}'$:

$$\begin{gathered} d_{zy}+\omega^2 d_{xz}+\omega d_{xy} \\ d_{zy}+\omega d_{xz}+\omega^2 d_{xy} \\ d_{zy}+d_{xz}+d_{xy}. \end{gathered}$$

Inspection shows that they are the same as

$$\begin{gathered} 2|\beta(2+\omega 3+\omega^2 4)\rangle \\ 2|\beta(2+\omega^2 3+\omega 4)\rangle \\ 3|\beta, 1\rangle-|\beta(2+3+4)\rangle \end{gathered}$$

respectively. The first two form a special case of a Λ_3 doublet, with $\lambda=1$, $\mu=0$, and the third is a special case of a Λ_1 singlet. Thus as Γ is approached from the (K, K, K) direction, a Λ_3 doublet and a Λ_1 singlet move into coincidence. The extra symmetry operations available at Γ can then be used to interchange the three states as required for a $\Gamma_{25}{}'$ representation. Similarly the states in Γ_{15} can be combined as

$$p_x+\omega p_y+\omega^2 p_z, \quad p_x+\omega^2 p_y+\omega p_z, \quad p_x+p_y+p_z$$

which are respectively the same as

$$-2|\alpha(2-\omega^2 3+\omega 4)\rangle, \quad -2|\alpha(2-\omega 3+\omega^2 4)\rangle \text{ and } 3|\alpha, 1\rangle+|\alpha(2-3+4)\rangle$$

and the states in Γ_1 and $\Gamma_2{}'$ can clearly be written as Λ_1 singlets.

Results of this type can be obtained quite generally by the methods of B.S.W. but it has seemed of value to derive them by the above algebraic considerations because the results of group theory are sometimes made clearer by such an investigation. In the notation of B.S.W., Γ_{25}' and Γ_{15} would both be said to be compatible with Λ_3 and Λ_1, whereas Γ_2' and Γ_1 would both be compatible only with Λ_1.

It is at first sight surprising that a similar analysis can be given for the states at H, for H does not lie in the (K, K, K) direction. This statement however does not take into account the peculiar structure of the Brillouin zones, as is shown by consideration of what happens if one proceeds along the (K, K, K) direction, through $P(\pi/a, \pi/a, \pi/a)$ to the point $(2\pi/a, 2\pi/a, 2\pi/a)$. In the simple cubic zone scheme this point would be equivalent to $(0, 0, 0)$, but in the body-centred lattice we have seen that both Γ and H correspond to $(0, 0, 0)$ for the simple cubic lattice. It transpires that $(2\pi/a, 2\pi/a, 2\pi/a)$ does in fact correspond to H, and not to Γ. Thus a point equivalent to H lies on (K, K, K) at $(2\pi/a, 2\pi/a, 2\pi/a)$. We shall call this point H′. It is necessary to distinguish between H and H′ because of the definitions of our states, which involve terms like $\exp(i\mathbf{K}.\mathbf{R}_n)$. Inspection of our definitions shows that

$$|\beta, 1, \mathrm{H}\rangle \equiv -|\beta, 1, \mathrm{H}'\rangle, \quad |\beta, 2, \mathrm{H}\rangle \equiv +|\beta, 2, \mathrm{H}'\rangle$$
$$|\beta, 3, \mathrm{H}\rangle \equiv +|\beta, 3, \mathrm{H}'\rangle, \quad |\beta, 4, \mathrm{H}\rangle \equiv -|\beta, 4, \mathrm{H}'\rangle$$

where the occurrence of H or H′ indicates that the corresponding value of $\mathbf{K}$ has been used.

Similar results hold for α-type states. Then, for example, expressing the states at H_{15} in the notation for H′, thus:

$$\begin{aligned} p_x&: -|\beta(1+2-3-4)\rangle \\ p_y&: -|\beta(1-2-3+4)\rangle \\ p_z&: -|\beta(1-2+3-4)\rangle \end{aligned}$$

we see that the linear combinations

$$\begin{aligned} &p_y+\omega p_x+\omega^2 p_z \\ &p_y+\omega^2 p_x+\omega p_z \\ &p_y+p_x+p_z \end{aligned}$$

are the same as

$$\begin{aligned} &-2|\beta(2+\omega^2 3+\omega 4)\rangle \\ &-2|\beta(2+\omega 3+\omega^2 4)\rangle \\ &-3|\beta, 1\rangle+|\beta(2+3+4)\rangle \end{aligned}$$

respectively. The value of this result lies in the observation that usually the energy is a reasonably smooth function of $\mathbf{K}$, so that if we know the energies at Γ and H it is likely that the energies at P will be intermediate between suitable pairs from Γ and H.

At P certain additional symmetry elements can be used, for the local function becomes multiplied by $\exp(i\mathbf{K}.\mathbf{r})$, where $\mathbf{K} \equiv (\pi/a, \pi/a, \pi/a)$ and $\mathbf{r} \equiv \frac{1}{2}a(\pm 1, \pm 1, \pm 1)$, on moving from a given nucleus to a neighbouring nucleus. For neighbours at positions 1, 3, 5 and 7 the factor is $-i$, while for neighbours at 2, 4, 6 and 8 the factor is $+i$. All rotations and reflections which leave the [1357] tetrahedron invariant can thus be used, and by inspection the states can be grouped thus:

$$\begin{array}{rlcl}
\mathrm{P}_1: & -\mathrm{s}+i\mathrm{f}_{xyz} & : & |\beta(1-2-3-4)\rangle \\
\mathrm{P}_2: & -\mathrm{f}_{xyz}+i\mathrm{s} & : & |\alpha(1+2-3+4)\rangle \\
\mathrm{P}_4: & \left\{\begin{array}{l} -\mathrm{d}_{yz}+i\mathrm{p}_x \\ -\mathrm{d}_{zx}+i\mathrm{p}_y \\ -\mathrm{d}_{xy}+i\mathrm{p}_z \end{array}\right. & \begin{array}{c} : \\ : \\ : \end{array} & \begin{array}{l} |\beta(1-2+3+4)\rangle \\ |\beta(1+2+3-4)\rangle \\ |\beta(1+2-3+4)\rangle \end{array} \\
\mathrm{P}_4: & \left\{\begin{array}{l} -\mathrm{p}_x+i\mathrm{d}_{yz} \\ -\mathrm{p}_y+i\mathrm{d}_{zx} \\ -\mathrm{p}_z+i\mathrm{d}_{xy} \end{array}\right. & \begin{array}{c} : \\ : \\ : \end{array} & \begin{array}{l} |\alpha(1+2+3-4)\rangle \\ |\alpha(1-2+3+4)\rangle \\ |\alpha(1-2-3-4)\rangle \end{array}
\end{array}$$

showing that at P there are two singlets and two triplets, the states being suitable linear combinations of the above states, which, as written, do not diagonalize the Hamiltonian completely. The P_1 states are readily seen to be compatible with Λ_1 and the P_4 sets are each compatible with Λ_3 and Λ_1, as follows, for example, because

$$\mathrm{X}+\omega\mathrm{Y}+\omega^2\mathrm{Z}, \quad \mathrm{X}+\omega^2\mathrm{Y}+\omega\mathrm{Z}, \quad \mathrm{X}+\mathrm{Y}+\mathrm{Z}$$

are respectively the same as $2|\alpha(2-\omega^2 3+\omega 4)\rangle$, $2|\alpha(2-\omega 3+\omega^2 4)\rangle$ and $3|\alpha, 1\rangle - |\alpha(2-3+4)\rangle$ where $(-\mathrm{p}_x+i\mathrm{d}_{yz})$ has been written as X etc.

If we now study the behaviour of the states as **K** moves from Γ through P to H and require that states of the same symmetry do not cross (for there will always be off-diagonal elements to prevent crossing) it follows that the Λ_1 state which leaves Γ_1 must finish at H_{25}', and Λ_3 which leaves Γ_{25}' must also end at H_{25}'. However, at P, this Λ_3 must coincide with a Λ_1, which can only be the Λ_1 coming from Γ_1. The P_4 triplets are, in their local properties, linear combinations of d_{yz}, d_{zx} and d_{xy} with, respectively, p_x, p_y and p_z. We may expect that the lower of the two P_4 triplets will be dominantly d-like. If it is pure d-like its energy is likely to be intermediate between that of Γ_{25}' and H_{25}'. To allow for small admixtures of p-like states we may suppose that its energy is lower than that for pure d-type; that is, its energy is less than the mean energies of Γ_{25}' and H_{25}'. This is indicated in Fig. 6. It is important now to note that the s-like state at Γ becomes dominantly d-like at P, which is quite different from the usual assumption in transition metals that there is a broad overlapping band of predominantly s-character. We may expect that in going from Γ to P its energy will change appreciably, because of the change in local character. In going from P to H the change in character is much less and we might expect that the Λ_1 and Λ_3 states will here remain quite close in energy. By a similar argument, the Λ_3 doublet which leaves Γ_{15} must end at H_{15}, where it is joined by a Λ_1 singlet. This Λ_1 can only come from Γ_{25}'. Also, at P this Λ_3 doublet is coincident with a Λ_1 singlet, which can only be the singlet joining Γ_{15} to H_1. Further, the states in Γ_{15} and H_{15} are p-like, the Λ_3 which joins them is predominantly p-like, so we may suppose that the energy of this P_4 is slightly greater than the mean energies of Γ_{15} and H_{15}. It is to be noted that the Λ_1 from Γ_{15} remains mainly p-like to P, and thus remains fairly close to the Λ_3 doublet from Γ_{15} to P_4. However, the energy change for this singlet from P_4 to H_1 is likely to be appreciable, as the local symmetry is changing. The rest of the energy level structure for Γ–P–H can now be readily deduced as the Λ_1 singlet from Γ_2' can only end at H_2'.

Thus it is seen that from a knowledge of the relative states and energies at Γ and H it is possible to deduce a good deal about the behaviour from Γ to P and then from P to H, which is equivalent to the edge of the first Brillouin zone. This edge is denoted by F (B.S.W.) and as might now be expected, its symmetry properties are the same as those for Λ. This explains why the energy bands joining P to H in Fig. 6 have been labelled by Λ rather than the customary F.

In the first Brillouin zone of the body-centred cubic lattice there is one point labelled Γ, but there are six points equivalent to H, namely $(\pm 2\pi/a, 0, 0)$, $(0, \pm 2\pi/a, 0)$, $(0, 0, \pm 2\pi/a)$. It is immaterial which of the six directions Γ to H are considered, as the energy against $|K|$ curves will be the same for each. The states are not identical except at Γ and H. Similarly the directions from Γ to the four points equivalent to P,

$$(\pi/a, \pi/a, \pi/a), \quad (-\pi/a, -\pi/a, \pi/a), \quad (-\pi/a, \pi/a, -\pi/a), \quad (\pi/a, -\pi/a, -\pi/a),$$

give identical curves. The states are only identical at the four equivalent points and at Γ. The same curves are obtained for the lines joining Γ to the other four points equivalent to P,

$$(-\pi/a, -\pi/a, -\pi/a), \quad (\pi/a, \pi/a, -\pi/a), \quad (\pi/a, -\pi/a, -\pi/a), \quad (-\pi/a, \pi/a, \pi/a),$$

and the states at these four points are identical but different from those at the other set of four. Most writers on band theory choose the points H, P and N in the positions used by B.S.W. In the present paper we do the same for H and P (though we prefer to use right-handed axis in $\mathbf{K}$ space), but for N it is convenient to make a different choice. The curves for Γ to N will be unaffected by our different choice.

§ 9. THE POINT N and the LINES JOINING IT TO Γ, H and P

We now consider the direction $(K, 0, K)$ and the point $N=(\pi/a, 0, \pi/a)$. For a general value of K the symmetry operations which permute the Bloch functions are rotations through multiples of π about (1, 0, 1) and reflections in the symmetry planes through this line. The functions group naturally as:

$$\begin{array}{lll} \Sigma_1: |\beta(1+4)\rangle, & \Sigma_1: |\alpha(1+4)\rangle, & \Sigma_1: |\beta(2+3)\rangle \\ \Sigma_3: |\beta(1-4)\rangle, & \Sigma_3: |\alpha(1-4)\rangle, & \Sigma_3: |\alpha(2-3)\rangle \\ \Sigma_2: |\beta(2-3)\rangle, & & \Sigma_4: |\alpha(2+3)\rangle \end{array}$$

All the levels will be non-degenerate, there being three Σ_1-type bands with the states compounded from the three above Σ_1 states, three Σ_3 bands, one Σ_2 and one Σ_4 band. At Γ, which is a special point on this line, $|\beta(2-3)\rangle$ is locally the same as $[d_{yz}-d_{xy}]/\sqrt{2}$, which is a typical d-like function but so orientated that it is perpendicular to the (1, 0, 1) direction. This result is also obtained for a general K, except that the local function changes by $\exp(i\mathbf{K}.\mathbf{r})$ on moving from one nucleus to another. However, if it is assumed that the local d-function is more or less confined to the [2367] plane it is to be expected that because $\mathbf{K}$ is perpendicular to this plane, the energy variation with K will be small. This has been emphasized in Fig. 6 by drawing Σ_2 as if its energy were independent of K. In fact at Γ it is entirely bonding and at N it has some antibonding features so it is probable that its energy increases slightly from Γ to N. A somewhat similar picture emerges for Σ_4, which is locally p-like with the p-axis perpendicular to **K**. It is presumably more sensitive to K, for p-functions are less planar than d's, and we would thus expect the Σ_4 state which leaves Γ_{15} to decrease slightly in energy as N is approached, where it is more bonding. At N extra symmetry arises because on moving to a neighbour in the 2, 3, 6 or 7 direction the local function is unaltered, whereas for neighbours in the 1, 5, 8 and 4 directions the local function is reversed. The functions can now be grouped as:

$N_1 : s+d_{xy} : |\alpha(1+4)\rangle \qquad N_1 : s-d_{xy} : |\beta(2+3)\rangle$

$N_1' : p_x+p_z : |\beta(1+4)\rangle$

$N_2 : -d_{xy}+d_{zy} : |\beta(2-3)\rangle$

$N_4' : p_z-p_x : |\alpha(2+3)\rangle$

$N_3 : d_{xy}+d_{yz} : |\alpha(1-4)\rangle$

$N_3' : p_y-f_{xyz} : |\alpha(2-3)\rangle \qquad N_3' : f_{xyz}+p_y : |\beta(1-4)\rangle$

It can easily be seen that N_1 and N_1' are both compatible with Σ_1, N_3 and N_3' are both compatible with Σ_3, N_4' with Σ_4 and N_2 with Σ_2. Now consider $|\alpha(1-4)\rangle$. This is a d-like function locally, lying in the [1485] plane. On moving to a neighbouring site in this plane, the local function reverses, so that as far as this particular plane is concerned the function is the same as one which can be constructed from the three antibonding d-functions in H_{25}'. There is a difference between the two functions on moving to neighbours in the [2376] plane, for at N there is no change in the local function, whereas at H the local function is reversed in sign. If then it is assumed that the d-like function is confined to the [2376] plane the energy of N_3 will be the same as that of H_{25}'. This result is indicated in Fig. 6, though in fact because N_3 is more bonding than H_{25}' it will be slightly lower in energy than H_{25}'. This result may also be deduced by considering the direction $\mathbf{G}=(K, 0, 2\pi/a-K)$ which joins $H(0, 0, 2\pi/a)$ to $N(\pi/a, 0, \pi/a)$, for the [1485] plane is perpendicular to this direction. N_3 is compatible with Σ_3, which is compatible with Γ_{25}', so we expect to have a Σ_3 level joining Γ_{25}' and N_3. Similarly $|\beta(1+4)\rangle$ is a p-like function with its axis in the [1485] plane, and it bears the same relation to one of the states in H_{15} as $|\alpha(1-4)\rangle$ does to one of the states in H_{25}'. The p-like functions will be less planar than the d-like functions, so we expect N_1' to be slightly higher in energy than H_{15}. Compatibility requires that this level be joined to Γ_{25}' by a Σ_1 level. The only other state of physical importance is the Σ_1 state which leaves Γ_1, and becomes N_1 at N. It will be a linear combination of $|\alpha(1+4)\rangle$ and $|\beta(2+3)\rangle$ at N. Now $\{|\alpha(1+4)\rangle+|\beta(2+3)\rangle\}$ is locally s-like, with four bonding and four antibonding neighbours, so its mean energy is likely to be intermediate between that of Γ_1 and H_1. Similarly $\{|\beta(2+3)\rangle-|\alpha(1+4)\rangle\}$ is locally the same as $\{|\beta(2+3)\rangle-|\beta(1+4)\rangle\}$ at Γ. That is, it is locally like d_{zx}, with four bonding and four antibonding neighbours. Its mean energy will therefore lie between Γ_{25}' and H_{25}'. This energy is probably less than the energy of

$$\{|\alpha(1+4)\rangle+|\beta(2+3)\rangle\}$$

so we infer that the Σ_1 level which leaves Γ_1 arrives at N (where it is denoted by N_1) with an energy somewhat less than the mean energy of Γ_{25}' and H_{25}'. Thus we are able to deduce a good deal about the direction $(K, 0, K)$ from a straightforward study of the local character of the respective states. On continuing along Σ beyond N, the point $(2\pi/a, 0, 2\pi/a)$, which belongs to Γ in both the simple cubic and body-centred Brillouin zone schemes, is reached. As the energy levels at N are all singlets, the energy versus **K** curves are horizontal at N.

At this stage we have dealt with all the points in the Brillouin zone of high symmetry, and the lines joining these to Γ and also the line P to H. The lines N to H and N to P can be investigated using similar methods, though for the behaviours of the bands it is enough to know the compatibility relations. The results of such a study are given in Fig. 6.

It may be noted that there is no implication that covalent bonds occur in b.c.c. transition metals, for the properties of the symmetric and antisymmetric 'link' functions, which might be termed bonding and antibonding, are removed when Bloch functions are formed.

§ 10. The $\mathrm{e_g}$ Bands

The above discussion began with a model which seemed to incorporate the idea of covalent bonds between neighbouring atoms and then went over into a band description. It might therefore be thought to be satisfactory as it incorporates a number of features which seem to be needed. It is however deficient in one very important respect. From the point of view of symmetry operations it would have been desirable, in building the initial directed orbitals, to have used states which transform according to all the irreducible representations of the cubic group. In fact a number of irreducible representations were not used, namely Γ_2, Γ_{12}, Γ_{15}', Γ_1', Γ_{12}' and Γ_{25}. To see whether anything important has been omitted we may ask what atomic orbitals transform according to these representations. Without going into full details the answer is that Γ_{12} is spanned by the x^2-y^2, $3z^2-r^2$ orbitals, but that none of the others occur with principal quantum number less than 4. The latter are unlikely to be important in the 3d transition group and can safely be ignored. $3\mathrm{d}_{x^2-y^2}$ and $3\mathrm{d}_{3z^2-r^2}$ cannot, however be ignored.

In attempting to incorporate $d_{x^2-y^2}$ and $\mathrm{d}_{3z^2-r^2}$ there is no reason to introduce hybridization, and the first step is to form Bloch functions from them in the standard way, with the orbitals centred on lattice points. We should now go back to the beginning in our problem of finding the eigenfunctions, and work with ten Bloch functions for each **K**. That is, the eight we have discussed at length above, and the two new ones from $\mathrm{d}_{x^2-y^2}$ and $\mathrm{d}_{3z^2-r^2}$, which are usually referred to as $\mathrm{e_g}$ bands. This however is unnecessary if the matrix elements between the original eight and the two new ones are small compared with the energy differences, for we can then use perturbation theory. Our first step is to show that there is good reason to suppose that the matrix elements are indeed small. They are not small compared to the energy differences for all values of **K**, for on neglecting them levels of the same symmetry will cross for certain values of **K**. At these points there will be a good deal of mixing of the levels, but if the matrix elements are small this mixing will be confined to very limited regions in **K** space and, as will be shown later, can probably be neglected as far as physical properties are concerned.

The reason we suppose that the matrix elements are small is that, in their evaluation, it is necessary to determine the matrix elements of the lattice potential between $d_{x^2-y^2}$ and $\mathrm{d}_{3z^2-r^2}$ orbitals located on lattice sites and bonding or antibonding functions located on links. From simple symmetry arguments all such matrix elements are zero if the lattice site is at one end of the link. The only contributions come from lattice sites and links for which the link does not join up to the lattice site in question. Thus the magnitudes depend on the radial extents of the $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ orbitals and the localization of the bonding and antibonding orbitals. But the important observation is that the elements which might have been expected to give the major contribution do in fact give zero for symmetry reasons. Further, there is no reason to suppose, in a cubic environment, that the radial parts of the $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ functions (which will be identical) will be the same as the radial parts of d_{xy}, d_{yz} and d_{zx}. We suggest that, possibly because of the bonding which takes place, the interatomic spacing is determined so that the radial extent of d_{xy}, d_{yz} and d_{zx} is expanded in the metal compared with that in the free atom but that the radial extent of $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ is much the same as in the atom; this does, in fact, make the latter 'inner' orbitals in the metal. Any tendency in this direction decreases the matrix elements between the eight and the two, and leads to the concept of pure $d_{x^2-y^2}$ and $d_{3z^2-r^2}$, or e_g, bands. (In accord with common usage, the $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ atomic orbitals are referred to as e_g orbits instead of Γ_{12}, the B.S.W. notation used elsewhere in this paper). The variation in energy with **K** of these bands is determined by overlap of functions on different nuclei, and the more 'inner' these orbitals are the less the energy will vary with **K**. Also *xy* etc. at Γ_{25}' have lower energies than in the atoms whereas *xy* etc. at H_{25}' have higher energies than in the atoms. We therefore expect the $3d_{x^2-y^2}$ and $3d_{3z^2-r^2}$ bands to be narrow and lie between these limits. In an exaggeration of the expected situation and for clarity, we have drawn the two extra bands in the direction Δ only, with energy independent of **K**, and have allowed states of the same symmetry to cross (Fig. 6). It may be noticed that no concept of crystal field splitting has been used.

It is difficult to compare directly the band structure calculations discussed here with previous work due to the nature of, and the many differences in, the approximations and assumptions made. Many previous discussions and calculations on the band theory of iron have been published (Manning 1943, Slater 1953, Slater and Koster 1954, Callaway 1955, Stern 1959) and a detailed study has been undertaken at the Massachusetts Institute of Technology (Wood 1960, Slater and Wood†).

The forms of the energy bands deduced here from simple physical consideration are supported by the much more detailed calculations of Wood for the same symmetry directions.

§ 11. THE ELECTRONIC ARRANGEMENT

Having obtained a band structure for a number of points and directions in **K** space it is possible, by interpolation, to infer something about the density of states curve. However, recent thinking suggests that the independent electron model is not perhaps the best way of viewing the situation, and we shall therefore be concerned first with the ground state of the many electron system, and then excited states which are only slightly above the ground state in energy. To obtain the ground state, we have to place the electrons in suitable states to give the minimum possible energy and we assume that this can be done in some cases to a good approximation, by filling up the band scheme with paired-off electrons to a Fermi level. The many-electron wave function is then a single determinantal function.

---

† see footnote to p. 1321.

The low temperature phase of titanium is close-packed hexagonal, so it would seem appropriate to begin our discussion of the transition metals with vanadium, which is body-centred cubic and has five electrons outside the argon core. An examination of the energies up to H_{25}' shows that, ignoring the e_g bands, there are three complete bands starting from Γ_{25}' and part, probably about one half, of the band which starts from Γ_1. Thus up to energy H_{25}', we might expect to be able to accommodate about seven electrons even without using the e_g bands. In vanadium it would seem that the five electrons can be accommodated in the single band from Γ_1 and the three bands from Γ_{25}' filled up to a level which is somewhere between Γ_{25}' and H_{25}' in energy, and which is probably nearer to H_{25}' than to Γ_{25}', since the number of states with a given $|\mathbf{K}|$ increases with $\mathbf{K}$ in regions away from the zone boundaries. We assume that the e_g bands are above this level and are unoccupied. The Hall constant of vanadium has been measured by Foner (1957) who reports that it is positive. To account for this we need to study the slightly excited states which may not be single determinantal states, at least in our representation. It is, however, interesting to note that, on the independent electron model, the electrons at the top of the distribution in the bands from Γ_{25}' probably have $\partial^2 E/\partial K^2$ negative and so behave as positive charge carriers. The electrons in the band which starts at Γ_1 may not act as positive charge carriers, in which case the question arises as to whether their mobilities are less than or greater than those of the positive holes. In the direction Γ to P it is seen that although the band from Γ_1 starts as s-like it is d-like at P, and we suggest that there is no real reason to suppose that the mobilities of the electrons at the Fermi level in the band from Γ_1 will be substantially different from those of the holes in the other bands. The hole contribution to the Hall effect will then outweigh the electron contribution.

Chromium, the next body-centred cubic metal, has six electrons per atom to be accommodated. They can be accommodated below H_{25}' without using the e_g levels, but it may be that some of the electrons are in the e_g levels. However, chromium is known to be antiferromagnetic, so our use of a simple determinantal function to describe the ground state cannot be correct, and it is not entirely clear how to proceed. One observation though may be important; states near H_{25}' are now being used and an electron in one of these is aware of the crystal structure, since the wavelength of its Bloch function is comparable with the lattice parameter. It may be that this property helps to stabilize an antiferromagnetic structure (Friedel, Leman and Olszewski 1960, private communication). (It may also have a bearing on the alloying properties of chromium.)

Above H_{25}' the band structure has the special feature that an electron has a very limited choice of levels. Below H_{25}', and for any line through Γ, there will, in general, be several states of the same energy. Above H_{25}' (but below H_{15}) there will only be one state. Thus on moving to the next metal, manganese, the extra electrons, one per atom, will either have to go into levels of appreciably higher energy or they will have to go into the e_g levels, assuming these are energetically suitable. The interesting fact is that manganese does neither of these things, for it does not have a body-centred cubic lattice, suggesting either that e_g is not available (in which case it is probably not available in chromium either) or that, having put electrons into e_g, the lattice undergoes a Jahn–Teller type of distortion (Griffith and Orgel 1958).

The next metal, iron, with eight electrons per atom outside the argon core, is body-centred cubic at low temperatures, and is ferromagnetic. Mott and Stevens (1957) explain this by postulating that the ground state is approximately one in which the extra two electrons above chromium (for which it can be assumed that e_g is empty) are in the e_g bands with their spins parallel. If the e_g bands are regarded as consisting of + spin and − spin bands, the bands of +spin are completely full, whereas the −spin bands are empty. The +spins do not take part in electrical conduction etc., because the +band is full. Further, by using a well-known theorem (Wannier 1937) an equivalent description can be given in terms of localized Wannier functions. In this description it is then seen that the energy associated with the determinantal state is not simply that given by summing the energies of all the occupied single electron states, but that there is likely to be an important contribution from the so-called exchange interactions between parallel spins on the same lattice site. There are other smaller energy terms as well; the importance of this intra-atomic energy is that it provides an explanation of why a ground state with a large spin moment is energetically favoured. It is further postulated that the low-lying excited states are like spin-wave states in which spin-deviations of unity are propagating through the lattice. States which consist dominantly of determinantal functions in which electrons have either been removed from e_g and placed at the Fermi level, or have been taken from the Fermi level and placed in the empty e_g −spin bands are supposed to be appreciably higher in energy.

A number of further refinements can be added, though these are more easily described physically than mathematically. In atoms it is known that the energies of outer unpaired electrons are spin dependent when there are unpaired electrons in inner shells. That is, the spins of outer electrons have a tendency to set parallel to the spins of inner electrons. In the model of iron it therefore seems reasonable to suppose that the conduction bands (that is, all the bands except e_g) should also be regarded as composed of separate + and − spin bands, and that, due to the localized moments, the $\mathbf{K}^+$ states will be lower in energy than the $\mathbf{K}^-$, at least near the Fermi level. On filling to a Fermi level there will then be a spin polarization in the conduction band. As this polarization is due to the localized moments and is in an electron distribution which conducts, there is the further desirable effect that, through it, the localized moments are indirectly coupled. There is also a more subtle effect, as follows. It has been assumed that there are no matrix elements of the lattice potential between the e_g bands and the other bands. Suppose now that this is not true, and that there are small off-diagonal elements. When these are included the e_g bands and the conduction bands will be repelled slightly. But the e_g+bands are filled and are below the Fermi level. Thus a + spin conduction state near the Fermi level will have its energy increased. On the other hand the e_g− bands are empty and are thus above the Fermi level, so that a −spin conduction state at the Fermi level has its energy reduced. Anderson (1960, private communication) argues that the net result of this effect and the direct spin polarization effect is to give almost a cancellation, which helps to remove the difficulty of accounting for the relatively small spin polarization actually observed in the conduction bands.

Having lifted the assumption that there are no matrix elements between the e_g and the conduction bands a further step is possible, particularly where bands would otherwise cross. Consider an e_g**K**$^+$ state which has almost the same energy as a **K**$^+$ conduction state. If we assume that both of these states contain electrons then the determinantal function is unaltered by using the correct linear combinations to diagonalize the sub-matrix. The same argument can be given for $-$spin states which cross, except that now neither state will contain electrons. Thus the neglect of the off-diagonal elements is not an approximation provided that both the states involved either do or do not contain electrons. The possibility that, with such a pair of states, one does and the other does not contain electrons seems unlikely with small off-diagonal matrix elements.

There are no other body-centred cubic metals in the first transition group, so it seems appropriate to end our discussion of the implications of the band structure which we have deduced, at this point. There are, of course, many properties of vanadium, chromium and iron which we have not considered, some of which seem to support our band scheme and some of which are difficult to interpret. It is our hope, though, that the rather lengthy discussion which we have given will improve the accuracy of some of the criticisms which have been levelled at the Mott and Stevens theory of iron, by providing a better target.

Electron Spin Resonance in Two Salts containing Gadolinium

By J. M. BAKER AND F. I. B. WILLIAMS†
Clarendon Laboratory, Oxford

MS. received 1st *June* 1961

Abstract. The electron spin resonance spectra of Gd^{3+} have been measured in gadolinium hexa-antipyrene iodide (HAPI), lanthanum HAPI, and cadmium fluoride. In CdF_2 the Gd^{3+} ions are sometimes in sites of cubic and sometimes in sites of tetragonal symmetry. In the latter the zero field splitting is remarkably small, being about 0·05 cm^{-1}. In the HAPI there is a large zero field splitting, about 0·98 cm^{-1} overall, and even in the undiluted salt the line width is only about 230 gauss, so that it may be suitable for a zero field maser. An Appendix gives a discussion of the general problem of rotation of the frame of reference in which the crystal field is described so that the spin Hamiltonian may be written in a form diagonal in the applied magnetic field. The coefficients have been tabulated for the polynomials involved in the general rotation matrix for the operator equivalents. The polynomials have been plotted as a function of angle. There is also a table of factors to relate some of the untabulated matrix elements of the operator equivalents to the Wigner 3–*j* symbols.

§ 1. INTRODUCTION

THE trivalent gadolinium ion, which is in an S state, is the natural one to choose to investigate the symmetry of the crystalline electric field about a site for lanthanon ions in a host crystal. The electron spin resonance spectrum is normally visible at liquid air temperatures, if not above, and the symmetry of the spin Hamiltonian reflects that of the crystal field.

There is also the possibility, as the eightfold degeneracy of the ground state is partially raised by high-order effects of the crystal field, that the magnitude of the zero magnetic field splittings may be such as to make the crystal a useful maser element.

The gadolinium spectrum has been studied in two salts, cadmium fluoride, and gadolinium hexa-antipyrene iodide both pure and diluted with the lanthanum salt. The former material was kindly grown from the melt by Dr. R. W. H. Stevenson of Aberdeen University; the latter is easily grown from aqueous solution following the recipe given by Marsh (1951).

Cadmium fluoride belongs to the $O_h{}^5$ space group, and is isomorphous with calcium fluoride, but its lattice constant is slightly smaller—5·40 Å as compared with 5·45 Å. It is of interest to compare the spectra of gadolinium in these two salts. In calcium fluoride one sometimes finds that the symmetry of the gadolinium site is cubic like that of the calcium which it replaces, and sometimes it is tetragonal (Friedman and Low 1960). Low has shown that the two forms are interconvertible by the appropriate heat treatment. The tetragonal symmetry is thought to be due to an interstitial fluorine ion in a site near the trivalent ion; whether such ions have a chance to diffuse to this energetically favoured site, or get trapped in other parts of the lattice, depends upon the way in which the melt is cooled.

---

† Now at Institut d'Astrophysique, Cointe-Selessin, Belgium.

The hexa-antipyrene iodides (HAPI) are of interest because they are very magnetically dilute. The chemical formula $[\mathrm{Ln}(\mathrm{C_{11}H_{12}ON_2})_6]\mathrm{I_3}$ indicates that there are a large number of diamagnetic atoms between the paramagnetic ones. One might thus expect to find narrow electron spin resonance lines even in material which has not been diluted with the isomorphous diamagnetic lanthanon salt. This in itself would be a great convenience in preparing samples for maser use. The HAPI are also of interest because they form a homologous series throughout the lanthanon group in which it might be possible to study the effects of a uniform crystal environment on all of the lanthanon ions. The results of this complete investigation are discussed in the following paper (Baker and Rubins 1961, to be referred to as II).

Preliminary investigations by x-ray methods of the crystal structure of yttrium HAPI have been made independently by Dr. G. Garton of the Clarendon Laboratory and Dr. J. W. Jeffery of the University of London. They find that the space group is $R\bar{3}$ and that the symmetry at the lanthanon site is probably $\bar{3}$. This symmetry is confirmed by the electron spin resonance measurements. Dr. Garton also measured the hexagonal unit cell dimensions obtaining $a = 13{\cdot}5$ Å and $c = 33{\cdot}5$ Å; there are three molecules in this cell, all three metal ions having identical magnetic properties.

§ 2. The Spin Hamiltonian

For both crystals the spin Hamiltonian takes the same form

$$\mathscr{H} = \beta\mathbf{H}\,.\,g\,.\,\mathbf{S} + \sum_{0}^{2} B_2^m O_2^m + \sum_{0}^{4} B_4^m O_4^m + \sum_{0}^{6} B_6^m O_6^m,$$

where the O_n^m are operator equivalents in the notation of Baker, Bleaney and Hayes (1958). These O_n^m are present in the sums which transform in the same way as the symmetry operations of the point symmetry of the lanthanon site. For the cubic form in cadmium fluoride

$$\mathscr{H} = \beta\mathbf{H}\,.\,g\,.\,\mathbf{S} + B_4(O_4^0 + 5O_4^4) + B_6(O_6^0 - 21O_6^4),$$

and the tetragonal form may be written in the following way so that the departure from cubic symmetry is apparent:

$$\begin{aligned}\mathscr{H} = \beta\mathbf{H}\,.\,g\,.\,\mathbf{S} + B_2^0O_2^0 + B_4(O_4^0 + 5O_4^4) + B_4^0O_4^0 \\ + B_6(O_6^0 - 21O_6^4) + B_6^0O_6^0.\end{aligned}$$

For the hexa-antipyrene iodides the spin Hamiltonian may be written in terms of a z axis parallel to the hexagonal crystal axis as

$$\begin{aligned}\mathscr{H} = \beta\mathbf{H}\,.\,g\,.\,\mathbf{S} + B_2^0O_2^0 + B_4^0O_4^0 + B_4^3O_4^3 + B_6^0O_6^0 \\ + B_6^3O_6^3 + B_6^6O_6^6.\end{aligned}$$

The hyperfine structure terms have been omitted in all of these spin Hamiltonians.

When the external field is not directed along the axis in terms of which the operator equivalents have been defined it is often convenient to work in terms of a set of axes rotated so that the new z axis is parallel to the applied field. In this representation the Zeeman term in the spin Hamiltonian, which is usually the largest, is diagonal and the effects of the crystalline field may be treated by perturbation theory. The way in which the operator equivalents transform under such a rotation is discussed in the Appendix.

§ 3. CADMIUM FLUORIDE

Two batches of crystals were grown from powders of different origins. Both were grown from the melt by the same method. The first batch, A, had about 0·05% Mn^{2+} impurity, while the other, B, had less than 0·01%. Crystals of batch A, containing 4, 0·5 and 0·03% gadolinium to cadmium, gave only cubic spectra except that the most concentrated one showed numerous weak lines (more than 50) of other symmetries, but these were too weak to analyse. Crystals of batch B, containing 1, 0·1 and 0·03% gadolinium to cadmium, all had about 40% of these impurity ions in cubic sites and the other 60% in three non-equivalent tetragonal sites whose principal axes corresponded with those of the cubic ones.

The spin Hamiltonians for both these cases were given in the last section. The values of the parameters of these Hamiltonians are listed below and compared with those for calcium fluoride. All our measurements were made at room temperature and with 1·4 cm microwaves.

Table 1

Diluent Symmetry parameter	Cadmium fluoride		Calcium fluoride	
	Cubic	Tetragonal	Cubic (Low 1958)	Tetragonal (Sierro & Lacroix 1960)
$3B_2^0$	—	42 ± 3	—	+1488 ± 5
$60B_4$	47·4 ± 0·3	45·2 ± 1·0	+46·25 ± 0·5	30·4 ± 2·0
$60B_4^0$	—	1·5 ± 0·3	—	−7 ± 3
$1260B_6$	0·0 ± 0·3	0·0 ± 0·3	−1·0 ± 0·5	0·1 ± 0·3
$1260B_6^0$	—	0·2 ± 0·5	—	1 ± 2
g	1·992 ± 0·002	1·992 ± 0·002	1·991 ± 0·002	1·993 ± 0·003

Table 2. Spin Hamiltonian Parameters for Gd HAPI

	Undilute	Dilute	
	300°K	300°K	90°K
$g_\parallel$	1·990 ± 0·002	1·991 ± 0·003	1·9931 ± 0·0005
$g_\perp$		1·989 ± 0·003	
$3B_2^0$	711 ± 5	$702{\cdot}7^{+2{\cdot}5}_{-0{\cdot}2}$	$827^{+2{\cdot}5}_{-0{\cdot}2}$
$60B_4^0$	1·72 ± 0·35	1·3 ± 1·6	2·8 ± 1·6
$\lvert 3B_4^3 \rvert$	—	—	8·0 ± 1·8
$1260B_6^0$	−0·8 ± 0·5	−0·8 ± 1·0	−1·1 ± 1·0
$\lvert 36B_6^3 \rvert$	—	—	0·8 ± 1·4
$1260B_6^6$	†	7·3 ± 0·9	6·9 ± 0·5

The B_4^3 and B_6^3 terms are ~15° out of phase. All B_n^m are given in units of 10^{-4} cm^{-1}

† Too small to be measured, sixfold variation within the line width.

The signs are only relative except those of Low. All crystal field parameters are in units of 10^{-4} cm^{-1}.

The doubling reported by Ryter (1957) and Horai (1960) for the cubic spectrum of the calcium fluoride when the magnetic field was not along a principal axis was not seen here.

§ 4. HEXA-ANTIPYRENE IODIDE

Measurements were made on both the undiluted salt and on a crystal of the lanthanum salt containing 0·3% Gd. As the crystal field splitting is large measurements were made at K-band (~23 Gc/s). The parameters of the spin Hamiltonian are listed in Table 2. The values of $g_{\parallel}$, B_2^0, B_4^0, B_6^0 were obtained from the spectrum when the magnetic field was parallel to the crystal axis. When it is in the plane perpendicular to this axis the spin Hamiltonian becomes

$$\mathscr{H} = g_{\perp}\beta H S_2 - \tfrac{1}{2}B_2^0 O_2^0 + \tfrac{3}{8}B_4^0 O_4^0 - \tfrac{5}{16}B_6^0 O_6^0 + \tfrac{1}{16}B_6^6 \cos 6\alpha O_6^0$$
$$+ \tfrac{3}{2}B_2^2 O_2^2 + \tfrac{15}{32}B_6^6 O_6^2 \cos 6\alpha + \dots,$$

where other terms are too small to give significant contributions and α is the rotational angle in the plane (see Appendix, Euler angles α, $\pi/2$, 0). Thus one observes a sixfold rotational symmetry from which the B_6^6 term may be found. The B_4^3 and B_6^3 coefficients were found by comparing the spectra on either side of the crystal axis in a plane containing it. For a given angle β to the axis the even coefficients will give the same contribution on both sides of the axis, but the odd terms will change sign. Thus upon a rotation $(\alpha, \beta, 0)$ O_4^3 becomes

$$\tfrac{1}{8}\sin^3\beta\cos\beta O_4^0\cos 3\alpha + \dots,$$

and O_6^3 becomes $\tfrac{1}{16}\sin^3\beta\cos\beta(11\cos^2\beta - 3)O_6^0\cos 3\alpha + \dots$. The largest O_4^0 term occurs at $\beta = 60°$ and the largest O_6^0 term at $\beta = 39°$, and the size of B_4^3 and B_6^3 were obtained from measurements at these two angles to the axis of the crystals.

There are small changes in the parameters for the dilute salt between room temperature and 90°K. The signs in the table are relative only. It was not possible to determine the absolute signs as this requires going to temperatures sufficiently low that the population differences between the various states give rise to noticeable intensity differences between the lines, and at these temperatures the crystal structure has undergone a change in which the number of ions in the unit cell changes, and the point symmetry at the gadolinium site is rhombic (see II). In this distorted low temperature state the spectrum is very complicated and there are a large number of overlapping lines so no measurements were made in this temperature region.

Above the transition the narrowest lines observed in the lanthanum salt containing small quantities of Gd^{3+} or Ce^{3+} (see II) are 10 gauss wide, suggesting that this is the line width due to nuclei in the material. This indicates that there are some protons which are near neighbours to the lanthanon ions; the other nuclei in the antipyrene molecule would not give such a large line width at likely interatomic distances of about 2 Å.

In the undiluted salt the central line of the Gd^{3+} spectrum, measured with the external field parallel to the crystal axis, is 230 ± 10 gauss wide. This is greater than the root mean square line width calculated from the theory of Van Vleck (1948) for dipolar interaction between similar ions, and this theory would give too high an estimate as ions in different states cannot be regarded as similar. The other transitions have broader lines indicating that there is some spread of crystal field splitting over the ions in the crystal. This effect is frequently observed in the Gd^{3+} spectrum in other host crystals; also in other HAPI salts there is evidence (see II) that even above the transition there is incipient distortion of the C_{3v} point symmetry at the lanthanon site.

§ 5. DISCUSSION

Above its transition temperature (about 90°K for the undiluted salt and 15°K when diluted with the lanthanum salt) the HAPI has some interest as a maser material as it has a large zero field splitting, about 0·98 cm^{-1} overall. It also has only one type of magnetic ion in the unit cell, is easy to prepare as large specimens, and the lines in the undiluted salt are narrow compared with other undiluted lanthanon salts so far investigated by electron spin resonance. It has of course the disadvantage that it is water soluble; it appears otherwise to be fairly stable, but it does tend to crack after many successive coolings to low temperatures. It compares favourably in stability with potassium cobalticyanide which has been used extensively as a maser material.

Cadmium fluoride, doped with gadolinium, is a more stable material as it is grown from the melt and has no water of crystallization. However, its small crystal field splitting, even in the tetragonal crystal field, makes it of no use as a low field maser.

It is of interest to compare the crystal field parameters for Gd^{3+} in CdF_2 with those for CaF_2. When the crystal field is cubic the parameters in the two host crystals are nearly equal. This is to be expected as the lattice constants are little different, and also because the gadolinium ion is larger than the ion it replaces, it probably influences the position of its ligands more than the host lattice. However, the tetragonal crystal fields in the two host lattices are quite different. In CdF_2 the axial terms are much smaller and also the B_4 and B_6 terms are approximately the same as they are in the cubic field. There is evidence that when some trivalent ions are incorporated in CaF_2 charge compensation is achieved by an interstitial fluorine $\frac{1}{2}a$ along the $\langle 100\rangle$ direction from the trivalent ion; this causes the tetragonal terms in the crystal field (see, e.g. Baker, Hayes and O'Brien 1960). It seems reasonable to suppose that this is the mechanism for Gd^{3+} in CaF_2 in view of the large effect. If the charge compensation mechanism is the same in both CaF_2 and CdF_2 and the large differences in B_2^0 arise because this term is extremely sensitive to the differences between lattice constants, one expects this term to be very temperature sensitive. A rough experiment cooling CdF_2 to 90°K shows that this term increases by only 23 ± 6%. B_4 in the cubic sites increases by 7 ± 3%. The strain produced by cooling CaF_2 to 90°K is about 0·4%; that produced in CdF_2 will probably be somewhat smaller, about $\frac{1}{8}$ the change in lattice parameter between CaF_2 and CdF_2. Hence it is possible that there may be a different mechanism in CdF_2 which gives rise to the smaller tetragonal departure from the cubic field. Whatever the mechanism it must be due to an effective additional negative charge situated along the $\langle 100\rangle$ direction. It is possible that the Ca^{2+} ion distant a is replaced by a monovalent ion, or that there is an F^- ion in the interstitial site $1\frac{1}{2}a$ away. There are objections to both of these possibilities but there is no direct evidence from which the details of the mechanism may be deduced.

In the absence of a complete theory relating the parameters of the crystal field in the spin Hamiltonian to the crystalline electrostatic potential for S state ions one cannot make further deductions from these comparisons or from the absolute values of the measured parameters. This material is the only one so far investigated where the B_2^0 term, when it exists, is smaller than other terms; in all other salts, including the HAPI the B_2^0 term is by far the biggest.

ACKNOWLEDGMENTS

The authors wish to thank Dr. R. W. H. Stevenson for growing the specimens of CdF_2, Professor Bleaney for his many helpful suggestions, Mr. R. S. Rubins and Dr. W. Hayes for advice, Mr. J. Hurrell and Miss C. Dorlet for making some of the measurements, and Dr. L. Fox for the use of the Oxford University computer. One of the authors (F.I.B.W.) is indebted to the Rhodes Trust for a Scholarship.

APPENDIX

The most convenient way to find the eigenvalues of the spin Hamiltonian is to use perturbation theory. Often the largest term is the interaction of the magnetic field with the electronic magnetic moment, so that the representation in which this interaction is diagonal is chosen. The crystalline electric field is normally expressed as a series of terms with the symmetry of the spherical harmonics in terms of spherical polar axes determined by the symmetry axes of the crystal structure. We want to re-express this crystal field in terms of a z axis parallel to the direction of the magnetic field.

An expression will be given for the matrix elements of this crystalline field—a real combination of spherical harmonics—within a constant angular momentum manifold for a direction of quantization along the z axis of a set of axes which has been rotated by Euler angles (α, β, γ) from that in which the field is known.

Define

$$\begin{aligned}\Theta_{lm} &= \frac{1}{2}\left(\frac{4\pi}{2l+1}\right)^{1/2}[\mathrm{Y}_{lm}+(-1)^m\mathrm{Y}_{l-m}]\\ &=(-1)^m\left(\frac{(l-m)!}{(l+m)!}\right)^{1/2}\mathrm{P}_l^m(\cos\theta)\cos m\phi \qquad \ldots\ldots(\mathrm{A1})\end{aligned}$$

$$\Theta_{lm}^{(-)}=\frac{1}{2}\left(\frac{4\pi}{2l+1}\right)^{1/2}[\mathrm{Y}_{lm}-(-1)^m\mathrm{Y}_{l-m}]. \qquad \ldots\ldots(\mathrm{A2})$$

The P_l^m and Y_{lm} are as defined by Edmonds (1960). The Euler angles also correspond to those of Edmonds: α about the original z axis, β about the new y axis and γ about the newer z axis. A positive rotation is one which advances a right-hand screw in a positive direction along the axis. Stevens (1952) has given a rule for calculating these matrix elements by using an operator equivalent. Their form and values have been tabulated for most cases usually met (Stevens 1952, Elliott and Stevens 1953, Judd 1955, Baker, Bleaney and Hayes 1958 Baker, Jones and Pope 1959).

The matrix elements of these operators—O_l^m in the notation of Baker, Bleaney and Hayes (1958)—are related to those of the Θ_{lm} and to the Wigner 3–j symbols as follows:

$$\begin{aligned}\langle j\mu|O_l^m|j\mu'\rangle &= \frac{F(l,j)}{K(\gamma,l,j)}f(l,m)\langle j\mu|\Theta_{lm}|j\mu'\rangle\\ &= F(l,j)f(l,m)\left\{(-1)^{j-\mu}\begin{pmatrix} j & l & j\\ -\mu & m & \mu'\end{pmatrix}+(-1)^{m+j-\mu}\begin{pmatrix} j & l & j\\ -\mu & -m & \mu'\end{pmatrix}\right\}\end{aligned} \qquad \ldots\ldots\text{(A3)}$$

$$f(l,m)=(-1)^m\left(\frac{(l+m)!}{(l-m)!}\right)^{1/2}\Big/(\text{R.F. of } P_l^m(\cos\theta))$$

where R.F. means rational factor, γ denotes a dependence on other quantum numbers, j is the angular momentum of the manifold and μ is the projection of j on the z axis.

Using the rotation matrices for the spherical harmonics (e.g. Edmonds 1960, Wigner 1959) and letting $P_{\{\alpha,\beta,\gamma\}}$ symbolize the rotation of the coordinate system, one finds in the new system that:

$$\begin{aligned}\langle j\mu|P_{\{\alpha,\beta,\gamma\}}\Theta_{lm}|j\mu'\rangle &= \langle j\mu|d^l{}_{0m}(\beta)\cos m\alpha\Theta_{l0}\\ &\quad+\sum_{m'=1}^{l}\{d^l{}_{m'm}(\beta)\exp[\mp i(m\alpha+m'\gamma)]\\ &\quad+(-1)^{m'}d^l{}_{-m'm}(\beta)\exp[\pm i(m\alpha-m'\gamma)]\}\Theta_{lm'}|j\mu'\rangle,\end{aligned} \qquad \ldots\ldots\text{(A4)}$$

where

$$\begin{aligned}d^l{}_{m'm}(\beta) &= (-1)^{l-m'}d^l{}_{-m'm}(\beta-\pi)=\left(\frac{(l+m')!(l-m')!}{(l+m)!(l-m)!}\right)^{1/2}\\ &\quad\times\sum_s\begin{pmatrix} l+m\\ l-m'+s\end{pmatrix}\begin{pmatrix} l-m\\ s\end{pmatrix}(-1)^{l-m'-s}\left(\cos\frac{\beta}{2}\right)^{2s+m'+m}\left(\sin\frac{\beta}{2}\right)^{2l-2s-m'-m}.\end{aligned}$$

The top signs are used for $\mu' > \mu$ and the bottom ones for $\mu > \mu'$

since $\langle j\mu|\Theta_{lm}{}^{(-)}|j\mu\pm m\rangle = \mp\langle j\mu|\Theta_{lm}|j\mu\pm m\rangle$.

γ may often be chosen arbitrarily—as, for example, in our case since the magnetic field is axially symmetric—to simplify the expression.

There are two special cases of particular interest. (i) One wants to know the diagonal matrix elements to see how a spectrum should behave to first order under a general rotation of the magnetic field. These are simply proportional to the Legendre polynomials. In terms of the O_l^m,

$$\langle j\mu|\mathrm{P}_{\{\alpha,\beta,\gamma\}}O_l^m|j\mu\rangle = \frac{\text{R.F. of } \mathrm{P}_l^0(\cos\theta)}{\text{R.F. of } \mathrm{P}_l^m(\cos\theta)}\,\mathrm{P}_l^m(\cos\beta) \times \cos m\alpha\langle j\mu|O_l^0|j\mu\rangle. \quad \ldots\ldots(\mathrm{A}5)$$

(ii) One wants to rotate the magnetic field (and with it the quantization axis) in a plane perpendicular to the z axis of the coordinates in which the field is known. Here the solution for all the matrix elements is quite simple. It may be shown that, for $(-1)^l=1$,

$$\langle j\mu|\mathrm{P}_{\{\alpha,\frac{1}{2}\pi,\gamma\}}\Theta_{lm}|j\mu'\rangle = \langle j\mu|d^l{}_{0m}(\tfrac{1}{2}\pi)\cos m\alpha\Theta_{l0} + 2\sum_{m'=1}^{l}[\delta_{(-1)^{m-m'},1}\cos m\alpha\exp(\mp im'\gamma)-\delta_{(-1)^{m-m'},-1}\sin m\alpha \times\exp[\mp i(m'\gamma+\tfrac{1}{2}\pi)]d^l{}_{m'm}(\tfrac{1}{2}\pi)\Theta_{lm'}|j\mu'\rangle \quad \ldots\ldots(\mathrm{A}6)$$

where δ_{mn} is the Kronecker delta. These matrix elements have been tabulated for all even l and m up to $l=6$ by Baker, Jones and Pope (1959). Their results are obtained by putting $\gamma=\pi/2$ which should make all their matrix elements real.

NUMERICAL CALCULATION OF THE MATRIX ELEMENTS UNDER A GENERAL ROTATION

For $\gamma=0$, Eqn (A4) may be written in terms of the O_l^m as follows:

$$\langle j\mu|\mathrm{P}_{\{\alpha,\beta,0\}}O_l^m|j\mu'\rangle = \langle j\mu|D^l{}_{0m}\cos m\alpha O_l^0 + \sum_{m'=1}^{l}\{D^{l+}{}_{m'm}\cos m\alpha \pm iD^{l-}{}_{m'm}\sin m\alpha\}O_l^{m'}|j\mu'\rangle,$$

where again the top sign is used for $\mu'>\mu$ and the bottom one for $\mu>\mu'$. These $D^{l\pm}{}_{m'm}$ have been calculated at 5° intervals for $\beta=0°$ to $90°$ on the Oxford University Mercury computer. They are plotted in Figs (1) to (11) for $m=0$, 2, 3, 4, 6 and $l=2$, 4, 6.

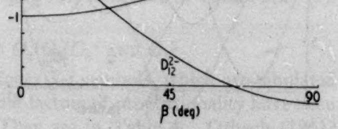

Fig. 2

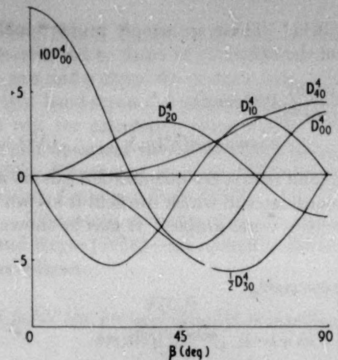

Fig. 3

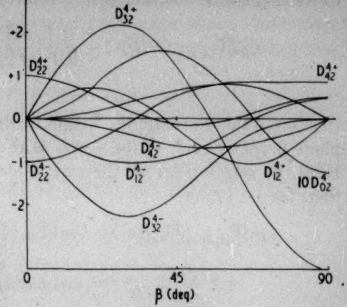

Fig. 4

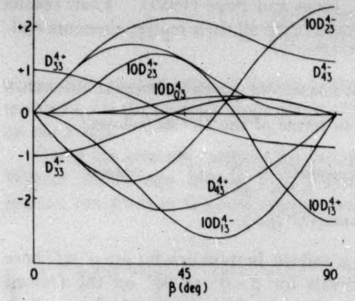

Fig. 5

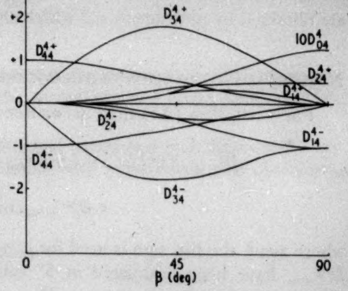

Fig. 6

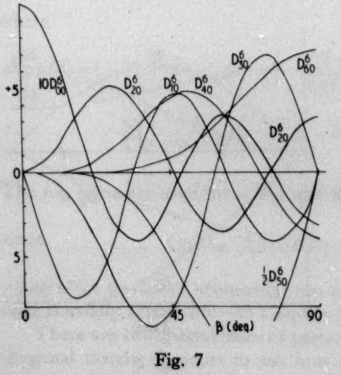

Fig. 7

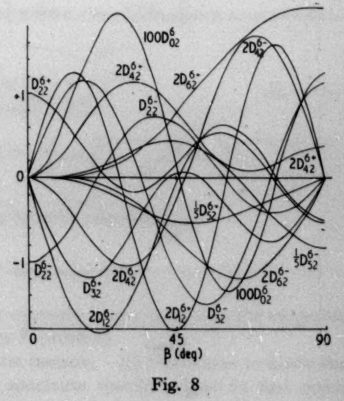

Fig. 8

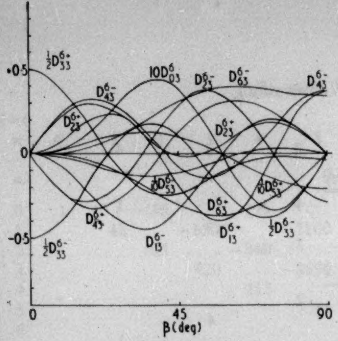

Fig. 9

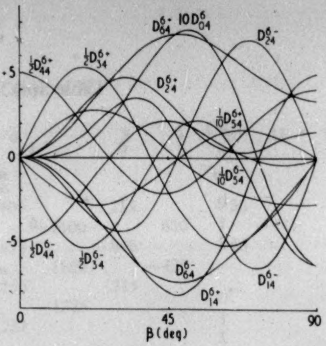

Fig. 10

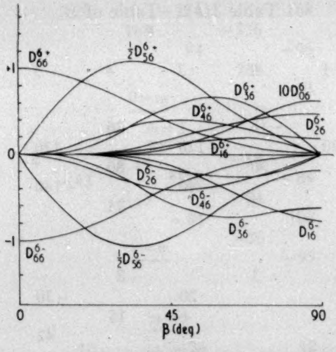

Fig. 11

These $D_{m'm}{}^{l\pm}$, like the $d_{m'm}{}^{l}(\beta)$, may be written as a homogeneous polynomial of order 2l in sin $(\beta/2)$ and cos $(\beta/2)$. Specifically,

$$D_{0m}{}^{l} = \sum_{n=0}^{2l} B_n \left(\cos\frac{\beta}{2}\right)^n \left(\sin\frac{\beta}{2}\right)^{2l-n}$$

$$D^{l+}{}_{m'm} = \sum_{n=0}^{2l} B_n \left[(-1)^{l+n} \left(\sin\frac{\beta}{2}\right)^n \left(\cos\frac{\beta}{2}\right)^{2l-n} \pm \left(\cos\frac{\beta}{2}\right)^n \left(\sin\frac{\beta}{2}\right)^{2l-n} \right].$$

The B_n, which are functions of l, m and m' only, are tabulated in Tables 3(*a*)–(*c*).

MATRIX ELEMENTS OF $O_2{}^1O_4{}^1O_6{}^1$ AND $O_6{}^5$

Since these are proportional to the Wigner 3–j symbols, which are tabulated up to $j = 8$ (Rotenberg *et al.* 1959), only the factors of proportionality have been given—the $F(l, j)f(l, m)$ of Eqn (A3). They are in Table 4. Orbach (1961) has tabulated the explicit forms of these operators.

8	*0210, 0011,	*2412, 0111,	*4421, 2111, 1	*5321, 1111, 1

The *n*th digit represents the power of the *n*th prime starting with 2 and it is understood that the square root of the product is to be taken. An asterisk denotes that the negative square root is to be used and a line underneath indicates that the power is negative. This convention follows that of Rotenberg *et al.* (1959).

Electron Spin Resonance in Two Groups of Lanthanon Salts

By J. M. BAKER and R. S. RUBINS†
Clarendon Laboratory, Oxford

MS. received 1st *June* 1961

Abstract. Electron spin resonance measurements have been made on lanthanon ions in the hexa-antipyrene iodide (HAPI) salts and also in lanthanum trifluoride. At room temperature the HAPI have trigonal symmetry with one lanthanon ion per unit cell but at low temperatures there is a change of crystal structure. For all ions except Ce^{3+} and Gd^{3+} electron spin resonance is observed only at temperatures below the transition. The lanthanon ion in the HAPI at low temperatures and in the trifluoride have rhombohedral point symmetry and there are several ions in the unit cell. Not all ions with Kramers degeneracy exhibited resonance in both salts, and the few non-Kramers cases investigated also exhibited no resonance. In both salts the most extensive measurements were made on Ce^{3+}. In the HAPI Ce^{3+} has a remarkably long relaxation time and the spectrum is visible at 90°K. The measurements on Ce^{3+} in LaF_3 are correlated with the theoretical discussion given by Van Vleck and Hebb in 1934.

§ 1. INTRODUCTION

SOME of the most interesting results of electron spin resonance studies of the lanthanon ions have come from homologous series of salts. In such salts the crystalline electric field varies from one lanthanon ion to the next mainly because of the change in the radial dependence of the 4f electron wave function, and not because of a change of surroundings. For example in the ethyl sulphates (Elliott and Stevens 1952) it has been possible to find the parameters which describe the crystal field from the electron spin resonance spectrum of one of the ions. Approximate extrapolation to neighbouring lanthanon ions could then be refined from a detailed knowledge provided by the electron spin resonance spectrum.

This paper describes measurements on two similar series: the hexa-antipyrene iodides (HAPI), a truly homologous series, and lanthanum fluoride containing about 0·3% of the other lanthanons as impurities (incorporation of this small quantity has been found possible in spite of the fact that the trifluorides do not form a homologous series throughout the whole group).

Either of these series might be of interest as maser elements. They contain no water of crystallization and so may be expected to withstand successive coolings to low temperatures without cracking (in fact the HAPI crystals do sometimes crack at low temperatures). Exchange interactions between lanthanon neighbours are likely to be small as the 4f electrons are deep seated in the ion, and it may be possible to work with quite a high concentration of paramagnetic ions, indeed the HAPI may be sufficiently dilute without the addition of the diamagnetic salt as the lanthanon ions are about 8 Å apart.

§ 2. THE LANTHANON HEXA-ANTIPYRENE IODIDES

The hope that one might be able to make an extrapolation of the crystal field from one lanthanon ion to the next in the group was frustrated by a crystallographic transition at low temperatures. The simple C_{3v} symmetry with one magnetically distinguishable ion in the unit cell, which was found morphologically and by x-ray analysis by both Dr. G. Garton and Dr. J. W. Jeffery (both unpublished), becomes distorted below the transition temperature into a symmetry with more than one ion in the unit cell.

The transition temperatures in the various lanthanon salts have been studied by observing the spectrum of about 1% Gd^{3+} incorporated into each of them. The results of these experiments are shown in Table 1. The transition is seen to depend on the size of the lanthanon ion; in particular the upper temperature limit of the transition varies in an approximately linear manner with ionic radius.

Table 1. Transition Data for Hexa-antipyrene Iodides

Metal ion	Radius	Upper limit of the transition (°K)	Approximate range of transition	No. of ions per unit cell at 20°K
Yb^{3+}	1·00	130	see note a	
Er^{3+}	1·04	125	125–20	12
Y^{3+}	1·06	120	120–20	12
Dy^{3+}	1·07	120	see note b	
Tb^{3+}	1·09	100	100–20	12
Gd^{3+}	1·11	80	see note c	
Nd^{3+}	1·15	60	60–25	6
Pr^{3+}	1·16	60	60–25	6
Ce^{3+}	1·18	40	40–15	3
La^{3+}	1·23	15	15–5	1

Note a. At 20°K resonance lines from Yb^{3+} obscure those from Gd^{3+}.
Note b. Below 90°K Gd^{3+} lines broaden to about 100 gauss ½ width.
Note c. Lines are too broad for detailed investigation.
With the exceptions of Ce^{3+} and La^{3+} HAPI, investigations were not taken below 14°K.

By measuring the resonant frequency of a cavity containing the crystal it was established that there is no large change in dielectric constant at the transition. Nuclear resonance of the protons in a crystal of NdHAPI showed no change of line width between room temperature and 14°K, indicating that the transition does not arise because of the freezing out of hindered rotations of large molecular groups. It thus seems most likely that the transition is related to small movements of the molecular groups surrounding the lanthanon ion.

2.1. *Resonance Results*

Most of the measurements were made on the Ce^{3+} ion, as it is the only ion apart from Gd^{3+} (Baker and Williams 1961, to be referred to as I) which is observable both above and below the transition. Resonance was also observed (Rubins 1961) in the Nd^{3+}, Er^{3+} and Yb^{3+} salts at 4°K but the rhombic g-tensors do not uniquely define the ground state. No resonance was observed in the Dy^{3+} salt, although in a rhombic crystal field one is expected. In the Nd^{3+} salt diluted with the La^{3+} salt, no resonance was observed; this may be due to a very small value of $g_\perp$, but this is unlikely to be the reason in other cases. In ions without Kramers degeneracy transitions are unlikely as all the states are probably singlets in a rhombic field; no resonance was observed in Tb^{3+} or Pr^{3+}, the only two such ions studied.

The cerium spectrum is remarkable in that it can be observed at 90°K. This indicates a considerably longer spin–lattice relaxation time than that found in cerium salts previously. Line width measurements show that T_1 is approximately $3{\cdot}5 \times 10^{-10}$ sec at 90°K and greater than 10^{-9} sec at 20°K. The spectrum has been observed in the undiluted salt and also in the lanthanum and neodymium salts containing 1% Ce^{3+}. The spin Hamiltonian for each ion is:

$$\mathscr{H} = g_x \beta H_x S_x + g_y \beta H_y S_y + g_z \beta H_z S_z \qquad \ldots\ldots(1)$$

where g_x, g_y and g_z are the principal values of the g-tensor and $S=\frac{1}{2}$. The g-values and number of ions in the unit cell are given in Table 2. Where there is one ion in the unit cell the symmetry is axial; and when there are more than one it is orthorhombic. In the latter case the principal direction of the g-tensor corresponding to the largest principal value g_z lies very close to the crystal axis; the angle θ in the table is that between these two directions. Changes in the g-value are seen to occur over a much wider range than that of the transition region. At temperatures too low for spin–lattice relaxation to contribute, the line width in both dilute (see I) and undiluted salts in the parallel direction is about that expected from dipolar interaction; but in the perpendicular direction it is much greater. This is probably due to a spread of values of $g_\perp$ due to the incipient distortion.

The only other ion which was measured completely is neodymium. Resonance is observed at 4·2°K and below. There are three ions in the unit cell with g-values $g_x = 0{\cdot}51 \pm 0{\cdot}01$, $g_y = 0{\cdot}77 \pm 0{\cdot}02$, $g_z = 4{\cdot}34 \pm 0{\cdot}05$; the angle between the z axis and the crystal axis is 10°.

2.2. *Discussion*

The g values of Ce^{3+} above the transition cannot be fitted to any ground state within $J=5/2$ in a field of C_{3v} symmetry. They can be fitted with admixtures to the ground state from the $J=7/2$ state, but there are too many parameters for unambiguous fitting. The rhombic g-values below the transition are also easily fitted by a suitable admixture of states by the rhombic terms, but here again there are too many parameters for unambiguous assignment.

It is hoped that additional information might become available about the excited levels from susceptibility or infra-red absorption measurements, or about the crystal field when the surroundings of the lanthanon ion are completely determined by x-ray analysis. If complete information were obtained it would be of considerable interest to attempt to explain theoretically the spin–lattice relaxation in view of the great difference between the relaxation time in this salt and that in other cerium salts.

§ 3. LANTHANUM TRIFLUORIDE

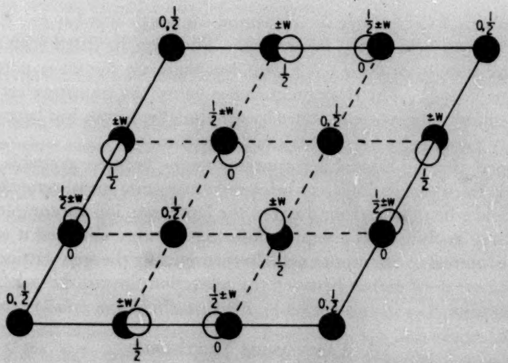
Two slightly different crystal structures have been proposed for LaF_3. One has a bimolecular unit cell with C6/mmc symmetry, the other a hexamolecular cell with C6/mcm symmetry (see Wyckoff 1951); the latter is derived from the

Table 2. g-values of Ce^{3+} in HAPI Salts

Diluent metal ion	La^{3+}	Ce^{3+}	Nd^{3+}
Temperature			
90°K		$2{\cdot}62 \pm 0{\cdot}01(1)$	
		$g_\perp = 0{\cdot}553 \pm 0{\cdot}002$	
60°K	$2{\cdot}664 \pm 0{\cdot}005(1)$		
20°K	$2{\cdot}686 \pm 0{\cdot}001(1)$	$2{\cdot}649 \pm 0{\cdot}002(6)$	$2{\cdot}619 \pm 0{\cdot}003(6)$
	$g_\perp = 0{\cdot}5281 \pm 0{\cdot}0003$	$g_x = 0{\cdot}51 \pm 0{\cdot}01$	$\theta = 5 \pm 1$
		$g_y = 0{\cdot}55 \pm 0{\cdot}01$	
		$\theta = 3 \pm 1$	
14°K	$2{\cdot}687 \pm 0{\cdot}002(1)$		
4°K	$2{\cdot}692 \pm 0{\cdot}004(3)$		
	$\theta = 5 \pm 1°$		

---

former by very slight displacements of the lanthanon ions. The electron spin resonance results on Gd^{3+} in LaF_3 favoured the hexamolecular structure as three magnetically distinct ions were observed in the unit cell; the six ions in the hexamolecular unit cell being magnetically equivalent in pairs. The present results on other lanthanon impurities also favour the hexamolecular cell. The Figure is a sketch of the positions of the F^- and La^{3+} ions in this hexamolecular structure. The surroundings of a lanthanon ion have orthorhombic symmetry. In non-S-state ions with Kramers degeneracy the crystalline electric field will give rise to a ground doublet with a rhombic g-tensor. Two of the principal values of this tensor lie in the plane perpendicular to the crystal axis and the overall hexagonal symmetry of the crystal requires that the six ions in the unit cell fall into three groups of two, the two ions in each group being identical and the g-tensors of the three groups being the same except for 120° rotations about the crystal axis: this is the situation in Gd^{3+}.



Plan of the hexamolecular unit cell of CeF_3. The shaded circles are F^- ions and the unshaded ones Ce^{3+} ions. Numbers above the circles are the coordinates of the F^- and those below the circles refer to Ce^{3+}: $w = 0{\cdot}175$.

The measurements on Ce^{3+} are compared with the interpretation by Van Vleck and Hebb (1934) of the susceptibility of CeF_3 and the Faraday rotation in Tysonite, where it was necessary to postulate 3 or 6 ions in the unit cell, each in a rhombic crystal field of the type described in the last paragraph.

3.1. *Resonance Results*

The crystals used for this work were grown from the melt by Dr. D. A. Jones in Aberdeen. The details of the method used are described by Jones, Baker and Pope (1959).

Resonance lines from those ions which have Kramers degeneracy have been observed either at 20 or 4°K. There are six ions in the unit cell with identical but differently oriented g-tensors. These are derived from one another by 120° rotations about the crystal axis and reflection in the plane perpendicular to it. The spin Hamiltonian for each ion is given by Eqn (1) in § 2.1 if hyperfine structure is neglected. One Cartesian axis, chosen to be the y axis, lies in the plane perpendicular to the crystal hexad axis. This plane is easily determined in LaF_3, as it is a cleavage plane which reflects light in an almost metallic manner. The other two Cartesian axes bear no obvious relationship to the external crystal faces; of these, the z axis is assumed to make an angle θ with the crystal axis. The resonance results which are set out in Table 3, show that in general the spectra are strongly rhombic.

Table 3. Resonance Results for Rare Earth Ions in Lanthanum Trifluoride

Ion	Temp. (°K)	g_z	g_x	g_y	θ	HFS(gauss)
Ce^{3+} $4f^1$	20	2·608 ±0·005	0·32 ±0·01	0·90 ±0·02	14±1	
$Nd^{3+}4f^3$	4·2	3·11 ±0·03	1·356±0·006	1·092±0·005	45±2	
$Dy^{3+}4f^9$	4·2	13·8 ±0·5	7·0 ±0·5	1·5 ±0·1	9±3	
Er^{3+} $4f^{11}$	20	10·89 ±0·05	2·99 ±0·05	4·91 ±0·04	44±1	73·5±2·0†
	14	11·09 ±0·04	2·98 ±0·03	4·91 ±0·03	45±½	
Yb^{3+} $4f^{13}$	20	1·210±0·005	3·76 ±0·03	5·20 ±0·01	10±3	586 ±20 ‡

Note 1. In the results for Dy^{3+}, the large error quoted for g_z arises from the extrapolation method used to determine this quantity, that for g_x arises from the large line width at this orientation, and that for g_y from the large effect on the g-value of a slight misorientation of the crystal.

Note 2. θ was generally obtained by measuring the angle of rotation of the magnet between the z-direction and the parallel direction. For Er^{3+}, however, θ was determined by measuring $g_\parallel$ and using the relation $g_\parallel^2 = g_x^2 \sin^2\theta + g_z^2 \cos^2\theta$

† cf. 71·5±0·4 in $LaCl_3$ (Hutchison and Wong 1958) and 72±1 gauss in CaF_2 (see Orton 1959).

‡ cf. 572·0±5 in yttrium acetate (Cooke and Park 1956).

No resonance lines were observed from the crystal containing Pr^{3+} when experiments were conducted at 20°K or 14°K with both the steady and microwave magnetic field directed parallel to the crystal axis. The negative result is not surprising as one would expect a singlet state to lie lowest in a 'non-Kramers' ion situated in a crystalline field of such low symmetry. For this reason no experiment at 4·2°K was carried out.

3.2. *g-values of Cerium—Discussion*

In view of the rhombic spectrum which is observed in Ce^{3+}, it is convenient to begin by assuming the ground doublet to be of the form

$$a|\tfrac{5}{2}, \pm\tfrac{5}{2}\rangle + b|\tfrac{5}{2}, \pm\tfrac{1}{2}\rangle + c|\tfrac{5}{2}, \mp\tfrac{3}{2}\rangle$$

where admixtures from the $J=7/2$ level are neglected.
The principal g-values are then given by:

$$\begin{aligned} g_z &= 6(5a^2+b^2-3c^2)/7 \\ \tfrac{1}{2}|g_x+g_y| &= 6(2\sqrt{5}ac+3b^2)/7 \\ \tfrac{1}{2}|g_x-g_y| &= 6(4\sqrt{2}bc)/7 \end{aligned}$$

where $a^2+b^2+c^2=1$.

The best set of values for a, b and c is $a=0{\cdot}717$, $b=0{\cdot}604$, $c=-0{\cdot}216$ which give g-values $g_x=0{\cdot}33$, $g_y=0{\cdot}93$ and $g_z=2{\cdot}71$. The differences between the theoretical and experimental values are small and may be accounted for in terms of admixtures from the higher $J=7/2$ level, which is only some 2240 cm^{-1} (Lang 1936) above the ground state.

It is of interest to compare these values for a, b and c with those obtained by Van Vleck and Hebb (1934). Using the measurements of Becquerel and de Haas (1934) on the Faraday rotation in Tysonite, and the susceptibility of CeF_3 powder (de Haas and Gorter 1930), they inferred that $g_\parallel=2{\cdot}36$ and $g_\perp=1{\cdot}44$, and obtained for the ground state parameters $a=0{\cdot}762$, $b=0{\cdot}525$, $c=-0{\cdot}379$.

For comparison of these g-values our g-tensor has a value $g_\parallel=2{\cdot}53$ along the crystal axis and $g_\perp=0{\cdot}81$ as an average in the perpendicular plane. The discrepancies between these two results may be due to (i) other paramagnetic impurities contributing to the Faraday rotation (ii) differences between the lattice spacing of Tysonite and lanthanum trifluoride leading to different g-values.

3.3. *g-values of Ytterbium—Discussion*

In Yb^{3+} the ground state is a $J=7/2$ level and is separated by 10 300 cm^{-1} from the excited $J=5/2$ level (Gobrecht 1938). In view of the large separation, admixtures from the excited level should be negligible. Thus if the crystal field is of rhombic symmetry it should be possible to fit the experimentally determined g-values exactly to a ground state of the form:

$$a|\tfrac{7}{2}, \pm\tfrac{7}{2}\rangle + b|\tfrac{7}{2}, \mp\tfrac{3}{2}\rangle + c|\tfrac{7}{2}, \mp\tfrac{1}{2}\rangle + d|\tfrac{7}{2}, \mp\tfrac{5}{2}\rangle$$

where $a^2+b^2+c^2=1$. The principal g-values are given by

$$\begin{aligned} g_z &= 8(7a^2+3b^2-c^2-5d^2)/7 \\ \tfrac{1}{2}|g_x+g_y| &= 8(2\sqrt{7}ad+2\sqrt{15}bc)/7 \\ \tfrac{1}{2}|g_x-g_y| &= 8(2\sqrt{12}bd+4c^2)/7. \end{aligned}$$

Fairly close agreement is obtained by taking $a=\pm 0{\cdot}13$, $b=\mp 0{\cdot}73$, $c=0{\cdot}64$, $d=\pm 0{\cdot}20$ which gives principal g-values $g_z=1{\cdot}2$, $g_x=3{\cdot}6$, $g_y=5{\cdot}0$. The agreement is close but not exact, suggesting that the crystal field may not be one of purely rhombic symmetry.

3.4. *Discussion*

The measurements on Ce^{3+} in LaF_3 are in essential agreement with the theory of Van Vleck and Hebb but give more detailed information about the ground state of the ion than the experiments on which their theory was based. Our results go further in that they suggest six rather than three ions in the unit cell: from the measurements on bulk properties it was not possible to distinguish between these two possibilities.

Unlike the measurements on Gd^{3+} in LaF_3 the present results indicate even lower point symmetry at the lanthanon site than that suggested by the crystallographic arrangement described in § 1. To explain the present results one needs a further distortion of the surroundings of the lanthanon ion, or a displacement of the lanthanon ion out of the plane of the diagram in the Figure. In order to maintain the overall crystal symmetry it would be necessary to displace some ions upwards and some downwards, hence making all six ions magnetically inequivalent. In a site of such low symmetry one would need to know a great deal about the excited states as well as the ground state of a lanthanon ion before the crystal field acting on it could be determined. As one cannot therefore interpret the g-tensors of the various impurities in terms of the crystal field one cannot say how much the crystal field varies from ion to ion. However, the fact that the symmetry for Gd^{3+} is entirely different from that of the other ions suggests that the crystal field does depend upon the nature of the impurity ion. Thus, although our results support the hexamolecular unit cell structure, the electron spin resonance data from which this support is derived is all taken from impurity sites in mixed crystals, so that one cannot positively infer that the hexamolecular cell is also appropriate for the pure lanthanum trifluoride.

§ 4. CONCLUSION

Although some results of interest have come out of this investigation as described in the previous sections, the low point symmetry of the lanthanon sites and the large number of ions in the unit cell in both crystal structures makes the salts of little general interest. For this reason the measurements were not extended to other specimens. For the same reason they would not make useful maser elements with any paramagnetic ion except gadolinium. The properties of the gadolinium salts as maser elements have been discussed by Jones, Baker and Pope (1959) and by Baker and Williams (Paper I).

ACKNOWLEDGMENTS

It is with great pleasure that we acknowledge the untiring assistance given to us by Dr. D. A. Jones of Aberdeen University in preparing the lanthanon trifluoride specimens. We wish to thank Professor B. Bleaney for the interest he has shown in this work and the many helpful suggestions he has made. We are indebted to Dr. G. Garton and Dr. J. W. Jeffery for allowing us to quote some of the results of their crystal structure determinations. We are grateful to Professor R. V. Jones for providing the crystal growing facilities, and to the Board of Admiralty and the U.S. Air Force for financial support.

The Lorenz Parameter in Dilute Silver–Manganese Alloys at Liquid Helium Temperatures

By M. S. R. CHARI
National Physical Laboratory of India, New Delhi, India

MS. received 14*th February* 1961, *in revised form* 23*rd June* 1961

Abstract. Thermal conductivity data at liquid helium temperatures, on polycrystalline rods of three dilute silver alloys (containing respectively 0·55, 0·32 and 0·14 at. % of manganese in solid solution) in magnetic fields ranging from 0 to 25 kilogauss, have been analysed afresh. The electronic and lattice components of the thermal conductivity are separated by the method of Grüneisen and de Haas. It is inferred that the electronic Lorenz parameter L_e (i) is independent of the magnetic field but varies with the temperature in the liquid helium region, (ii) exhibits a minimum at a temperature which increases with the increase in manganese content, and (iii) is much smaller than the normal 'Sommerfeld' value, but seems to extrapolate to that value at about 1°K.

This behaviour of L_e is explained on the basis of inelastic scattering of the conduction electrons by the magnetic impurity centres having closely spaced energy states, for such an inelastic scattering would contribute considerably to the electronic thermal resistivity while making only a small contribution to the electrical resistivity. Further, since such a scattering cannot occur at 0°K, L_e should approach the normal value at the lowest temperatures.

§ 1. Introduction

Low temperature electrical resistivity measurements (Gerritsen and Linde 1951a) on silver alloys containing small amounts of manganese in solid solution, showed that instead of attaining a temperature-independent 'residual' resistivity at low temperatures, each of them exhibited a resistance minimum somewhat below liquid hydrogen temperatures, followed by a maximum T_m at still lower temperatures. The electrical magnetoresistance was also found (Gerritsen and Linde 1951b) to be anomalous, being negative, below a temperature T_1 (T_1 being somewhat higher than T_m). Korringa and Gerritsen (1953) made a close study of such behaviour in a number of noble metal alloys containing a small amount of transitional metal in solid solution, and suggested that this behaviour could be due to a re-arrangement scattering of the electrons from the impurity, with resonance close to the Fermi level. They visualized electron states localized near the impurity ion and split by the magnetic interaction so as to lie just above and below the Fermi level.

Owen *et al.* (1957) and Van Itterbeek, Peelaers and Steffens (1960) studied the magnetic susceptibility of such alloys around about these temperatures and concluded that they exhibited a slow transition to anti-ferromagnetism, with indications of ferromagnetism as well. The specific heat C of such alloys at helium temperatures showed an anomalous behaviour, the $(C/T, T)$ curve exhibiting a pronounced 'hump' (de Nobel and du Chatenier 1959, Zimmerman and Hoare 1960).

Schmitt and Jacobs (1956, 1957) discussed their experimental data on the electrical and magnetic behaviour of dilute copper–manganese alloys. They suggested that some form of cooperative magnetic transition occurred in these alloys; and, below the temperature of transition, the spin degeneracy of each impurity ion is removed and the scattering which involves spin-flips of the conduction electron and the ion becomes inelastic. This inelastic scattering would not occur at 0°K. Yosida (1957) and Brailsford and Overhauser (1960) have also discussed the scattering by impurity centres having closely spaced energy states.

Thermal conductivity measurements on three silver–manganese alloy specimens, containing respectively 0·55, 0·32 and 0·14 at.% manganese, showed (Chari 1956, Chari and de Nobel 1959 a) an anomalous behaviour at liquid helium temperatures, in a zero magnetic field. This anomaly consisted in the (λ, T) curve† exhibiting a 'knee'. In other words, the lower portion (below 2·3°K) of the (λ, T) curve had higher values than should follow from a simple extension of the higher temperature part (viz. that above 2·8°K) of the curve. The $(\lambda/T, T)$ curve exhibited this anomaly in the form of a 'dip' at about 2·8°K followed by a 'hump' near 2·3°K. The thermal magnetoresistance was also anomalous, being negative.

The shape of the (λ, T) curves was not significantly altered even in strong magnetic fields of about 25 kilogauss. It was therefore suggested that this anomaly might be due to an *extra* contribution to the *lattice* thermal conductivity, owing probably to a partial uncoupling of the longitudinal and transverse phonons (Chari 1956, Klemens 1954, 1956, 1958).

In the present paper, our thermal conductivity data at liquid helium temperatures have been analysed afresh and information is obtained regarding the variation of the Wiedemann–Franz–Lorenz parameter for electronic conduction (referred to, in the rest of this paper, as the Lorenz parameter) with respect to temperature and magnetic fields.

In §2, we explain the full significance of assuming the Wiedemann–Franz relation to be valid. The method of Gruneisen–de Haas for the separation of λ_e and λ_g, without a specific assumption of the validity of this relation, is discussed in §3. A possible explanation for the behaviour of the electronic Lorenz parameter with respect to temperature, as derived by this method, is discussed in §4.

§ 2. THE WIEDEMANN–FRANZ RELATION

It has been mentioned above that the thermal conductivity of certain alloys measured by us was anomalous at liquid helium temperatures. Following the procedure usually employed in the case of non-superconducting alloys, we then separated the measured λ into its components, λ_e and λ_g, employing the Wiedemann–Franz relation $\lambda_e = L_n T/\rho_0$, where L_n is the normal 'Sommerfeld' value of the Lorenz parameter in a zero field. The anomaly in λ was thus attributed wholly to the lattice component.

---

† The symbols λ, w, σ and ρ will be used to represent respectively the thermal conductivity, thermal resistivity, electrical conductivity and electrical resistivity; and, where necessary, the qualifying subscripts e, o and g respectively to signify electronic, residual and lattice. λ will be expressed in w cm^{-1} deg^{-1}, and ρ in ohm cm.

This assumption of the validity of the Wiedemann–Franz relation implied (i) that the Lorenz parameter L_e for electronic conduction is a constant, independent of temperature, at any rate, for the liquid helium region, and (ii) that L_e has the normal value ($2{\cdot}45 \times 10^{-8}\,\mathrm{w}\,\Omega\,\mathrm{deg}^{-2}$) in zero magnetic field. It was also difficult to anticipate how L_e would vary with the strength H of the magnetic field, in these alloys, although this is known in the case of zinc (Alers 1956) and tungsten (de Nobel 1957).

Dilute Ag–Mn alloys exhibit antiferromagnetism, with indications of ferromagnetism (Owen *et al.* 1957), in this temperature region, and their anomalous electrical resistivity in a zero field can be simply attributed to a temperature-dependent relaxation time for elastic–inelastic impurity scattering of the conduction electrons (Schmitt 1956). Since it was shown by Kohler (1941) that the Lorenz parameter should be independent of temperature for elastic scattering of the electrons, such an assumption of the validity of the Wiedemann–Franz relation seems questionable in the case of these anomalous alloys.

§ 3. THE METHOD OF GRÜNEISEN AND DE HAAS

We have now analysed (Chari 1961a) our experimental data on the thermal and electrical conductivity of dilute silver–manganese alloys at liquid helium temperatures in transverse magnetic fields (ranging from 0 to 25·5 kilogauss), employing the method of Grüneisen and de Haas (see, for instance, Kohler 1949). This method has been employed earlier by de Haas, Gerritsen and Capel (1936) and Reddemann (1934) for bismuth, Rausch (1947) for antimony, Grüneisen and Adenstedt (1938) for tungsten and beryllium, Grüneisen and Erfling (1940) for beryllium, and de Haas and de Nobel (de Haas and de Nobel 1938, de Nobel 1949) for tungsten at liquid hydrogen temperatures. White and Woods (1958) applied it to their data on antimony at liquid air temperatures.

We have $\lambda = \lambda_e + \lambda_g = \sigma L_e T + \lambda_g$. Here, L_e is looked upon simply as the quotient $\lambda_e/\sigma T$, at temperature T, without making any specific assumptions as to its behaviour. If λ and σ are measured for a few values of the magnetic field H, then, for any particular value of T, we can write $\lambda_{[H]} = \sigma_{[H]} L_e T + \lambda_g$. The subscript $[H]$ here signifies measurements in a magnetic field; we actually used transverse fields of the respective strengths 0, 12, 19 and 25·5 kilogauss. This assumes, firstly, that λ_g is unaffected by magnetic fields. Even though, at these temperatures, λ_g is supposed, in normal alloys, to be limited principally by the conduction electrons, and the paths of the electrons are affected by the magnetic fields, it was shown (Makinson 1938) that the electron–lattice interaction depends solely on the equilibrium constants of the lattice, provided no electric current is flowing (Sondheimer and Wilson 1947). One would thus be justified in assuming λ_g to be unaffected by H.

The other assumption is that L_e is independent of H. This would only be justified if $\lambda_{[H]}$ against $\sigma_{[H]} T$ turns out to be a straight line graph, at fixed T. Figs 1, 2 and 3 show that this is indeed the case, within the experimental uncertainties, for the dilute silver–manganese alloys at liquid helium temperatures.

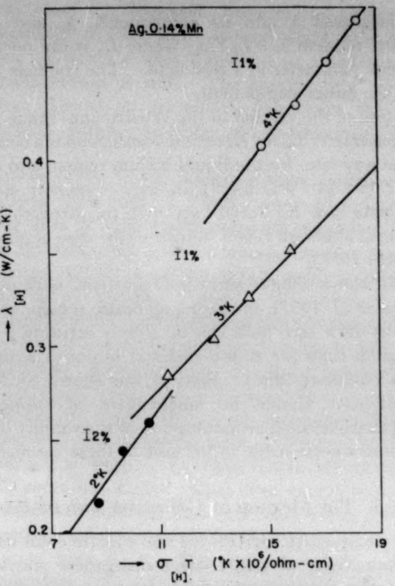

Fig. 1. $\lambda_{[H]}$ plotted against $\sigma_{[H]}T$, for the Ag–0·14% Mn specimen.

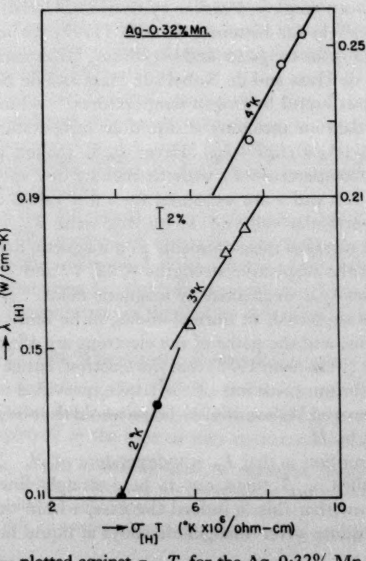

Fig. 2. $\lambda_{[H]}$ plotted against $\sigma_{[H]}T$, for the Ag–0·32% Mn specimen.

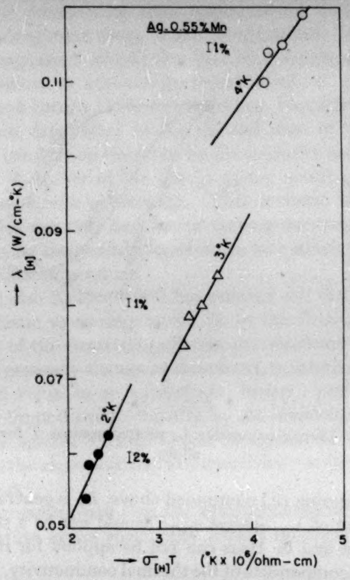

Fig. 3. $\lambda_{[H]}$ plotted against $\sigma_{[H]}T$, for the Ag–0·55% Mn specimen.

In order to avoid confusion, the plots for 1·5, 2·5 and 3·5°K are omitted from these figures. The slope of each of these straight lines gives the value of L_e at that temperature.

Plotting L_e against T (Fig. 4), we find (i) that L_e is smaller than the Sommerfeld value L_n and probably attains that value near about 1°K; (ii) that L_e has a minimum value (at a temperature T_{min}); we direct attention to the similarity with the results of Rosenberg (1955) for pure iron, and Roder, Powell and Hall (1959) for 'high purity' copper; (iii) that T_{min} varies with the manganese content c, shifting to a higher value with increasing c; and (iv) that the depth of the minimum is reduced by increase of c.

We wish to emphasize that two circumstances have made it possible to derive information regarding the behaviour of L_e with temperature and magnetic field, in the silver–manganese specimens: (i) the large (though negative) magnetoresistance, especially the thermal magnetoresistance, and (ii) the rectilinearity of the $\lambda_{[H]}$ against $\sigma_{[H]}T$ curves, indicating an L_e more or less independent of H. In the case of alloys which have a normal (that is, positive), magnetoresistance, the magnitude (especially of the thermal magnetoresistance) is quite small. In fact, our measurements on a Ag–0·24% In specimen (Chari 1956, Chari and de Nobel 1959a) gave a positive electrical magnetoresistance of about 1%, while the thermal magnetoresistance was of about the same order of magnitude as our accuracy of measurement.

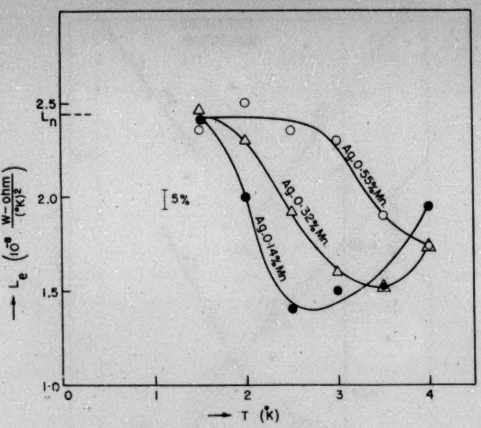

Fig. 4. The electronic Lorenz parameter L_e plotted against T for the silver–manganese alloys.

As regards the criterion (ii) mentioned above, L_e is generally not independent of H, so that the plot of $\lambda_{[H]}$ against $\sigma_{[H]}T$ would not be a straight line, and the method of Grüneisen and de Haas can not be applied for the separation of the lattice and electronic components of the thermal conductivity. Hence, in general, information regarding L_e in alloys would be difficult to obtain.

§ 4. Discussion

4.1. *The 'Dip' in the Value of L_e, below the Normal Value L_n*

The law of Wiedemann–Franz–Lorenz is known to hold at high temperatures ($T \gg \theta$), where the change in energy of the conduction electron by the emission or absorption of a phonon would be very much less than kT; and also at sufficiently low temperatures, where the predominant scattering of the conduction electrons is due to static, irregular imperfections or impurity centres. This is because, in both these cases, the scattering can be considered to be effectively elastic, and the relaxation times for electrical and thermal conduction would be identical. In the intervening range of low temperatures, the phonons available for scattering of the electrons would be of long wavelength and the angle of scattering of the conduction electrons small. Such small-angle scattering, whether elastic or otherwise, can make only a small contribution to the electrical resistivity. But inelastic small-angle scattering can contribute substantially to the heat resistivity. In other words, in the presence of the latter type of electron scattering, the electronic Lorenz parameter L_e would fall significantly below the normal value L_n (see Makinson 1938, Fig. 3).

The question arises as to how inelastic impurity scattering would show itself out, in the temperature region where the electrons are scattered predominantly by the impurity centres. Could the 'dip' in the value of L_e (Fig. 4) be due to inelastic electron scattering?

Schmitt (1956) and Schmitt and Jacobs (1957) made specific reference to such a scattering, for interpreting their experimental data on the electrical resistivity of copper–manganese alloys at low temperatures, where (as in the case of our dilute silver–magnanese alloys) the resistivity decreased with fall of temperature. The transition to antiferro/ferromagnetism of these alloys (Owen *et al.* 1957, Schmitt and Jacobs 1956, van Itterbeek, Peelaers and Steffens 1960) could remove the spin degeneracy of the ground state of the manganese ion. The scattering of the conduction electrons by the impurity centres, each of which could occupy one or the other of the energy states, could give rise to inelastic scattering (apart from elastic scattering). This inelastic scattering would be temperature-dependent not only because of varying occupation of the states by the ions, but also because the availability of states into which the electrons can be scattered will vary with temperature.

Ziman (1960, see also Kohler 1949) has pointed out that the critical test for the existence of inelastic scattering would be in the thermal resistivity. The 'vertical' transitions of the electrons (wherein the electrons gain or lose energy without suffering a significant change in direction), to which heat conductivity is very sensitive, would result in an anomalous 'hump', provided the electronic thermal resistivity is limited predominantly by the inelastic impurity scattering. In our graphs of $w_e T$ against T (Fig. 5) and w_e against T, we find evidence for such an extra term in the electronic thermal resistivity; in the former, this shows as a pronounced 'peak'.

Starting from the assumption that the anomalous fall of electrical resistivity with fall of temperature arises specifically from the magnetic character of the

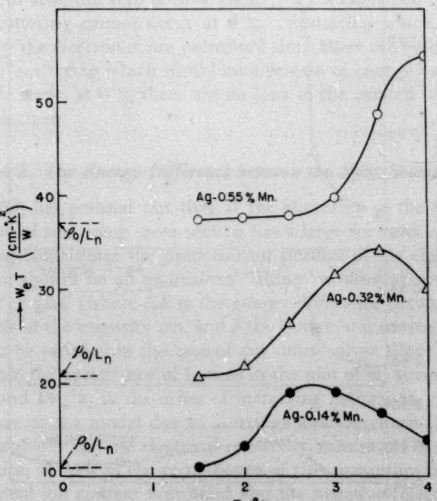

Fig. 5. *T* times the electronic thermal resistivity, plotted against *T*.

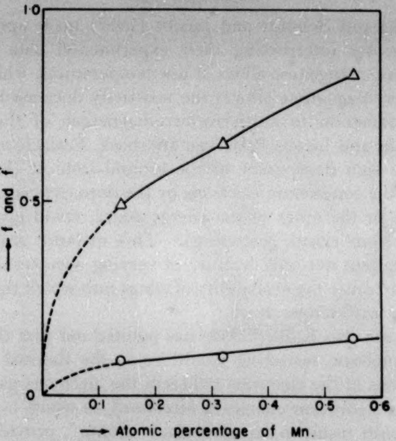

Fig. 6. f (lower curve) and f' (upper curve), the maximum contributions of inelastic impurity scattering expressed as fractions of ρ_0 and $(w_e T)_0$ respectively plotted against the atomic percentage of manganese.

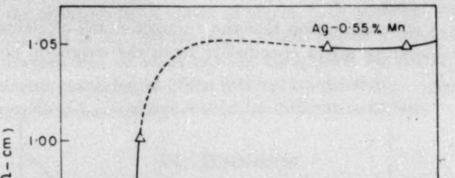

Fig. 7. Electrical resistivity ρ plotted against T (Chari 1956).

impurity metal, Schmitt and Jacobs (1957) find, in the case of their copper–manganese alloy specimens, that spin–flip scattering processes contribute, in the paramagnetic limit, about 10% of the residual electrical resistivity. Following them, we put $f = [(\rho_{\mathrm{m}}/\rho_0) - 1]$ (where ρ_{m} is the electrical resistivity at the 'hump' of the ρ–T curve at low temperatures, and ρ_0 is the value at $T \to 0$), and find that in our silver–manganese specimens also, the contribution of inelastic impurity scattering processes, at the hump, amounts to a fraction $f \simeq 0{\cdot}1$ of ρ_0. There may even be a slight variation of f with the manganese concentration, as indicated in the lower curve of Fig. 6. However, we must emphasize (i) that these estimates of ours are based on interpolation to the temperature region between liquid helium and liquid hydrogen temperatures (Fig. 7), and (ii) that these ignore any temperature-dependent contribution from elastic scattering by the impurity (solute) ions.

We make a similar estimation in the case of the electronic thermal resistivity, writing $f' = [\{(w_{\mathrm{e}}T)_{\mathrm{m}}/(w_{\mathrm{e}}T)_0\} - 1]$. Here, $(w_{\mathrm{e}}T)_{\mathrm{m}}$ and $(w_{\mathrm{e}}T)_0$ are the values at the peak and at $T \to 0$, respectively. Using the values of these from Fig. 5, we obtain $f' \simeq 0{\cdot}5$, $0{\cdot}6_5$ and $0{\cdot}8_3$, in the order of decreasing manganese content. Thus the contribution of inelastic impurity scattering processes, at the 'peak', amounts to a large fraction of the value of $(w_{\mathrm{e}}T)_0$. This is shown graphically in the upper curve of Fig. 6.

The fact that inelastic impurity scattering makes such a large contribution to the electronic thermal resistivity of these alloys at liquid helium temperatures, while making only a comparatively small contribution to the electrical resistivity, accounts for the 'dip' in the value of L_{e} (Fig. 4) with respect to the normal value L_{n} (Chari 1961b). The further result that L_{e} seems to approach L_{n} at temperatures close to absolute zero (below about 1°K) is explained by the fact that this inelastic scattering cannot occur at 0°K. Scattering which would involve loss of energy by the electron is not permitted since there are no lower electronic states available; scattering which would involve gain of energy by the electron is also not possible since, at 0°K, there are no ions in the excited states to transfer energy to the electron.

4.2. *The Energy Difference between the Split States*

Ziman (1960) has pointed out that, if the scattering of the electron is such that the differential scattering cross section has a large forward lobe, and the inelastic scattering contributes the predominant portion of the electronic thermal resistivity, there should be an anomalous 'hump' around about a temperature T_2 given by $kT_2 \simeq \frac{1}{4}\Delta E$ (where ΔE is the energy difference between the resolved degenerate levels of the impurity ion, and k the Boltzmann constant). Assuming these criteria to be satisfied in the case of our dilute silver alloys, and taking the values of T_2 from the occurrence of humps in the plot of w_{e} against T, we obtain $\Delta E/k \simeq 10$, 11 and $14{\cdot}_4$°K, in the order of increasing manganese content.

We refer now to the model due to Korringa and Gerritsen (1953); this was postulated to account for the electrical resistivity maximum in a zero magnetic field (the position as well as the prominence of this maximum being dependent on the transitional ion content only) and also the negative (electrical) magnetoresistivity. (Magnetic susceptibility and other data on such alloys were forthcoming only in 1956.) From their analysis of the electrical resistivity data of

Gerritsen and Linde, on the dilute alloys Ag–Mn, Cu–Mn, Au–Mn and Au–Cr, the above authors found the relation $\epsilon = 1{\cdot}54\,kT_{\mathrm{m}}$ satisfied. Here, as elsewhere in this paper, T_{m} represents the temperature of occurrence of the electrical resistivity maximum; $\pm\epsilon$ is the energy separation of the resolved local energy state with respect to the Fermi level. Substituting the values of T_{m} estimated by us (by interpolation between the liquid hydrogen and liquid helium temperatures in Fig. 7) into this relation, we obtain $\epsilon/k \simeq 9{\cdot}2$, 10·8 and 13·9°K, in the order of increasing manganese content. This is in satisfactory agreement with the above-mentioned values for ΔE obtained from our thermal conductivity data.

§ 5. CONCLUSION

In the present method of analysis, which employs the method of Grüneisen and de Haas, w_{e} is considered an exact counterpart of the Gerritsen–Linde anomaly in the electrical resistivity at low temperatures. This leads to an electronic Lorenz parameter which is more or less unaffected by the magnetic fields, but presents a marked minimum within the liquid helium region itself.

Apparently, the transition of these alloys to antiferro/ferromagnetism in the region of helium temperatures, which can account for the anomalous fall of their electrical resistivity with fall of temperature (at the lowest temperatures), is also responsible for the anomalous behaviour of L_{e} with respect to temperature in the helium temperature region.

ACKNOWLEDGMENTS

The author is grateful to the late Sir K. S. Krishnan, F.R.S., for the benefit of valuable discussions, to Dr. P. G. Klemens (of the Westinghouse Research Laboratories, United States of America) for some useful correspondence and to Dr. K. G. Ramanathan and Mr. R. Sundaram for helpful suggestions.

The experimental work on these alloys was done during 1955–56, while the author was a Research Fellow at the Kamerlingh Onnes Laboratory, Leiden, Holland. Grateful acknowledgment is made of the interest taken by Professor C. J. Gorter and Dr. J. de Nobel.

Dispersion Relations for Superconductors

By A. W. B. TAYLOR
Department of Theoretical Physics, University of Liverpool

Communicated by H. Fröhlich; *MS. received* 31*st May* 1961

Abstract. The general macroscopic description of the electromagnetic behaviour of superconductors and normal conductors is developed and dispersion relations for the frequency dependent material functions are rigorously established. From these dispersion relations expressions similar to the usual sum rules of electromagnetic theory are derived. Using these, Ferrell's proof that the Meissner effect is a consequence of the energy gap is shown to be unsound. Using the complex surface impedance it is shown macroscopically that as a consequence of the Meissner effect the area under the absorptivity curve for a superconductor is less than for the normal state.

§ 1. INTRODUCTION

THE dispersion relations which relate the real and imaginary parts of the frequency dependent material functions describing a system's electromagnetic behaviour, e.g. the complex conductivity, provide a possible means of relating in a completely macroscopic manner the zero frequency behaviour of the system to its electromagnetic absorption properties. This is of interest when the system is superconducting for then the energy gap in the superconducting state reduces the superconducting absorptivity below its normal state value for frequencies less than the gap frequency. We therefore have a possible means of relating macroscopically the energy gap or at least the effects of the energy gap to the zero frequency behaviour viz. the Meissner effect.

In §§2 and 3 the electromagnetic behaviour of linear isotropic systems is described by means of space–time dependent material functions and criteria to distinguish the zero frequency behaviour of superconductors and normal conductors are rigorously established.

In §4 the dispersion relations applicable to superconductors and normal conductors for these functions are rigorously derived. These dispersion relations lead directly to an expression which relates the Meissner effect to the difference between the normal state and superconducting state values of the integral over all frequencies of the real part of the transverse conductivity. This relation is similar to the well-known optical sum rule. This however cannot be used to relate the Meissner effect to the absorption properties. Ferrell's proof (1959) that the Meissner effect is a consequence of the energy gap which is based on a similar expression is unsound.

The frequency dependent material function which is directly related to the electromagnetic absorptivity is the complex surface impedance. Assuming the Meissner effect and also that the high frequency behaviour is the same in both superconductors and normal conductors, we have shown macroscopically by means of rigorously established dispersion relations that the total area under the absorptivity curve for the superconducting state is reduced below its normal state value. This is verified experimentally.

This however does not follow from the mere existence of an energy gap unless an additional assumption about the absorptivity for frequencies greater than the gap frequency is made. Such an additional assumption is certainly needed to distinguish the superconductor from the insulator which also has an energy gap but does not of course exhibit the Meissner effect.

§ 2. ISOTROPIC LINEAR SYSTEMS

In the following all space–time functions $f(\mathbf{r}, t)$ are transformed to Fourier space by

$$f(\mathbf{q}, \omega)=(2\pi)^{-4}\int d^3r\,dt\,f(\mathbf{r}, t)\exp(i\mathbf{q}\,.\,\mathbf{r}+i\omega t). \qquad \ldots\ldots(2.1)$$

If $f(\mathbf{r},t)$ is real then

$$f(-\mathbf{q}, -\omega)=f^*(\mathbf{q}, \omega). \qquad \ldots\ldots(2.2)$$

If $f(\mathbf{q}, \omega)$ is a vector $\mathbf{f}(\mathbf{q}, \omega)$ then its longitudinal component $\mathbf{f}^l(\mathbf{q}, \omega)$ and its transverse component $\mathbf{f}^t(\mathbf{q}, \omega)$ are defined by

$$\mathbf{f}(\mathbf{q}, \omega)=\mathbf{f}^t(\mathbf{q}, \omega)+\mathbf{f}^l(\mathbf{q}, \omega) \quad \mathbf{q}\wedge\mathbf{f}^l(\mathbf{q}, \omega)=\mathbf{q}\,.\,\mathbf{f}^t(\mathbf{q}, \omega)=0. \qquad \ldots\ldots(2.3)$$

From the identity

$$q^2\mathbf{f}(\mathbf{q}, \omega)=\mathbf{q}\mathbf{q}\,.\,\mathbf{f}(\mathbf{q}, \omega)-\mathbf{q}\wedge(\mathbf{q}\wedge\mathbf{f}(\mathbf{q}, \omega)) \qquad \ldots\ldots(2.4)$$

it follows that

$$\mathbf{f}^l(\mathbf{q}, \omega)=\frac{\mathbf{q}\mathbf{q}\,.\,\mathbf{f}(\mathbf{q}, \omega)}{q^2}, \quad \mathbf{f}^t(\mathbf{q}, \omega)=-\frac{\mathbf{q}\wedge(\mathbf{q}\wedge\mathbf{f}(\mathbf{q}, \omega))}{q^2}. \qquad \ldots\ldots(2.5)$$

Now Eqns (2.3) are invariant under the transformation

$$\mathbf{f}^t\to\mathbf{f}^t+\mathbf{G} \quad \mathbf{f}^l\to\mathbf{f}^l-\mathbf{G} \qquad \ldots\ldots(2.6)$$

where $\mathbf{G}$ is a function of $\mathbf{q}$ and ω satisfying

$$\mathbf{q}\,.\,\mathbf{G}=\mathbf{q}\wedge\mathbf{G}=0 \quad \text{i.e.} \quad \mathbf{G}\propto\mathbf{q}\delta(|\mathbf{q}|). \qquad \ldots\ldots(2.7)$$

Therefore, since $\mathbf{G}=0$ for $|\mathbf{q}|\neq 0$ but is indeterminate for $|\mathbf{q}|=0$ it follows that a vector in Fourier space can only be decomposed uniquely into its longitudinal and transverse components when $|\mathbf{q}|\neq 0$.

Maxwell's equations in Fourier space are

$$\mathbf{q}\wedge\mathbf{E}(\mathbf{q}, \omega)=-\frac{\omega}{c}\mathbf{B}(\mathbf{q}, \omega) \quad \mathbf{q}\,.\,\mathbf{B}(\mathbf{q}, \omega)=0 \qquad \ldots\ldots(2.8)$$

$$i\mathbf{q}\wedge\mathbf{H}(\mathbf{q}, \omega)=-\frac{4\pi}{c}\mathbf{J}(\mathbf{q}, \omega)+\frac{i\omega}{c}\mathbf{D}(\mathbf{q}, \omega) \quad i\mathbf{q}\,.\,\mathbf{D}(\mathbf{q}, \omega)=4\pi\rho(\mathbf{q}, \omega) \qquad \ldots\ldots(2.9)$$

and the continuity equation is

$$4\pi\mathbf{q}\,.\,\mathbf{J}(\mathbf{q}, \omega)=i\omega\mathbf{q}\,.\,\mathbf{D}(\mathbf{q}, \omega). \qquad \ldots\ldots(2.10)$$

Longitudinal equations. From (2.5), (2.8), (2.9), (2.10) the longitudinal field equations are

$$\mathbf{B}^l(\mathbf{q}, \omega)\equiv 0 \quad 4\pi\mathbf{J}^l(\mathbf{q},\omega)=i\omega\mathbf{D}^l(\mathbf{q}, \omega)=-4\pi\omega\rho(\mathbf{q}, \omega)\mathbf{q}/q^2. \qquad \ldots\ldots(2.11)$$

so that all longitudinal magnetic quantities are zero and there are two equations connecting the four quantities $\mathbf{E}^l$, $\mathbf{D}^l$, $\mathbf{J}^l$, ρ. Therefore, for a complete and unique description of the longitudinal behaviour two additional relations are required. For an isotropic linear system we take them to be

$$-i\omega\mathbf{J}^l(\mathbf{q},\omega)=S(\mathbf{q},\omega)\mathbf{E}^l(\mathbf{q},\omega),\quad \mathbf{D}^l(\mathbf{q},\omega)=\epsilon^l(q,\omega)\mathbf{E}^l(\mathbf{q},\omega) \qquad \ldots\ldots(2.12)$$

where $S(q,\omega)$, $\epsilon^l(q,\omega)$ are complex scalar functions of $q=|q|$ and ω.

Defining the complex longitudinal conductivity, $\sigma^l(q,\omega)$ by

$$\mathbf{J}^l(\mathbf{q},\omega)=\sigma^l(q,\omega)\mathbf{E}^l(\mathbf{q},\omega) \qquad \ldots\ldots(2.13)$$

we have from (2.12)

$$S(q,\omega)=-i\omega\sigma^l(q,\omega). \qquad \ldots\ldots(2.14)$$

Transverse equations. From (2.5), (2.8), (2.9) the transverse field equations are

$$\mathbf{q}\wedge\mathbf{E}^t(\mathbf{q},\omega)=-\frac{\omega}{c}\mathbf{B}(\mathbf{q},\omega),\quad i\mathbf{q}\wedge\mathbf{H}(\mathbf{q},\omega)=-\frac{4\pi}{c}\mathbf{J}^t(\mathbf{q},\omega)+\frac{i\omega}{c}\mathbf{D}^t(\mathbf{q},\omega). \qquad \ldots\ldots(2.15)$$

Now $\mathbf{J}^t(\mathbf{q},\omega)$, $\mathbf{D}^t(\mathbf{q},\omega)$ appear in these equations only in the combination

$$\frac{4\pi}{c}\mathbf{J}^t(\mathbf{q},\omega)-\frac{i\omega}{c}\mathbf{D}^t(\mathbf{q},\omega)$$

so that there are two equations connecting the four transverse fields, $\mathbf{B}$, $\mathbf{H}$, $\mathbf{E}^t$, $4\pi\mathbf{J}^t/c-i\omega\mathbf{D}^t/c$. Therefore, for a complete and unique description of the transverse behaviour two additonal relations are required. For an isotropic linear system we take these to be

$$\mathbf{B}(\mathbf{q},\omega)=\mu(q,\omega)\mathbf{H}(\mathbf{q},\omega)$$

$$\frac{4\pi}{c}\mathbf{J}^t(\mathbf{q},\omega)-\frac{i\omega}{c}\mathbf{D}^t(\mathbf{q},\omega)=\frac{K(q,\omega)i\mathbf{q}\wedge\mathbf{B}(\mathbf{q},\omega)}{q^2} \qquad \ldots\ldots(2.16)$$

where $\mu(q,\omega)$, $K(q,\omega)$ are complex scalar functions of $q=|\mathbf{q}|$ and ω. $\mu(q,\omega)$ is the conventional magnetic permeability.

Substituting (2.16) in the second equation of (2.15), we obtain the differential equation satisfied by $\mathbf{B}(\mathbf{q},\omega)$ in Fourier space as

$$L(q,\omega)\mathbf{B}(\mathbf{q},\omega)=-q^2\mathbf{B}(\mathbf{q},\omega) \qquad \ldots\ldots(2.17)$$

where

$$L(q,\omega)=K(q,\omega)-q^2\left[1-\frac{1}{\mu(q,\omega)}\right]. \qquad \ldots\ldots(2.18)$$

Substituting (2.16) in the first equation of (2.15) gives

$$c^2K(q,\omega)=-4\pi i\omega\sigma^t(q,\omega)-\omega^2\epsilon^t(q,\omega) \qquad \ldots\ldots(2.19)$$

where $\sigma^t(q,\omega)$, $\epsilon^t(q,\omega)$ are the conventional complex transverse conductivity and dielectric constant respectively, introduced by

$$\mathbf{J}^t(\mathbf{q},\omega)=\sigma^t(q,\omega)\mathbf{E}^t(\mathbf{q},\omega),\ \mathbf{D}^t(\mathbf{q},\omega)=\epsilon^t(q,\omega)\mathbf{E}^t(\mathbf{q},\omega). \qquad \ldots\ldots(2.20)$$

Hence $\sigma^t(q,\omega)$ and $\epsilon^t(q,\omega)$ are not defined separately in terms of $K(q,\omega)$, which is sufficient to describe the transverse behaviour completely. $\sigma^t(q,\omega)$ and $\epsilon^t(q,\omega)$ separately therefore overdescribe the transverse behaviour of the system.

The most usual ways of removing this ambiguity (cf. Fröhlich 1958) are:

(i) to put $\sigma^t(q,\omega)=0$ and use only a complex dielectric constant defined by

$$c^2K(q,\omega)=-\omega^2\epsilon_a{}^t(q,\omega), \qquad \ldots\ldots(2.21a)$$

(ii) to put $\epsilon^{\mathrm{t}}(q, \omega)=1$ and use only a complex conductivity defined by

$$c^2K(q, \omega)=-4\pi i\omega\sigma_{\mathrm{b}}{}^{\mathrm{t}}(q, \omega)-\omega^2, \qquad \ldots\ldots(2.21b)$$

(iii) to use only a real dielectric constant and a real conductivity defined by

$$c^2K(q, \omega)=-4\pi i\sigma_{\mathrm{c}}{}^{\mathrm{t}}(q, \omega)-\omega^2\epsilon_{\mathrm{c}}{}^{\mathrm{t}}(q, \omega). \qquad \ldots\ldots(2.21c)$$

These representations evidently provide equivalent macroscopic descriptions of the transverse behaviour and are connected by the well-known equation

$$4\pi\sigma_{\mathrm{b}}{}^{\mathrm{t}}(q, \omega)=i\omega(1-\epsilon_{\mathrm{a}}{}^{\mathrm{t}}(q, \omega)). \qquad \ldots\ldots(2.22)$$

Now for a conducting system $\lim_{\omega\to 0}\sigma^{\mathrm{t}}(q, \omega)$ is non-zero and finite and (2.22) then implies that $\lim_{\omega\to 0}\epsilon^{\mathrm{t}}(q, \omega)$ diverges. For example the Drude theory of an electron gas gives

$$\epsilon^{\mathrm{t}}(q, \omega)=1-\frac{\omega_{\mathrm{p}}{}^2}{\omega^2+i\tau\omega} \qquad \ldots\ldots(2.23)$$

where ω_{p}, τ are real positive constants.

i.e.

$$\lim_{\omega\to 0}\epsilon^{\mathrm{t}}(q, \omega)=(1-\omega_{\mathrm{p}}{}^2/\tau)+i\infty \qquad \ldots\ldots(2.24)$$

and

$$\lim_{\omega\to 0}\sigma^{\mathrm{t}}(q, \omega)=\omega_{\mathrm{p}}{}^2/4\pi\tau. \qquad \ldots\ldots(2.25)$$

Representation (i) above is therefore inconvenient for conducting systems in the stationary limit $\omega=0$. In the following representation (ii) will always be used.

Therefore from Eqns (2.16), (2.21*b*)

$$-4\pi i\omega\mathbf{J}^{\mathrm{t}}(\mathbf{q}, \omega)=\{c^2K(q, \omega)+\omega^2\}\mathbf{E}^{\mathrm{t}}(\mathbf{q}, \omega). \qquad \ldots\ldots(2.26)$$

Eqns (2.26), (2.12) and the first equation of (2.16) are the constitutive equations which we shall use with the Maxwell equations, to give a complete and unique description of the electromagnetic behaviour of a linear isotropic system.

Combining with (2.26), (2.12) gives

$$-4\pi i\omega\mathbf{J}(\mathbf{q}, \omega)=\{c^2K(q, \omega)+\omega^2\}\mathbf{E}^{\mathrm{t}}(\mathbf{q}, \omega)+4\pi S(q, \omega)\mathbf{E}^{\mathrm{l}}(\mathbf{q}, \omega) \qquad \ldots\ldots(2.27)$$

the constitutive equation relating the total electric current to the electric field.

Now from (2.6) and (2.7), $\mathbf{E}^{\mathrm{t}}(\mathbf{q}, \omega)$ and $\mathbf{E}^{\mathrm{l}}(\mathbf{q}, \omega)$ are not uniquely defined for $q=0$. Therefore in order that (2.27) provide a unique description in the limit $q=0$ we shall require

$$\lim_{q\to 0}\{c^2K(q, \omega)+\omega^2\}=\lim_{q\to 0}4\pi S(q, \omega), \qquad \ldots\ldots(2.28)$$

for then (2.27) is in the limit $q=0$

$$-4\pi i\omega\mathbf{J}=\{c^2\lim_{q\to 0}K+\omega^2\}\mathbf{E}=4\pi\lim_{q\to 0}S\mathbf{E} \qquad \ldots\ldots(2.29)$$

which is of course unique as it involves only the total field and the total current.

An alternative notation for the transverse equations is to define a magnetization vector $\mathbf{M}(\mathbf{q}, \omega)$ and a magnetization current $\mathbf{J}_{\mathrm{m}}(\mathbf{q}, \omega)$ by

$$4\pi\mathbf{M}(\mathbf{q}, \omega)=\mathbf{B}(\mathbf{q}, \omega)-\mathbf{H}(\mathbf{q}, \omega) \qquad \mathbf{J}_{\mathrm{m}}(\mathbf{q}, \omega)=-ci\mathbf{q}\wedge\mathbf{M}(\mathbf{q}, \omega). \qquad \ldots\ldots(2.30)$$

The transverse equations then become

$$\mathbf{q}\wedge\mathbf{E}^{\mathrm{t}}(\mathbf{q}, \omega)=-\frac{\omega}{c}\mathbf{B}(\mathbf{q}, \omega); \quad ic\mathbf{q}\wedge\mathbf{B}(\mathbf{q}, \omega)=-4\pi\{\mathbf{J}^{\mathrm{t}}(\mathbf{q}, \omega)+\mathbf{J}_{\mathrm{m}}(\mathbf{q}, \omega)\}+i\omega\mathbf{D}^{\mathrm{t}}(\mathbf{q},\omega) \qquad \ldots\ldots(2.31)$$

$$-4\pi\{\mathbf{J}^t(\mathbf{q},\omega)+\mathbf{J}_{\mathrm{m}}(\mathbf{q},\omega)\}+i\omega\mathbf{D}^t(\mathbf{q},\omega)=cL(q,\omega)i\mathbf{q}\wedge\mathbf{B}(\mathbf{q},\omega)/q^2, \qquad \ldots\ldots(2.32)$$

where $L(q,\omega)$ is defined by (2.18).

In this notation we define a complex conductivity $\sigma_{\mathrm{m}}(q,\omega)$ by

$$c^2L(q,\omega)=-4\pi i\omega\sigma_{\mathrm{m}}(q,\omega)-\omega^2 \qquad \ldots\ldots(2.33)$$

and therefore from (2.18), (2.25), (2.32)

$$\mathbf{J}^t(q,\omega)+\mathbf{J}_{\mathrm{m}}(\mathbf{q},\omega)=\sigma_{\mathrm{m}}(\mathbf{q},\omega)\mathbf{E}^t(\mathbf{q},\omega). \qquad \ldots\ldots(2.34)$$

§ 3. SUPERCONDUCTORS AND NORMAL CONDUCTORS

If we define $$L(q)=\lim_{\omega\to0}L(q,\omega) \text{ and } S(q)=\lim_{\omega\to0}S(q,\omega) \qquad \ldots\ldots(3.1)$$

then we shall prove below that

$$L(q),\ S(q) \text{ are real and finite} \qquad \ldots\ldots(3.2)$$

for superconductors and normal conductors, and that

$$\left.\begin{array}{ll}\text{for normal magnetism} & \lim_{q\to0} L(q)=0\\ \text{for Meissner effect} & \lim_{q\to0} L(q)>0\end{array}\right\} \qquad \ldots\ldots(3.3)$$

$$\left.\begin{array}{ll}\text{for normal conduction} & S(q)=0\\ \text{for perfect conductors} & S(q)\neq0\end{array}\right\}. \qquad \ldots\ldots(3.4)$$

Now Eqn (A8) of the appendix gives λ, the penetration depth of a stationary magnetic field into a semi-infinite system, as

$$\lambda=\frac{2}{\pi}\int_0^\infty\frac{dq}{q^2+L(q)}. \qquad \ldots\ldots(3.5)$$

For normal magnetic behaviour λ is infinite, i.e. the integral in (3.5) diverges and consequently $\lim_{q\to0}L(q)=0$. For the Meissner effect λ is finite and non-zero; i.e. the integral converges to a positive, non-zero limit and consequently we require $\lim_{q\to0}L(q)>0$. Eqn (3.3) is thus proved.

Consider now the longitudinal equations (2.12)

$$-i\omega\mathbf{J}^l(\mathbf{q},\omega)=S(q,\omega)\mathbf{E}^l(\mathbf{q},\omega) \qquad \ldots\ldots(3.6)$$

in the stationary limit $\omega=0$.

We have $\lim_{\omega\to0}\mathbf{J}^l(\mathbf{q},\omega)\not\equiv0$ and finite and hence

$$\lim_{\omega\to0}S(q,\omega)\mathbf{E}^l(\mathbf{q},\omega)=0. \qquad \ldots\ldots(3.7)$$

Perfect conduction means that stationary longitudinal currents flow in the absence of a (macroscopic) longitudinal electric field, i.e. when

$$\lim_{\omega\to0}\mathbf{E}^l(\mathbf{q},\omega)=0.$$

From (3.7) the necessary and sufficient condition for this is $\lim_{\omega\to0}S(q,\omega)\neq0$ and finite.

For normal conduction $\lim_{\omega\to0}\sigma^l(q,\omega)$ is finite so that from (2.14)

$$\lim_{\omega\to0}i\omega\sigma^l(q,\omega)=-\lim_{\omega\to0}S(q,\omega)=0. \qquad \ldots\ldots(3.8)$$

(3.4) is thus proved.

From (3.5) $L(q)$ is finite for both superconductors and normal conductors since the penetration depth λ is non-zero. From (3.4) $S(q)$ is also finite for both superconductors and normal conductors. Therefore, from the reality conditions (2.1)

$$S(q,-\omega)=S^*(q,\omega),\quad L(q,-\omega)=L^*(q,\omega) \qquad \ldots\ldots(3.9)$$

and $L(q)$, $S(q)$ are also real. This proves (3.1).

For example the second London equation for superconductors (London 1950) is given by

$$L(q)=\frac{1}{\lambda_L{}^2}=\text{constant} \qquad \ldots\ldots(3.10)$$

for then (2.17) becomes

$$-q^2\mathbf{B}(\mathbf{q})=\frac{\mathbf{B}(\mathbf{q})}{\lambda_L{}^2} \qquad \ldots\ldots(3.11)$$

which is the second London equation in Fourier space.

The 'non-local' theory of Pippard (1953) on the other hand requires a q-dependent $L(q)$

$$L(q)=\frac{3\xi}{2\lambda_L{}^2\xi_0(\xi q)^3}\{(1+\xi^2q^2)\arctan\xi q-\xi q\} \qquad \ldots\ldots(3.12)$$

where ξ, ξ_0 are positive constants and λ_L is the London constant of (3.10) above. Here

$$\lim_{q\to 0} L(q)=\frac{\xi}{\lambda_L{}^2\xi_0} \qquad \ldots\ldots(3.13)$$

and by (3.3) we do have a Meissner effect.

§ 4. DISPERSION RELATIONS

Define

$$S^\infty(q)=\lim_{\omega\to\infty}S(q,\omega),\quad L^\infty(q)=\lim_{\omega\to\infty}L(q,\omega). \qquad \ldots\ldots(4.1)$$

For infinitely high frequencies the current carriers of the system will behave as if free so that $S^\infty(q)$, $L^\infty(q)$ can both be assumed real.

We shall now show that for both superconductors and normal conductors the functions $S(q,\omega)-S^\infty(q)$, $L(q,\omega)-L^\infty(q)$ satisfy the conditions of the well-known Titchmarsh theorem (Titchmarsh 1948), namely that they are square integrable with respect to ω and that their Fourier transforms with respect to ω vanish for all negative times.

Now, by definition (4.1)

$$\lim_{\omega\to\infty}\{S(q,\omega)-S^\infty(q)\}=0 \qquad \ldots\ldots(4.2)$$

and by (3.2)

$$\lim_{\omega\to 0}\{S(q,\omega)-S^\infty(q)\}\text{ is real and finite} \qquad \ldots\ldots(4.3)$$

for both superconductors and normal conductors.

Equations (4.2), (4.3) are necessary conditions for square integrability of $S(q,\omega)-S^\infty(q)$. If we assume that $S(q,\omega)$ is not infinitely discontinuous for any finite ω then conditions (4.2), (4.3) are also sufficient.

Performing a Fourier transformation of Eqn (2.12) which defines $S(q,\omega)$ one finds

$$\frac{\partial}{\partial t}\mathbf{J}^l(\mathbf{r},t)=(2\pi)^{-4}\int d^3r'\int_{-\infty}^{+\infty}dt'\,S(|\mathbf{r}-\mathbf{r}'|,t-t')\mathbf{E}^l(\mathbf{r}',t') \qquad \ldots\ldots(4.4)$$

where $\mathbf{J}^{\mathrm{l}}(\mathbf{r}, t)$, $\mathbf{E}^{\mathrm{l}}(\mathbf{r}, t)$, $S(|\mathbf{r}|, t)$ are Fourier transforms of $\mathbf{J}^{\mathrm{l}}(\mathbf{q}, \omega)$, $\mathbf{E}^{\mathrm{l}}(\mathbf{q}, \omega)$, $S(q, \omega)$ respectively. Eqn (4.4) relates the longitudinal current response at time t to the values of the longitudinal electric field at *all* times t'. Causality requires that the field at time t' should have no effect on the response at earlier times $t \leqslant t'$. The limits of the t' integration in (4.4) therefore become $(-\infty, t)$. This is evidently equivalent to putting

$$S(|\mathbf{r}|, t) = 0 \text{ if } t < 0. \qquad \ldots\ldots(4.5)$$

Therefore the Fourier transform of $S(q, \omega)$ and hence also of $S(q, \omega) - S^{\infty}(q)$ with respect to ω vanishes for all negative times.

$S(q, \omega) - S^{\infty}(q)$ and similarly $L(q, \omega) - L^{\infty}(q)$ thus satisfy the conditions of the Titchmarsh theorem from which follow the Hilbert conjugate relations

$$\left.\begin{aligned} \mathscr{R}S(q, \omega) - S^{\infty}(q) &= \frac{1}{\pi}\int_{-\infty}^{+\infty} \frac{\mathscr{I}S(q, z)\,dz}{z - \omega} \\ \mathscr{I}S(q, \omega) &= -\frac{1}{\pi}\int_{-\infty}^{+\infty} \frac{\mathscr{R}S(q, z)\,dz}{z - \omega} \end{aligned}\right\} \qquad \ldots\ldots(4.6)$$

and similarly for $L(q, \omega)$.

Applying the reality conditions (2.2)

$$\mathscr{R}S(q, z) = \mathscr{R}S(q, -z) \qquad \mathscr{I}S(q, z) = -\mathscr{I}S(q, -z) \qquad \ldots\ldots(4.7)$$

to convert the limits of the z integration in (4.6) to $(0, \infty)$ gives the dispersion relations

$$\mathscr{R}L(q, \omega) - L^{\infty}(q) = \frac{2}{\pi}\int_{0}^{\infty} \frac{\mathscr{I}L(q, z)z\,dz}{z^2 - \omega^2} \qquad \ldots\ldots(4.8)$$

$$\mathscr{I}L(q, \omega) = -\frac{2}{\pi}\int_{0}^{\infty} \frac{\mathscr{R}L(q, z)\omega\,dz}{z^2 - \omega^2} \qquad \ldots\ldots(4.9)$$

$$\mathscr{R}S(q, \omega) - S^{\infty}(q) = \frac{2}{\pi}\int_{0}^{\infty} \frac{\mathscr{I}S(q, z)z\,dz}{z^2 - \omega^2} \qquad \ldots\ldots(4.10)$$

$$\mathscr{I}S(q, \omega) = -\frac{2}{\pi}\int_{0}^{\infty} \frac{\mathscr{R}S(q, z)\omega\,dz}{z^2 - \omega^2} \qquad \ldots\ldots(4.11)$$

where the principal value of the integrals is implied.

Taking the limit $\omega = 0$ in (4.8), (4.10) and using (2.14), (2.33)

$$\left.\begin{aligned} \int_{0}^{\infty} \mathscr{R}\sigma_{\mathrm{m}}(q, z)\,dz &= \tfrac{1}{8}c^2\{L^{\infty}(q) - L(q)\} \\ \int_{0}^{\infty} \mathscr{R}\sigma^{\mathrm{l}}(q, z)\,dz &= \tfrac{1}{2}\pi\{S^{\infty}(q) - S(q)\} \end{aligned}\right\} \qquad \ldots\ldots(4.12)$$

We now compare these equations with the sum rules

$$\left.\begin{aligned} \int_{0}^{\infty} \mathscr{R}\sigma_{\mathrm{m}}(q, z)\,dz &= \tfrac{1}{8}c^2 L^{\infty}(q) \\ \int_{0}^{\infty} \mathscr{R}\sigma^{\mathrm{l}}(q, z)\,dz &= \tfrac{1}{2}\pi S^{\infty}(q) \end{aligned}\right\} \qquad \ldots\ldots(4.13)$$

which obtain their familiar form with the values

$$S^{\infty}(q) = \frac{c^2 L^{\infty}(q)}{4\pi} = \frac{ne^2}{m} \qquad \ldots\ldots(4.14)$$

where n is the electron density (cf. Buckingham 1957).

Comparing these sum rules, (4.13) with (4.12), it is seen that, since by (3.3), (3.4), $L(q)$ and $S(q)$ are non-zero and finite for superconductors the sum rules (4.13) are not obeyed by superconductors.

Now the sum rules (4.13) can be derived from the Kramers–Kronig dispersion relations for $\sigma_{\mathrm{m}}(q,\omega)$ and $\sigma^{\mathrm{l}}(q,\omega)$ in a similar fashion to the derivation of (4.12) from the dispersion relations (4.8) to (4.11) (Ferrell and Glover 1958). However, the Kramers–Kronig dispersion relations for $\sigma_{\mathrm{m}}(q,\omega)$ and $\sigma^{\mathrm{l}}(q,\omega)$ are not obeyed by superconducting systems. For

$$\left.\begin{aligned} \lim_{\omega\to 0}\sigma_{\mathrm{m}}(q,\omega) &= -\lim_{\omega\to 0}\frac{c^2L(q,\omega)}{4\pi i\omega} \simeq i\infty \\ \lim_{\omega\to 0}\sigma^{\mathrm{l}}(q,\omega) &= -\lim_{\omega\to 0}\frac{S(q,\omega)}{i\omega} \simeq i\infty \end{aligned}\right\} \qquad \ldots\ldots(4.15)$$

and $\sigma_{\mathrm{m}}(q,\omega)$ and $\sigma^{\mathrm{l}}(q,\omega)$ will therefore not be square integrable with respect to ω unless it is postulated that

$$\mathscr{I}\sigma_{\mathrm{m}}(q,\omega)\simeq\delta(\omega), \quad \mathscr{I}\sigma^{\mathrm{l}}(q,\omega)\simeq\delta(\omega) \text{ for } \omega\to 0. \qquad \ldots\ldots(4.16)$$

But then the second condition of the Titchmarsh theorem is violated, for the delta functions will give non-vanishing time independent contributions to the Fourier transforms of $\sigma_{\mathrm{m}}(q,\omega)$ and $\sigma^{\mathrm{l}}(q,\omega)$, i.e. the Fourier transforms will not vanish for negative times. The Titchmarsh theorem is therefore not applicable to $\sigma_{\mathrm{m}}(q,\omega)$ and $\sigma^{\mathrm{l}}(q,\omega)$ for superconducting systems. This is the formal reason for the inapplicability of (4.13) to superconducting systems.

Now one may postulate that the high frequency behaviour of a system in the superconducting state is identical to its high frequency behaviour in the normal state. This is in accord with experiment (e.g. Serin 1956)

$$\text{i.e.} \quad \Delta_{\mathrm{ns}}L^{\infty}(q) \equiv L^{\infty}(q)_{\mathrm{normal}} - L^{\infty}(q)_{\mathrm{supercond.}} = 0. \qquad \ldots\ldots(4.17)$$

Therefore from (4.12)

$$\Delta_{\mathrm{ns}}\int_0^{\infty}\mathscr{R}\sigma_{\mathrm{m}}(q,z)\,dz = -\tfrac{1}{8}c^2\Delta_{\mathrm{ns}}L(q), \qquad \ldots\ldots(4.18)$$

and from (3.3) the Meissner effect implies

$$\lim_{q\to 0}\,\Delta_{\mathrm{ns}}\int_0^{\infty}\mathscr{R}\sigma_{\mathrm{m}}(q,z)\,dz > 0, \text{ finite.} \qquad \ldots\ldots(4.19)$$

Evidently if one could prove that Eqns (4.18) and (4.19) hold for some particular system denoted by the subscript s then this system will exhibit the Meissner effect.

Now Ferrell (1959) has in fact derived an equation equivalent to (4.18) for a system of electrons by applying perturbation theory to evaluate the system's current response to an external magnetic field.

In an attempt to deduce (4.19) he makes the assumption that the electron system possesses an energy gap in the one-electron energy spectrum. This energy gap will therefore annul the electron system's electromagnetic absorptivity for frequencies less than the gap frequency and if one now assumes in addition that (i) for frequencies greater than the gap frequency the absorptivity is the same as in the normal state, (ii) $\lim_{q\to 0}\mathscr{R}\sigma_{\mathrm{m}}(q,\omega)$ is proportional to the electromagnetic absorptivity for frequency ω (Ferrell's Eqn (13)), then (4.19) follows immediately from (4.18), i.e. the electron system exhibits the Meissner effect as a consequence of the energy gap and assumptions (i) and (ii) above.

However, assumption (i) is clearly an additional assumption which does not follow from the existence of an energy gap alone. Further, it would have to be shown that it does not contradict the assumption of an energy gap (cf. Buckingham 1957). Nevertheless such an additional assumption as (i) is required physically to distinguish the system from an insulator which also has an energy gap but which does not exhibit the Meissner effect.

Assumption (ii) is equivalent to the neglect of the spatial dispersion of the electromagnetic field by the system. For, from the well-known energy integral of Maxwell's equations the absorptivity is proportional to

$$\int_0^\infty \mathscr{R}\sigma_{\mathrm{m}}(q,\omega)|\mathbf{E}^t(\mathbf{q},\omega)|^2 dq$$

which is proportional to $\lim_{q\to 0}\mathscr{R}\sigma_{\mathrm{m}}(q,\omega)$ only when $|\mathbf{E}^t(\mathbf{q},\omega)|^2 \simeq \delta(q)$, i.e. when the electric field is assumed uniform in space. One cannot make this assumption since it is the very nature of the spatial dependence of the electromagnetic field which characterizes the Meissner effect.

We conclude that Ferrell's derivation of the Meissner effect is unsound.

§ 5. ELECTROMAGNETIC ABSORPTION

Consider a transverse electromagnetic wave normally incident on a system which may be in the superconducting or normal state. We assume that the radii of curvature of the surface of the system are everywhere sufficiently large to neglect the tangential derivatives of the fields (e.g. plane surface).

Hence, if we take the x axis as the inward normal at the surface with the origin lying on the surface, we can write the Maxwell induction relation as

$$\frac{\partial}{\partial x}E_z(x,t) = \frac{1}{c}\frac{\partial}{\partial t}B_y(x,t) \qquad \ldots\ldots(5.1)$$

where the electric field $E_z(x,t)$ is in the z direction and the magnetic induction $B_y(x,t)$ is in the y direction. Fourier transforming with respect to time t

$$\frac{\partial}{\partial x}E_z(x,\omega) = -\frac{i\omega}{c}B_y(x,\omega). \qquad \ldots\ldots(5.2)$$

Define a real function of time $Z(t)$ by

$$E_z(0,t) = \int_{-\infty}^{t} Z(t-t')B_y(0,t')dt'. \qquad \ldots\ldots(5.3)$$

$Z(t-t')$ thus relates $E_z(0,t)$, the electric field on the surface at time t to $B_y(0,t')$, the magnetic induction on the surface at all previous times t'.

Performing a Fourier transformation on Eqn (5.3) with respect to time

$$E_z(0,\omega) = Z(\omega)B_y(0,\omega) \qquad \ldots\ldots(5.4)$$

where

$$Z(\omega) = (2\pi)^{-1}\int_0^\infty Z(t)\,e^{i\omega t}dt. \qquad \ldots\ldots(5.5)$$

$Z(\omega)$ is the complex surface impedance. It provides in (5.4) a boundary condition to the Maxwell equation (5.2).

Since $Z(t)$ is real,

$$Z(-\omega) = Z^*(\omega). \qquad \ldots\ldots(5.6)$$

By its definition (5.4), $Z(\omega)$ is square integrable with respect to ω since $E_z(0, \omega)$ and $B_y(0, \omega)$ are necessarily square integrable. Also by (5.5) the Fourier transform of $Z(\omega)$ vanishes for all negative times. $Z(\omega)$ therefore satisfies the conditions of the Titchmarsh theorem.

The surface impedance $Z(\omega)$ is important because it is directly related to the electromagnetic absorptivity $A(\omega)$ by (Dingle 1953)

$$A(\omega)=\frac{4\mathcal{R}Z(\omega)}{|1+Z(\omega)|^2}. \qquad \ldots\ldots(5.7)$$

Therefore for a normal conductor $Z(\omega)\simeq b\omega^2$ as $\omega\to 0$ ......(5.8)
where b is a positive finite constant (Landau and Lifshitz 1960).

Now the penetration depth of a stationary magnetic field into the system is defined by

$$\lambda=\lim_{\omega\to 0}\int_0^\infty \frac{B_y(x,\omega)\,dx}{B_y(0,\omega)}. \qquad \ldots\ldots(5.9)$$

From (5.2), (5.4)

$$\lambda=\lim_{\omega\to 0}\frac{cE_z(\infty,\omega)}{i\omega B_y(0,\omega)}+\lim_{\omega\to 0}\frac{cZ(\omega)}{i\omega}. \qquad \ldots\ldots(5.10)$$

By (5.2) the first term is proportional to the magnetic induction at $x=\infty$ in the stationary limit $\omega=0$. For a bulk superconducting system this will vanish because of the Meissner effect. Therefore the superconducting penetration depth is related to the surface impedance by

$$\lambda_s=\lim_{\omega\to 0}\frac{cZ(\omega)}{i\omega} \qquad \ldots\ldots(5.11)$$

i.e. for superconductors $Z(\omega)\sim ic\lambda_s\omega$ as $\omega\to 0$. ......(5.12)

Having described the main properties of the surface impedance we now wish to formulate the dispersion relations for the complex function $F(\omega)$ defined by

$$F(\omega)=\left[\frac{Z_n(\omega)}{|1+Z_n(\omega)|^2}-\frac{Z_s(\omega)}{|1+Z_s(\omega)|^2}\right]\frac{i\omega}{A_n(\omega)} \qquad \ldots\ldots(5.13)$$

where the subscripts s, n refer to the same bulk system when in the superconducting state and when in the normal state respectively.

From (5.7), (5.8), (5.11)

$$\lim_{\omega\to 0}F(\omega)=\frac{\lambda_s}{b}\text{ real, finite and positive} \qquad \ldots\ldots(5.14)$$

also

$$\lim_{\omega\to 0}F(\omega)=0 \qquad \ldots\ldots(5.15)$$

since the high frequency behaviours of superconducting state and normal state are identical.

Equations (5.14) and (5.15) are necessary conditions for the square integrability of $F(\omega)$. Since by definition $A_n(\omega)>0$ for finite ω it is seen from definition of $F(\omega)$, (5.13), and definition of $Z(\omega)$, (5.4), that $F(\omega)$ has no infinite discontinuities for finite ω. (5.14) and (5.15) are therefore also sufficient conditions of square integrability. $F(\omega)$ is therefore square integrable with respect to ω.

Now, as $Z(\omega)$ satisfies the conditions of the Titchmarsh theorem it is an analytic function of ω in the upper half of the complex ω plane. By definition, $A_n(\omega)$

has no zeros in the upper half plane. Therefore from (5.13) $F(\omega)$ is an analytic function in the upper half plane and so satisfies the condition of Titchmarsh's theorem that it be analytic.

$F(\omega)$ therefore satisfies the conditions of the Titchmarsh theorem and the Hilbert conjugate relations follow.

From (5.6), (5.13)

$$F(-\omega)=F^*(\omega) \qquad \ldots\ldots(5.16)$$

so that the dispersion relations relating the real and imaginary parts of $F(\omega)$ follow immediately from the Hilbert conjugate relations.

One of the dispersion relations is

$$\mathscr{R}F(\omega)=\frac{2}{\pi}\int_0^\infty \frac{\mathscr{I}F(z)z\,dz}{z^2-\omega^2}. \qquad \ldots\ldots(5.17)$$

Now from (5.7), (5.13)

$$\mathscr{I}F(\omega)=\frac{[A_{\mathrm{n}}(\omega)-A_{\mathrm{s}}(\omega)]\omega}{4A_{\mathrm{n}}(\omega)} \qquad \ldots\ldots(5.18)$$

and therefore (5.17) gives

$$\int_0^\infty \frac{A_{\mathrm{n}}(z)-A_{\mathrm{s}}(z)}{A_{\mathrm{n}}(z)}\,dz=\lim_{\omega\to 0}2\pi\mathscr{R}F(\omega). \qquad \ldots\ldots(5.19)$$

Therefore from (5.14)

$$\int_0^\infty \frac{A_{\mathrm{n}}(z)-A_{\mathrm{s}}(z)}{A_{\mathrm{n}}(z)}\,dz>0 \text{ and finite.} \qquad \ldots\ldots(5.20)$$

This result, correlating the normal and superconducting absorptivities, is a rigorous consequence of the Meissner effect and the assumption that the high frequency behaviours in normal and superconducting states are identical. Eqn (5.20) has been verified experimentally (Biondi and Garfunkel 1959, Richards and Tinkham 1960).

ACKNOWLEDGMENTS

The author is indebted to Professor H. Fröhlich, who suggested this investigation, for his patient guidance and help. He also acknowledges receipt of a research studentship from the Senatus of Edinburgh University.

APPENDIX

In this appendix we derive an expression for the penetration depth of a stationary magnetic field into a system occupying the half space $x\geqslant 0$. The magnetic field is taken in the y direction and will be a function of x only.

We assume that the electrons are specularly reflected at the boundary $x=0$ of the system. This assumption simplifies the mathematics, but is unlikely to affect the results since we make the same assumption for both normal and superconducting systems and the results are only used in §§ 3 and 4 to compare the two.

Specularly reflected electrons correspond to electrons coming from a system in $x\leqslant 0$ which has the same field distribution as the system in $x\geqslant 0$ except that the magnetic field (and hence the Lorentz force) is reversed. In other words the system filling $x\geqslant 0$ can be represented by an infinite system with the discontinuity

$$B_y(x=0+)=-B_y(x=0-) \qquad \ldots\ldots(\mathrm{A1})$$

in the magnetic induction.

We can therefore Fourier analyse with respect to x by (2.1) and use the relations of § 2 if we take this discontinuity into account.

The differential equation satisfied by the magnetic induction in Fourier space, (2.17), becomes

$$L(q)B_y(q) = -q^2 B_y(q) + \frac{iqB_y(x=0+)}{\pi}, \qquad \ldots\ldots\text{(A2)}$$

i.e.

$$B_y(q) = \frac{iqB_y(x=0+)}{\pi[q^2+L(q)]}. \qquad \ldots\ldots\text{(A3)}$$

Therefore

$$\int_0^\infty B_y(x)dx = \int_0^\infty dx \int_{-\infty}^{+\infty} dq B_y(q)\,\mathrm{e}^{-iqx} \qquad \ldots\ldots\text{(A4)}$$

$$= \frac{B_y(x=0+)}{\pi} \int_{-\infty}^{+\infty} \frac{dq}{q^2+L(q)}, \qquad \ldots\ldots\text{(A5)}$$

since

$$\int_0^\infty dx\,\mathrm{e}^{-iqx} = \pi\delta(q) - P\frac{i}{q}, \qquad \ldots\ldots\text{(A6)}$$

where P denotes principal value.

The penetration depth λ is defined by

$$\lambda = \int_0^\infty \frac{B_y(x)\,dx}{B_y(x=0+)}. \qquad \ldots\ldots\text{(A7)}$$

Therefore from (A5)

$$\lambda = \frac{1}{\pi}\int_{-\infty}^{+\infty} \frac{dq}{q^2+L(q)} = \frac{2}{\pi}\int_0^\infty \frac{dq}{q^2+L(q)} \qquad \ldots\ldots\text{(A8)}$$

the last step following since $L(q)$ is even in q.

Electronic Conduction in Polar Semiconductors

By B. DURNEY
Department of Theoretical Physics, University of St. Andrews, Scotland

Communicated by R. B. Dingle; MS. received 22nd March 1961,
in revised form 7th June 1961

Abstract. The Boltzmann equation for polar semiconductors is solved formally as a series expansion. The form of the collision operator used is that derived by Howarth and Sondheimer. The method of solution is based on an iteration procedure analogous to Neumann's series solution for an integral equation. The solution has been computed numerically as a function of electron-energy–phonon-energy for certain typical combinations of values of the temperature and degeneracy parameters. Guided by these ' control solutions ' algebraic equations are derived which approximate to the Boltzmann equation in important limiting cases. From these algebraic equations the conductivity and the thermoelectric power are deduced.

§ 1. INTRODUCTION

THE distinctive feature of the electronic conduction phenomena in polar semiconductors is the predominant role played by the optical branch of the lattice vibrations in scattering conduction electrons. As a first approximation these vibrations can be treated as having a common frequency ν_0. In this limit the Boltzmann integral equation reduces to a second-order finite difference equation. Howarth and Sondheimer (1953) have shown how this difference equation can be solved, in successive approximations, using a variational principle. Delves (1959) has obtained some accurate numerical values of transport coefficients by numerical integration of the Boltzmann equation.

In the present paper the problem is re-examined along the following lines. The Boltzmann difference equation, for each of the two formal times of relaxation (Dingle 1956), can be considered as the limit of an integral equation when the vibrational spectrum of the polarization waves tends to a delta function. This suggests that the relevant solutions of the difference equations can be defined as the limit of appropriate Neumann series. Such definition avoids the difficulty that the solution of the difference equation itself is not unique; the general solution being $w_1u_1 + w_2u_2 + v$, where u_1 and u_2 are a fundamental system of solutions of the homogeneous equation, w_1 and w_2 are arbitrary functions of appropriate period and v is a particular solution of the complete equation (cf. Milne-Thompson 1960).

A digital computer has been used to calculate this solution to the Boltzmann equation for combinations of values of the temperature and degeneracy parameters typical of the cases of (i) no degeneracy, high temperatures, (ii) no degeneracy, low temperatures, (iii) degeneracy, high temperatures, (iv) degeneracy, low temperatures. Guided by these ' control solutions ', it is possible to simplify the difference equation and thereby obtain approximate solutions in closed algebraic form. (The results could, of course, be further improved in accuracy by successive approximations.) The results obtained reduce to well-known ones whenever the two formal times of relaxation turn out to be slowly varying functions; this is to be expected, for in these circumstances the precise form of the trial function inserted in the variational principle is not critical. However there is marked disagreement when the two formal times of relaxation are rapidly varying functions, as in the degenerate limit at low temperatures.

§ 2. Formal Solutions of the Difference Equations

2.1. *General Considerations*

It is convenient for the present purposes to express the electrical conductivity and thermoelectric effects in the following notation:

$$\sigma=e^2K_1,\quad \mathscr{G}=(K_2-\zeta K_1)/K_1T \qquad \ldots\ldots(2.1)$$

where

$$K_1=-\frac{8Ma^3\nu_0{}^3}{3e^4}\int_0^\infty \xi^{3/2}\tau_1(\xi)\,\frac{\partial f_0}{\partial\xi}\,d\xi,$$

$$K_2=-\frac{8Ma^3\nu_0{}^4h}{3e^4}\int_0^\infty \xi^{3/2}\tau_2(\xi)\,\frac{\partial f_0}{\partial\xi}\,d\xi. \qquad \ldots\ldots(2.2)$$

Here M is the reduced mass of the ions, a is the interionic distance, $\xi=E/h\nu_0$, where E is the electron energy and $h\nu_0$ the optical phonon energy, ζ is the Fermi energy level and $f_0=1/\{\exp[(h\nu_0\xi-\zeta)/kT]+1\}$ is the Fermi function. The two formal times of relaxation, $\tau_r(\xi)$ with $r=1, 2$, satisfy the following finite difference equations

$$\begin{aligned}\xi^{r-1/2}=\;&\frac{(N+1)f_0\{h\nu_0(\xi+1)\}}{f_0(h\nu_0\xi)}\,[\tau_r(\xi)\sinh^{-1}\xi^{1/2}\\&-\tau_r(\xi+1)\{(1+\tfrac{1}{2}\xi^{-1})\sinh^{-1}\xi^{1/2}-\tfrac{1}{2}(1+\xi^{-1})^{1/2}\}]\\&+h(\xi-1)\,\frac{Nf_0\{h\nu_0(\xi-1)\}}{f_0(h\nu_0\xi)}\,[\tau_r(\xi)\cosh^{-1}\xi^{1/2}\\&-\tau_r(\xi-1)\{(1-\tfrac{1}{2}\xi^{-1})\cosh^{-1}\xi^{1/2}-\tfrac{1}{2}(1-\xi^{-1})^{1/2}\}]\end{aligned} \qquad \ldots\ldots(2.3)$$

where $N=1/\{\exp(h\nu_0/kT)-1\}$ and $h(\xi-1)$ is the step function defined by $h(\xi-1)=0$ for $\xi<1$, $h(\xi-1)=1$ for $\xi\geqslant 1$. If $\tau_2(\xi)=\xi\tau_1(\xi)$, a universal time of relaxation can be defined by $\tau=Ma^3(h\nu_0)^{3/2}\tau_1/\{2\pi e^4(2m)^{1/2}\}$; the integrals (2.2) are easily seen to go over into their usual expressions for this case.

With

$$f_+(\xi)=\frac{(N+1)f_0\{h\nu_0(\xi+1)\}}{f_0(h\nu_0\xi)},\quad f_-(\xi)=\frac{Nf_0\{h\nu_0(\xi-1)\}}{f_0(h\nu_0\xi)} \qquad \ldots\ldots(2.4)$$

$$D(\xi)=f_+(\xi)\sinh^{-1}\xi^{1/2}+h(\xi-1)f_-(\xi)\cosh^{-1}\xi^{1/2},$$
$$\xi^{r-1/2}/D(\xi)=d_r(\xi) \qquad \ldots\ldots(2.5)$$

$$k_+(\xi)=(1+\tfrac{1}{2}\xi^{-1})\sinh^{-1}\xi^{1/2}-\tfrac{1}{2}(1+\xi^{-1})^{1/2}$$
$$k_-(\xi)=(1-\tfrac{1}{2}\xi^{-1})\cosh^{-1}\xi^{1/2}-\tfrac{1}{2}(1-\xi^{-1})^{1/2} \qquad \ldots\ldots(2.6)$$

$$K_+(\xi)=f_+(\xi)k_+(\xi)/D(\xi),\quad K_-(\xi)=f_-(\xi)k_-(\xi)/D(\xi). \qquad \ldots\ldots(2.7)$$

(2.3) can be written

$$\tau_r(\xi)-K_+(\xi)\tau_r(\xi+1)-h(\xi-1)K_-(\xi)\tau_r(\xi-1)=d_r(\xi). \qquad \ldots\ldots(2.8)$$

2.2. *The First Order Difference Equation*

All the essential features of the solution are present in the first-order difference equation obtained from (2.8) for $\xi < 1$ and $r = 1$

$$\tau(\xi) - \left\{\frac{k_+(\xi)}{\sinh^{-1}\xi^{1/2}}\right\}\tau(\xi+1) = \frac{\xi^{1/2}}{f_+(\xi)\sinh^{-1}\xi^{1/2}} = f(\xi) \qquad \ldots\ldots(2.9)$$

and thus, this equation will be dealt with first.

Consider the set of integral equations

$$\tau_y(\xi) - \int_0^\infty K_y(x, \xi)\tau_y(x)\,dx = f(\xi) \qquad \ldots\ldots(2.10)$$

where $K_y(x, \xi) \to \{k_+(\xi)/\sinh^{-1}\xi^{1/2}\}\delta\{x-(\xi+1)\}$ for $y \to \infty$. The limit of these integral equations is the difference equation (2.9).

If the Neumann's series is absolutely and uniformly convergent the solution of (2.10) will be given by

$$\tau_y(\xi) = f(\xi) + \int_0^\infty K_y(x, \xi)f(x)dx + \int_0^\infty\int_0^\infty K_y(x,t)K_y(t, \xi)f(x)dtdx + \ldots$$

For $y \to \infty$ $\qquad \ldots\ldots(2.11)$

$$\tau_y(\xi) \to \tau(\xi) = f(\xi) + \frac{k_+(\xi)}{\sinh^{-1}\xi^{1/2}}f(\xi+1)$$

$$+ \frac{k_+(\xi)k_+(\xi+1)}{\sinh^{-1}\xi^{1/2}\sinh^{-1}(\xi+1)^{1/2}}f(\xi+2) + \ldots \qquad \ldots\ldots(2.12)$$

which is a solution of (2.9). The proof that (2.12) is convergent presents no difficulty. Comparison of (2.12) with the general solution of a first-order difference equation (cf. Milne-Thomson 1960, p. 329) shows that it is determined by assigning the value ∞ to the arbitrary constant and 0 to the arbitrary periodic function.

2.3. *The Second Order Difference Equations*

The same method can be applied to the second-order difference equations (2.8). In a symbolic notation the solutions can be written

$$\tau_r(\xi) = d_r(\xi) + [K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]d_r(\xi)$$

$$\ldots + [K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]^n d_r(\xi) + \ldots \qquad \ldots\ldots(2.13)$$

where $0_+F(\xi) = F(\xi+1)$ and $0_-F(\xi) = F(\xi-1)$, $F(\xi)$ being an arbitrary function of ξ.

$[K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]^n d_r(\xi)$ is thus defined by

$$[K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]^{n-1}[K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]d_r(\xi)$$

and

$$[K_+(\xi)0_+ + h(\xi-1)K_-(\xi)0_-]d_r(\xi) =$$

$$K_+(\xi)d_r(\xi+1) + h(\xi-1)K_-(\xi)d_r(\xi-1).$$

The properties of the series (2.13) can best be visualized by the use of a graphical representation. If we plot the integers on the x axis and ξ on the y axis, $K_+(\xi)$ is represented by a line joining (p, ξ) and $(p+1, \xi+1)$ and $K_-(\xi)$ by a line joining (p, ξ) and $(p+1, \xi-1)$, where p is an arbitrary integer. Thus every term of the series (2.13) has a definite corresponding path, as seen in Fig. 1, where the terms $K_-(\xi)K_-(\xi-1)K_+(\xi-2)K_+(\xi-1)K_-(\xi)K_+(\xi-1)d_r(\xi)$ and $K_+(\xi)K_+(\xi+1)K_+(\xi+2)K_+(\xi+3)K_-(\xi+4)d_r(\xi+3)$ have been represented. It is clear that the terms in $d_r(\xi)$ contain $2n(n=0, 1, 2, \ldots)$ products of the form $K_+(\xi')K_-(\xi'+1)$. On the other hand the terms in $d_r(\xi+p)$ contain p unpaired

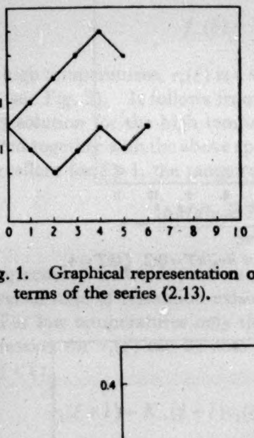

Fig. 1. Graphical representation of terms of the series (2.13).

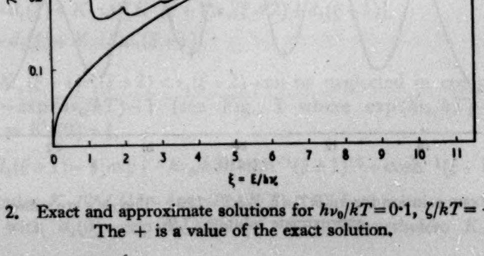

Fig. 2. Exact and approximate solutions for $h\nu_0/kT=0{\cdot}1$, $\zeta/kT=-20$. The + is a value of the exact solution.

$K_+(\xi')$. These facts suggest how the convergence of the series (2.13) can be established; it is sufficient to find an upper limit small enough for $K_+(\xi')K_-(\xi'+1)$ and $K_+(\xi')$. This topic is further discussed in the Appendix.

Values of $\tau_1(\xi)$ for some typical cases have been calculated with the help of a digital computer; these are plotted in Figs 2 to 5. For low temperatures the main feature of these curves is a strong oscillation with period one.

For high temperatures the oscillations rapidly disappear with increasing ξ and, for large ξ, $\tau_1(\xi)$ tends to a universal relaxation time.

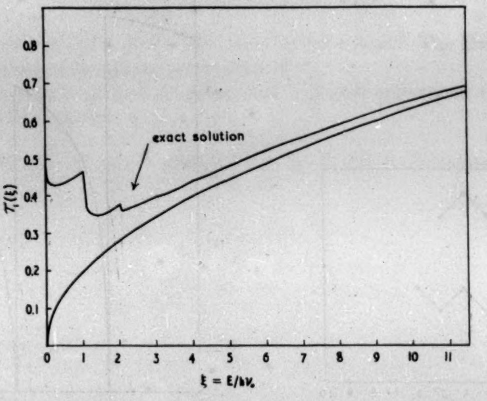

Fig. 4. Exact and approximate solutions for $h\nu_0/kT = 0{\cdot}2$, $\zeta/kT = 4$.

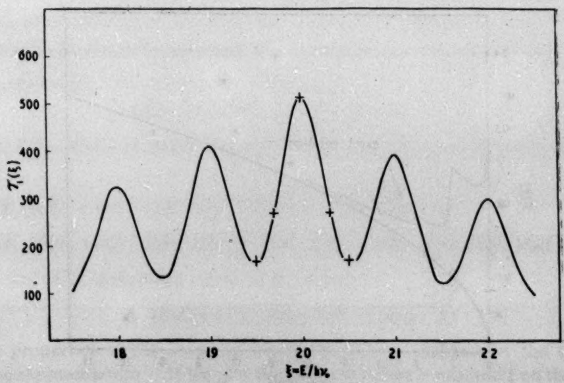

Fig. 5. Exact solution for $h\nu_0/kT = 6$, $\zeta/kT = 120$. The +'s are values of the approximate solution (3.9).

§ 3. LIMIT EXPRESSIONS FOR THE CONDUCTIVITY

3.1. *The Non-degenerate Limit*

The conductivity in this case is given by

$$\sigma = \frac{8Ma^3\nu_0{}^4h\exp(\zeta/kT)}{3e^2kT}\int_0^\infty \tau_1(\xi)\xi^{3/2}\exp(-h\nu_0\xi/kT)\,d\xi. \qquad \ldots\ldots(3.1)$$

If the variation of $\tau_1(\xi)$ with ξ is neglected the integrand has a maximum for $\xi = 3kT/2h\nu_0$; this suggests that at high temperatures only values of $\xi \gg 1$ contribute significantly to the conductivity, whereas at low temperatures only the range $\xi \ll 1$ is important. These conclusions are indeed confirmed by the resultant expressions.

As $-\zeta/kT$ is large and positive,

$$f_+(\xi) \sim (N+1)\exp(-h\nu_0/kT)$$

and

$$f_-(\xi) \sim N\exp(h\nu_0/kT).$$

For high temperatures, $\tau_r(\xi)$ is a slowly varying function of ξ for moderate values of ξ (see Fig. 2). It follows from (2.3) that $\tau_r(\xi) \sim \xi^{r-1/2}/(N+\frac{1}{2})$. In Fig. 2 the exact solution for the high temperature case $h\nu_0/kT = 0{\cdot}1$, $\zeta/kT = -20$ has been plotted together with the above approximate expression, both for $r = 1$; agreement is excellent for $\xi \gg 1$, the range required. By (3.1) the conductivity is

$$\sigma = \frac{16Ma^3\nu_0k^2T^2\exp(\zeta/kT)}{3e^2h^2}\{\exp(h\nu_0/kT) - 1\} \qquad \ldots\ldots(3.2)$$

in agreement with Howarth and Sondheimer's result. As $\tau_2(\xi) = \xi\tau_1(\xi)$, a universal time of relaxation exists in this case.

For low temperatures only the range $\xi \ll 1$ is important and an approximate expression for $\tau_1(\xi)$ can be obtained from the following relations (cf. 2.8) valid for $\xi < 1$:

$$\begin{aligned} \tau_1(\xi+1) - K_+(\xi+1)\tau_1(\xi+2) - K_-(\xi+1)\tau_1(\xi) &= d_1(\xi+1) \\ \tau_1(\xi) - K_+(\xi)\tau_1(\xi+1) &= d_1(\xi). \qquad \ldots\ldots(3.3) \end{aligned}$$

Eliminating $\tau_1(\xi+1)$,

$$\begin{aligned} \tau_1(\xi)[1 - K_+(\xi)K_-(\xi+1)] &\\ &= d_1(\xi) + K_+(\xi)[K_+(\xi+1)\tau_1(\xi+2) + d_1(\xi+1)] \\ &\sim d_1(\xi) + K_+(\xi)d_1(\xi+1) \qquad \ldots\ldots(3.4) \end{aligned}$$

since $K_+(\xi)K_+(\xi+1)\tau_1(\xi+2) < \tau_1(\xi+2)$ can be neglected in comparison with $d_1(\xi) \sim d_1(0) \sim \exp(h\nu_0/kT) - 1$ (see Fig. 3 where $\exp(h\nu_0/kT) - 1 = 22025$). For small ξ, as $K_+(0) = \frac{2}{3}$,

$$K_+(\xi)d_1(\xi+1) \sim \tfrac{2}{3}[\exp(-h\nu_0/kT)\sinh^{-1}(\xi+1)^{1/2} + \cosh^{-1}(\xi+1)^{1/2}]^{-1}$$

and in particular $K_+(0)d_1(1) \sim \frac{3}{4}\exp(h\nu_0/kT)$. This latter term is not small in comparison with $d_1(0) \sim \exp(h\nu_0/kT)$ (cf. 3.4). Nevertheless $K_+(\xi)d_1(\xi+1)$

decreases rapidly with the increase of $\cosh^{-1}(\xi+1)^{1/2}$ and for not too small values of ξ, $K_+(\xi)d_1(\xi+1)$ can be neglected. The rapid decrease of $K_+(\xi)d_1(\xi+1)$ can be appreciated from the following figures:

$$(h\nu_0/kT=10,\ \zeta/kT=-20,\ d_1(\xi)\sim d_1(0)\sim 22025)$$

ξ	0	10^{-5}	10^{-4}	10^{-1}
$\tau_1(\xi)$	44046	22235	22093	23340.

To calculate the conductivity the further approximation

$$\tau_1(\xi)\sim d_1(0)\sim \exp(h\nu_0/kT)-1$$

can be made as only small values of ξ make a significant contribution. Thus

$$\sigma=\frac{2\pi^{1/2}a^3(\nu_0 kT)^{3/2}}{e^2h^{3/2}}\{\exp(h\nu_0/kT)-1\}\exp(\zeta/kT) \qquad \ldots\ldots(3.5)$$

in agreement with Howarth and Sondheimer's expression.

The same approximations are valid for $\tau_2(\xi)$, resulting in

$$\tau_2(\xi)\sim d_2(\xi)\sim \xi\{\exp(h\nu_0/kT)-1\}\sim\xi\tau_1(\xi)$$

and again a universal time of relaxation exists.

3.2. *The Degenerate Limit*

For simplicity only the case $g=\zeta/h\nu_0\gg 1$ will be considered.

For high temperatures $\tau_r(\xi)\sim\xi^{r-1/2}/(N+\frac{1}{2})\sim\xi^{r-1/2}\{\exp(h\nu_0/kT)-1\}$ is a valid approximation as in the non-degenerate case. In Fig. 4, $\xi^{1/2}/(N+\frac{1}{2})$ has been plotted together with the exact solution for $h\nu_0/kT=0{\cdot}2$, $\zeta/kT=4$. Agreement is good for $\xi\gg 1$. Inserting $\tau_1(\xi)\sim\xi^{1/2}\{\exp(h\nu_0/kT)-1\}$ in the expression (2.2) for the conductivity

$$\begin{aligned}\sigma &\sim -\frac{8Ma^3\nu_0{}^3\{\exp(h\nu_0/kT)-1\}}{3e^2}\int_0^\infty \xi^2\frac{\partial f_0}{\partial\xi}\,d\xi\\ &\sim \frac{8Ma^3\nu_0\zeta^2\{\exp(h\nu_0/kT)-1\}}{3e^2h^2}\\ &\sim \frac{8Ma^3\nu_0{}^2\zeta^2}{3e^2hkT} \qquad \ldots\ldots(3.6)\end{aligned}$$

in agreement with Howarth and Sondheimer's result.

In the limit of low temperatures the integrals (2.2) need only to be evaluated between for example $g-\frac{1}{2}$, and $g+\frac{1}{2}$, since $\partial f_0/\partial\xi$ has a sharp maximum for $\xi=g$. An approximate expression for $\tau_r(\xi)$, in this region, can be obtained from the following relations (cf. 2.8).

$$\begin{aligned}\tau_r(\xi+1)-K_+(\xi+1)\tau_r(\xi+2)-K_-(\xi+1)\tau_r(\xi)&=d_r(\xi+1)\\ \tau_r(\xi)-K_+(\xi)\tau_r(\xi+1)-K_-(\xi)\tau_r(\xi-1)&=d_r(\xi) \qquad \ldots\ldots(3.7)\\ \tau_r(\xi-1)-K_+(\xi-1)\tau_r(\xi)-K_-(\xi-1)\tau_r(\xi-2)&=d_r(\xi-1).\end{aligned}$$

For large values of $h\nu_0/kT$ the following relations hold (with $X=\exp[(h\nu_0\xi-\zeta)/kT]$)

$$K_+(\xi)\sim\frac{k_+(g)}{(1+X)\sinh^{-1}g^{1/2}},\qquad K_-(\xi)\sim\frac{k_-(g)}{(1+X^{-1})\cosh^{-1}g^{1/2}} \quad \ldots\ldots(3.8a)$$

$$K_+(\xi-1)\sim k_+(g)/\sinh^{-1}g^{1/2},\qquad K_-(\xi+1)\sim k_-(g)/\cosh^{-1}g^{1/2} \quad \ldots\ldots(3.8b)$$

$$d_r(\xi)\sim\frac{\xi^{r-\frac{1}{2}}\exp(h\nu_0/kT)}{(1+X)(1+X^{-1})\sinh^{-1}\xi^{1/2}},\ K_+(\xi+1)\sim K_-(\xi-1)\sim 0 \quad \ldots\ldots(3.8c)$$

$$d_r(\xi-1)\sim\frac{(\xi-1)^{r-\frac{1}{2}}(1+X)}{\sinh^{-1}(\xi+1)^{1/2}},\qquad d_r(\xi+1)\sim\frac{(\xi+1)^{r-\frac{1}{2}}(1+X^{-1})}{\sinh^{-1}(\xi+1)^{1/2}}. \quad \ldots\ldots(3.8d)$$

As $k_+(\xi)/\sinh^{-1}\xi^{1/2}$ and $k_-(\xi)/\cosh^{-1}\xi^{1/2}$ are slowly varying functions of ξ, their values at $\xi=g$ have been taken. Also since ξ is large $\cosh^{-1}\xi^{1/2}/\sinh^{-1}\xi^{1/2}$ has been approximated to one. If the expressions (3.8) are substituted into (3.7) these equations can be solved giving

$$\tau_r(\xi)\sim\frac{\xi^{r-1/2}}{\{1-k^2(g)\}\sinh^{-1}\xi^{1/2}}\left[\frac{\exp(h\nu_0/kT)}{(1+X)(1+X^{-1})}+k(g)(1+X^{-1})\right] \quad \ldots\ldots(3.9)$$

where $k^2(g)=k_+(g)k_-(g)/\{\cosh^{-1}g^{1/2}\sinh^{-1}g^{1/2}\}$. Values of (3.9) are plotted in Fig. 5 for $h\nu_0/kT=6$, $\zeta/kT=120$, and agreement is seen to be excellent.

In this approximation a universal time of relaxation exists since $\tau_2(\xi)=\xi\tau_1(\xi)$.

The main contribution to the conductivity comes from the first term of (3.9). Neglecting the variation of $\xi^2/\sinh^{-1}\xi^{1/2}$ near g, it is found that

$$\sigma=\frac{4Ma^3\nu_0\zeta^2\exp(h\nu_0/kT)}{9e^2h^2\{1-k^2(\zeta/h\nu_0)\}\sinh^{-1}(\zeta/h\nu_0)^{1/2}}. \quad \ldots\ldots(3.10)$$

This result differs markedly from Howarth and Sondheimer's corresponding expression. It is therefore important to calculate the thermoelectric effects explicitly. The thermoelectric power is given by

$$\begin{aligned}\mathscr{G}/k=(K_2-\zeta K_1)/kK_1T&\sim\frac{6}{kg^2T}\left[h\nu_0\int_0^\infty\frac{\xi^3x}{(1+X)^4}\,dx-\zeta\int_0^\infty\frac{\xi^2x}{(1+X)^4}\,dx\right]\\&=\frac{12kT}{\zeta}\int_{-\infty}^{+\infty}\frac{t^2e^{2t}}{(1+e^t)^4}\,dt \quad \ldots\ldots(3.11)\end{aligned}$$

with $\xi=g+kT\log x/h\nu_0$. The integral K_1, in the denominator of $\mathscr{G}/k$ has been calculated as in the conductivity (cf. 3.10), and in the numerator the variation of $\sinh^{-1}\xi^{1/2}$ near g has been neglected. The integral in (3.11) can be evaluated as follows

$$\begin{aligned}\int_{-\infty}^{+\infty}\frac{t^2e^{2t}}{(1+e^t)^4}\,dt&=\frac{\partial^2}{\partial\alpha^2}\left[\int_{-\infty}^{+\infty}\frac{e^{t(1+\alpha)}}{(1+e^t)^4}\,dt\right]_{\alpha=1}=\left[\frac{\partial^2}{\partial\alpha^2}\int_0^\infty\frac{u^\alpha}{(1+u)^4}\,du\right]_{\alpha=1}\\&=\frac{1}{3!}\frac{\partial^2}{\partial\alpha^2}\Big[\Gamma(\alpha+1)\Gamma(3-\alpha)\Big]_{\alpha=1}=\frac{1}{3}\left(\frac{\pi^2}{6}-1\right). \quad \ldots\ldots(3.12)\end{aligned}$$

The thermoelectric power is then given by

$$\frac{\mathscr{G}}{k}=\frac{4kT}{\zeta}\left(\frac{\pi^2}{6}-1\right). \quad \ldots\ldots(3.13)$$

ACKNOWLEDGMENTS

The author is indebted to Professor R. B. Dingle for many helpful discussions and to Mr. J. Humberston and Dr. B. Pardoe for programming the series (2.13) on the University of London computer.

APPENDIX

It is possible to prove without difficulty that the series (2.13) is convergent, if

$$K_+(\xi) < ab, \text{ with } a < \tfrac{1}{2},\ b < 1 \text{ for large } \xi \qquad \ldots\ldots \text{(A1}a\text{)}$$

$$K_-(\xi)K_+(\xi-1) < c^2 < \tfrac{1}{4} \text{ for } \xi \geqslant 1. \qquad \ldots\ldots \text{(A1}b\text{)}$$

(A1*a*) is immediate, (A1*b*) holds for $\zeta/h\nu_0 < 1$. The proof is somewhat lengthy and will be omitted.

The series (2.13) can be written collecting the terms in $d_r(\xi \pm p)$

$$\tau_r(\xi) = A_{-m}d_r(\xi-m) + A_{-m+1}d_r(\xi-m+1) + \ldots A_0(\xi)d_r(\xi) + \ldots A_pd_r(\xi+p) + \ldots \qquad \ldots\ldots \text{(A2)}$$

where m is the largest integer smaller than ξ. With the help of Stirling's formula the series A_0 is easily seen to be convergent. Comparing A_p with A_0 and using (A1) it can be shown that $A_pd_r(\xi+p) < Cb^pd_r(\xi+p)$, where C is a constant independent of p. (A.2) is thus convergent as $Cb^pd_r(\xi+p)$ is the general term of a convergent series.

The inequalities (A1) are sufficient conditions for the convergence of (2.13), but far from necessary; in fact it seems very likely that this series will always converge.

The Infra-red Faraday Effect in Germanium

By A. K. WALTON and T. S. MOSS
Radio Department, Royal Aircraft Establishment, Farnborough, Hants.

MS. received 5*th May* 1961, *in revised form* 22*nd June* 1961

Abstract. Measurements of the infra-red Faraday effect have been made in n-type, p-type and intrinsic germanium. The Faraday rotations observed are interpreted as being due to free electrons in n-type germanium, valence to conduction band transitions in intrinsic germanium, and light and heavy holes and intervalence band transitions in p-type germanium. The rotations obtained for variously doped n-type specimens are used in conjunction with Hall effect measurements on the same specimens to evaluate the Hall scattering constant as a function of the impurity content. In p-type material the rotations obtained are used to estimate the relative population of the light and heavy hole states.

§ 1. INTRODUCTION

In recent years a great deal of interest has been revived in the Faraday effect. This has occurred because measurements of the infra-red Faraday rotation and Hall coefficient in a suitably doped semiconductor yield accurate values of the effective mass of the free carriers. The first experiments of this nature were carried out by Moss, Smith and Taylor (1959). Their results for variously doped InSb specimens were used to obtain the (E, k) relationship for the conduction band edge of this material. Good agreement was obtained with the theoretical (E, k) curve derived by Kane (1957). The Faraday effect method has subsequently been applied to obtain the effective mass of conduction band electrons in GaAs (Moss and Walton 1959 a), InP (Moss and Walton 1959 b), Ge (Walton and Moss 1959 a) and Bi_2Te_3 (Austin 1960).

The present paper describes a detailed investigation of the infra-red Faraday effect in germanium. In n-type germanium where the electron effective mass is accurately known from alternative (cyclotron resonance) experiments (Dresselhaus, Kip and Kittel 1955, Lax, Zeiger and Dexter 1956), the results are used to evaluate the Hall scattering constant. For intrinsic germanium the rotation has been measured into the absorption edge and a reversal of sign observed. In p-type germanium the observed Faraday rotation is a complex function of the wavelength and is interpreted as being due to light and heavy holes and intervalence band transitions.

A recent paper by Hartmann and Kleman (1960) presents some interesting Faraday results for intrinsic and n-type germanium, but reports no observable rotation in p-type germanium.

§ 2. THEORY

The Faraday effect is the rotation of the plane of polarization of a beam of electromagnetic radiation when a magnetic field is applied along the direction of propagation. The rotation is given by

$$\theta = \frac{\omega l}{2c}(n_R - n_L) \qquad \ldots\ldots(1)$$

where ω is the pulsatance, l the specimen thickness, c the velocity of light and n_R and n_L are the refractive indices for the right and left circularly polarized components into which the plane polarized beam may be resolved. Here, right and left circularly polarized components are defined respectively as the components whose electric vectors describe right and left helices in space at any fixed time. A positive value of θ corresponds to a clockwise rotation for a wave propagated along the direction of the magnetic field away from the observer.

At infra-red wavelengths, the magnetic dispersion for a semiconductor may be due to either free or bound carriers. A simple classical treatment shows that the rotation due to free carriers (Mitchell 1955, Moss 1959) is given by

$$\theta = \frac{e^3 B N \lambda^2 l}{8\pi c^3 \epsilon_0 n (m^*)^2} \qquad \ldots\ldots(2)$$

in rationalized units, provided that

$$\omega^2\tau^2 \gg 1, \quad \omega^2 \gg \omega_c{}^2, \quad k^2 \ll n^2 \qquad \ldots\ldots(3)$$

where N is the carrier concentration, e the electronic charge, B the magnetic induction, λ the wavelength corresponding to pulsatance ω, ϵ_0 the permittivity of free space, n the refractive index, m^* the effective mass, τ the relaxation time, $\omega_c = eB/m^*$, the cyclotron resonance pulsatance, and k the absorption index. The requirements of Eqn (3) are readily met beyond the absorption edge of semiconductors. Thus, in semiconductors, the infra-red free carrier Faraday rotation should be proportional to wavelength squared and the magnetic induction. Such dependences have been verified for several materials. The most important feature of Eqn (2) is, however, that the rotation is inversely proportional to effective mass squared so that the effect provides a potentially accurate method of determining effective mass.

A more detailed treatment of the free carrier Faraday effect by Stephen and Lidiard (1958) starting from the Boltzmann transport equation yields an expression identical to that given in Eqn (2) provided that m^* is interpreted correctly according to the band structure. It should be noted in passing however that the sense of rotation is given incorrectly in their paper. The rotation due to free electrons is clockwise for a wave propagated along the direction of the magnetic field away from the observer (Walton 1960), i.e. is that of the current in the coils which produce the magnetic field. The rotation due to free holes is of course in the opposite sense.

Now the equi-energy surfaces for electrons in the conduction band of germanium are four ellipsoids of revolution along the [111] directions (Dresselhaus *et al.* 1955, Lax *et al.* 1956 and Herman 1955). For such ellipsoidal energy surfaces, whatever the degeneracy of the electrons, the infra-red free carrier Faraday rotation is (Lax and Zwerdling 1960)

$$\theta = \frac{N e^3 B \lambda^2 l}{8\pi^2 c^3 n \epsilon_0} \cdot \frac{K(K+2)}{3 m_l{}^2} \qquad \ldots\ldots(4)$$

where $K = m_l/m_t$ is the ratio of the longitudinal to the transverse effective mass.

In the valence band of germanium there are two types of carrier, that is both light and heavy holes. It readily follows that in this case the infra-red free carrier Faraday rotation is given by

$$\theta = -\frac{e^3 B \lambda^2 l}{8\pi^2 c^3 n \epsilon_0}\left[\frac{p}{m_p^2} + \frac{q}{m_q^2}\right] \qquad \ldots\ldots(5)$$

where q and p are the light and heavy hole concentrations and m_q and m_p are the light and heavy hole masses. The ratio q/p is theoretically equal to the density of states ratio which is $(m_q/m_p)^{3/2}$ so that the few light holes should contribute more than the heavy holes to the free carrier Faraday rotation. The ratio of the contributions of the light and heavy holes is in fact $(m_p/m_q)^{1/2}$ amounting to $\sqrt{8}$ in germanium.

Application of simple classical theory to the bound electrons shows (e.g. Moss 1959) that the rotation due to these electrons is

$$\theta = \frac{N e^3 \omega^2 B l}{2 n c \epsilon_0 (\omega_0{}^2 - \omega^2)^2 m^2} \quad \text{for } \omega \gg \omega_c \qquad \ldots\ldots(6)$$

where ω_0 is the resonant pulsatance of the bound electrons. Thus, in general, infra-red Faraday rotations due to free and bound charges are different functions of wavelength and consequently can be separated.

§ 3. FARADAY EFFECT APPARATUS

The apparatus was developed from that described by Smith *et al.* (1959) and is shown schematically in Fig. 1. Radiation from the source S passed through the polarizer P_1 and was focused by the mirrors M_1 and M_2 on to the germanium specimen situated at the centre of the electromagnetic gap. The source S was

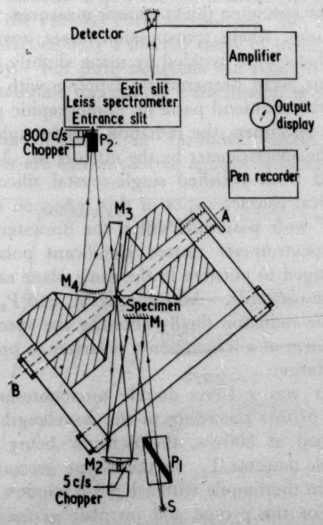

Fig. 1. Schematic diagram of Faraday effect apparatus. (Note that the beam of radiation is deflected in the vertical plane by M_4 on to P_2 which reflects horizontally into the entrance slit of the spectrometer.)

either a tungsten filament lamp with a sapphire window or a Nernst filament according to the wavelength range required. Both sources were suitably stabilized.

A pile of polyethylene plates set at the Brewster angle constituted the polarizing element P_1. Twelve plates each five microns thick were used. With these very thin plates sufficient transmission was obtained between the polyethylene absorption bands to allow Faraday rotations to be measured at selected wavelengths from 13 microns down to 1·5 microns.

The germanium specimen was orientated so that a normal to its surface made an angle of 50° in the horizontal plane with the geometric axis of the magnet. Because of the high refractive index of the germanium, the approximately normally incident radiation was refracted to traverse the specimen accurately normal to its surface. Thus the Faraday rotations observed corresponded to the magnetic field resolved through 50°. The magnet was always used in the saturated condition so that the magnitude of the field was unaltered (by hysteresis) upon reversing its direction. The magnitude of the required resolved component of the magnetic induction was measured directly with the aid of a search coil mounted on the same support that had carried the specimen. In this way the difficulty of measuring the orientation of the specimen with respect to the magnetic axis was avoided. Resolved fields up to 13 000 gauss were used.

For the n- and p-type specimens, the absorption was such that the radiation was considerably attenuated in a single traverse of the specimen thickness. This loss, together with the attenuation at each reflection, meant that multiple internal reflections were negligible and the Faraday rotation appropriate to only a single traverse of the specimen thickness was measured. In the measurements on intrinsic germanium, where transmission losses were rather low, multiple internal reflection effects were avoided by using slightly non-parallel specimens (see § 6). Specimens were prepared by lapping with carborundum powder and then polishing with diamond paste on photographic paper.

After leaving the specimen, the radiation was brought to a second focus at the entrance slit of the spectrometer by the mirrors M_4, M_3 and P_2. P_2 was the analyser, constructed from polished single-crystal silicon set at its Brewster angle. The theoretical characteristics of this reflection analyser show that the polarization for a 10° wide beam incident at the Brewster angle is 99%. Since the optics of the spectrometer caused significant polarization ($\sim 3:1$), the analyser P_2 was arranged to polarize in the same plane as the spectrometer and the polarizer P_1 made rotatable. Accordingly M_4 and P_2 deflected the beam in the vertical plane, the radiation finally entering the spectrometer horizontally. P_1 was made in the form of a transmission polarizer to prevent the image of the source moving on rotation.

The spectrometer was a Leiss double monochromator containing either NaCl, CaF_2 or LiF prisms according to the wavelength range and resolution radiation was chopped at 800 c/s, the detector being either a gold doped focused onto a suitable detector T. In the n-type germanium experiments the detector was a vacuum thermopile with a KRS-6 window and the radiation was chopped at 5 c/s. For the p-type and intrinsic germanium experiments the radiation was chopped at 800 c/s. the detector being either a gold doped germanium or indium antimonide cell cooled to 77°K. The detected signal was amplified, rectified, smoothed and fed to a pen recorder.

Measurements were made by slowly rotating the polarizer P_1 through the crossed position with the magnetic field in a given direction and recording the detected signal. A contact breaker marked every degree on the record. This process was then repeated with the magnetic field reversed. Records of two symmetrical minima were obtained in this way and half the angular difference between the two minima was the required Faraday rotation. The minimum of each record was found in the following way. The mean of the two angles at which the signal had a given value was found for various signal levels at which the signal was changed rapidly with angle and the average value taken as the angle corresponding to the minimum. An accuracy to better than $\pm 0{\cdot}2^\circ$ was obtained by this method.

Measurements of the Faraday rotation were made at room temperature and at 77°K. In the latter case specimens were situated in a demountable liquid nitrogen cryostat which had CaF_2 windows.

§ 4. MEASUREMENT OF CARRIER CONCENTRATION BY FARADAY ROTATION

For semiconductors where the effective mass is known accurately from other magneto-optical experiments, the free carrier Faraday effect provides a new method of determining the carrier concentration N (see Eqn (2)). This method of obtaining N has two advantages over the Hall effect method, namely: (i) The interpretation of the results does not depend on a knowledge of the scattering mechanism since the infra-red free carrier Faraday rotation is independent of scattering. (ii) No electrical contacts are required, which is important since suitable contacts are difficult to provide for many materials.

Disadvantages of the Faraday effect method are: (*a*) The effective mass must be known. (*b*) In practice only a limited range of carrier concentration can be measured in this way. For pure materials the rotation is too small while for extremely impure materials the optical transmission is too low because of the low mobility.

Faraday rotations measured in variously doped single-crystal n-type germanium specimens are shown plotted against wavelength squared in Fig. 2.

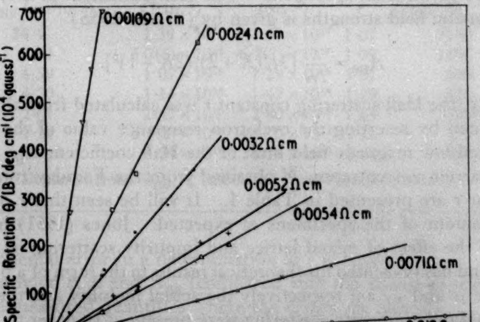

Fig. 2. Faraday rotation in variously doped n-type germanium specimens.

For each specimen, the experimental points fit a straight line through the origin extremely well. The sense of the rotations is that of the current in the coils which produces the magnetic field as expected for free electrons (see §2).

The carrier concentration for each germanium specimen was calculated from the observed Faraday rotation as follows. Rewriting Eqn (4) we have that the carrier concentration in n-type germanium is given by

$$N=\frac{8\pi^2c^3n\epsilon_0(m^*)^2\theta}{e^3B\lambda^2l} \qquad \ldots\ldots(7)$$

where

$$m^*=[3/K(K+2)]^{\frac{1}{2}}m_l. \qquad \ldots\ldots(8)$$

The slopes of the straight lines of Fig. 2 give $\theta/lB\lambda^2$ for each specimen. Now the conduction band of germanium should be parabolic due to the high density of states, so that m^* is a constant, independent of N, and may be calculated from cyclotron resonance data (Dresselhaus *et al.* 1955, Lax *et al.* 1956) to be $0{\cdot}134m$. Using the refractive index data of Salzberg and Villa (1958) with allowance for free carrier dispersion, it is found that $n=3{\cdot}99$ for the doped germanium of the present experiment over the wavelength range involved. Values obtained for the carrier concentration N on inserting the above data into Eqn (7) are given in Table 1.

These experiments show that the Faraday effect method of determining N is practicable in germanium over the range $N=10^{16}$–$10^{19}\,\text{cm}^{-3}$. The higher concentrations of this range are difficult to determine by the Hall effect method since the Hall voltages are very small and the Hall scattering constant is particularly difficult to evaluate theoretically when neither the non-degenerate nor the degenerate statistical approximation applies to the conduction band electrons.

§ 5. DETERMINATION OF THE HALL SCATTERING CONSTANT IN n-TYPE GERMANIUM

In addition to measuring N by the Faraday effect method described above, measurements of the low field Hall coefficient and resistivity were made on the same n-type germanium specimens. The Hall coefficient in n-type germanium at low magnetic field strengths is given by (Brooks 1955)

$$A_{\mathrm{H0}}=\frac{r}{Ne}[3K(K+2)/(2K+1)^2]. \qquad \ldots\ldots(9)$$

Accordingly, the Hall scattering constant r was calculated from this equation for each specimen by inserting the cyclotron resonance value of the mass ratio K, the measured low magnetic field limit of the Hall coefficient A_{H0} and the corresponding carrier concentration N obtained from the Faraday rotation. Values obtained for r are presented in Table 1. It will be seen that r depends on the impurity content of the specimens as expected. Jones (1951) has treated the problem of the effect of mixed lattice and impurity scattering on the scattering constant r and has presented his theoretical results in the form of a plot of r against μ/μ_{I}, where μ and μ_{I} are respectively the actual mobility and the mobility that would arise if only impurity scattering were present. In order to facilitate comparison of the present experimental results with the theory of Jones, the parameter μ/μ_{I} has been evaluated for each specimen. The mobility μ was calculated from the carrier concentration N and the measured resistivity. Now the mobility μ_L, when scattering is by lattice vibrations only, is known to be $3800\,\text{cm}^2\,\text{sec}^{-1}\,\text{v}^{-1}$ from drift experiments (Prince 1953) on near intrinsic germanium. Thus μ/μ_L was known and μ/μ_I found from the theoretical curve of Conwell (1952).

Figure 3 shows the experimental values of r plotted against μ/μ_I, together with the theoretical curve of Jones. It will be seen that Jones's theory fits the experimental results for $\mu/\mu_I < 0{\cdot}5$. At larger values of μ/μ_I it does not fit. However, in his treatment Jones assumed non-degenerate statistics to apply throughout, whereas in germanium at room temperature N exceeds $10^{19}\,\text{cm}^{-3}$ when $\mu/\mu_I < 0{\cdot}8$ so that degenerate statistics apply. Thus, at large values of μ/μ_I, r is expected to approach unity somewhat as shown by the broken lines of Fig. 3.

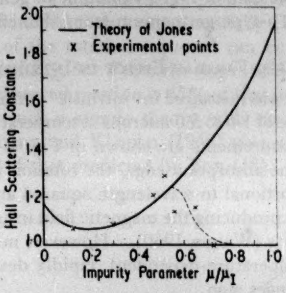

Fig. 3. Hall scattering constant r in n-type germanium as a function of the parameter μ/μ_I.

Table 1. Carrier Concentrations by Faraday and Hall Effect Methods and Values obtained for the Hall Scattering Constant r

Resistivity (ohm cm)	A_{H0} (cm³/c⁻¹)	N/r† (cm⁻³)	N‡ (cm⁻³)	r	μ (cm² sec⁻¹ v⁻¹)	μ/μ_I
0·0180	34·4	$1{\cdot}39\times10^{17}$	$1{\cdot}49\times10^{17}$	1·07	2330	0·13
0·00710	8·54	$5{\cdot}7(5)\times10^{17}$	$6{\cdot}2(7)\times10^{17}$	1·09	1400	0·30
0·00536	4·59	$1{\cdot}07\times10^{18}$	$1{\cdot}29\times10^{18}$	1·21	900	0·47
0·00519	4·30	$1{\cdot}14\times10^{18}$	$1{\cdot}47\times10^{18}$	1·29	820	0·52

0·00109	0·368	$1{\cdot}34\times10^{19}$	$1{\cdot}34\times10^{19}$	1·00	430	0·73

† Calculated from A_{H0}; ‡ calculated from Faraday rotation.

The experimental error in a determination of r is approximately $\pm 6\%$ since r depends linearly on θ, B and A_{H0} (compared with the square root dependence of m^* on these measured quantities where the errors are halved).

Another way of determining the scattering constant r is from the low and high magnetic field limits of the Hall coefficient which are given by:

$$A_{H0} = \frac{r}{Ne}\,\frac{3K(K+2)}{(2K+1)^2}\,; \quad A_{H\infty}\,\frac{1}{Ne}$$

so that

$$A_{\mathrm{H}0}/A_{\mathrm{H}\infty} = \frac{3K(K+2)r}{(2K+1)^2}. \qquad \ldots\ldots(10)$$

Geballe and Kunzler (1959) have measured the ratio $A_{\mathrm{H}0}/A_{\mathrm{H}\infty}$ accurately for 20 Ω cm n-type germanium at 77°K and have obtained $r = 1{\cdot}16$ in close agreement with the theoretical value of $3\pi/8$. To determine $A_{\mathrm{H}\infty}$ a magnetic field strength H is required such that $\mu H \gg 1$. Thus to find r by this method for highly doped n-type germanium, where the mobility is low owing to impurity scattering, inconveniently high magnetic fields would be required. This method and the Faraday rotation method of finding r are thus complementary, the former being applicable to pure materials and the latter to impure.

It is suggested that the data of Fig. 3 should be of general use in determining carrier concentrations in n-type germanium from Hall effect measurements.

§ 6. THE INFRA-RED FARADAY EFFECT IN INTRINSIC GERMANIUM

The Faraday rotation was measured in 'intrinsic' germanium (60Ω cm p-type) over the wavelength range of 1·6 to 5·0 microns at temperatures of 300°K and 77°K. The results of these measurements are shown in Fig. 4. At wavelengths long compared with that of the absorption edge, the rotation is independent of temperature, inversely proportional to wavelength squared and is in the same sense as the current in the coils producing the magnetic field in agreement with classical theory for bound electrons (Walton 1960). However, near the absorption edge the rotation becomes temperature-dependent, rapidly deviates from the inverse square law and soon changes sign.

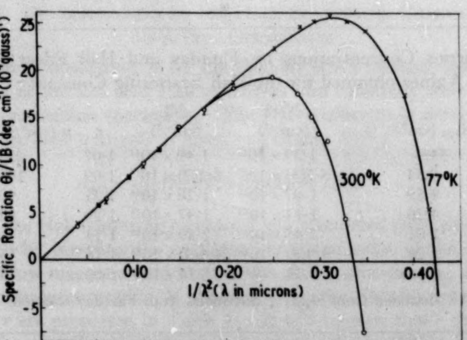

Fig. 4. Faraday rotation in intrinsic germanium at 300°K and 77°K.

The specimens used in these measurements on intrinsic germanium were deliberately made slightly non-parallel (an angle of 1° between transmitting faces) to avoid multiple internal reflection effects. In plane parallel specimens, where multiply reflected components were detected, rotations were about 13% larger than in the non-parallel specimens. Calculations show that the rotation can be as much as 23% too large.

In the original classical treatment, it was shown by Becquerel (1897) that the specific rotation is

$$\frac{\theta}{lB} = -\frac{e\lambda}{2mc}\frac{dn}{d\lambda} \qquad \ldots\ldots(11)$$

where $dn/d\lambda$ is the dispersion in the absence of the magnetic induction B and m is the free electron mass. This equation may be rewritten

$$\frac{\theta}{lB} = \frac{e}{mc\lambda^2}\frac{dn}{d(1/\lambda^2)}. \qquad \ldots\ldots(12)$$

Now at wavelengths long compared with that of the absorption edge, $dn/d(\lambda^{-2})$ is a constant in germanium, as shown by the data of Salzberg and Villa (1958) which are plotted in Fig. 5. Thus this theory predicts that the specific rotation should vary as λ^{-2}, as is indeed found experimentally (Fig. 4). Furthermore, the absolute magnitude of the rotation expected can be found from Eqn (12) using the dispersion data of Fig. 5. From the slopes of the straight lines in Figs 4 and 5 we find that the observed rotation is 65% of that predicted—a remarkable degree of agreement for such a simple theory with no adjustable parameters. Recent results by Hartmann and Kleman (1960) give a similar figure, namely that the rotation is 60% of that predicted by Eqn (12).

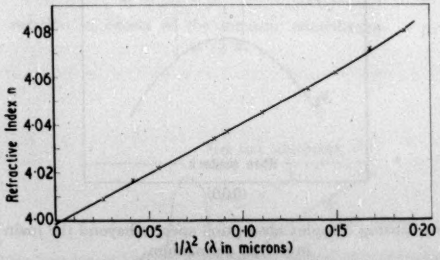

Fig. 5. Dispersion in intrinsic germanium (Salzberg Villa 1958).

The dispersion has not been measured accurately at wavelengths below 2·3 μ. However by using the fact that the refractive index and absorption are interrelated (Moss 1959) it can be shown that n will reach a maximum in the neighbourhood of the absorption edge and then fall. Thus the dispersion, and hence the Faraday rotation, should fall to zero and then become negative. Since the absorption edge shifts to shorter wavelengths on cooling, the Faraday rotation is expected to change sign at shorter wavelengths for the cooled material.

This simple classical dispersion theory is seen to give good qualitative (and reasonable quantitative) explanations of the rotation due to bound charges. A full theoretical treatment of the intrinsic effect would need to consider virtual transitions between quantized energy levels in the region of the band edge. This type of treatment has been outlined by Lax and Zwerdling (1960) but it has not yet been developed to the state where it can explain the form and magnitude of the observed behaviour.

§ 7. The Infra-red Faraday Effect in p-type Germanium

The infra-red Faraday rotation was measured in p-type germanium both at room temperature and at 77°K. Plane parallel specimens of 0·0278 and 0·0100 Ω cm resistivity were used and the measurements extended over the wavelength range of 2 to 6·3 microns, that is, right through the absorption bands (Briggs and Fletcher 1953, Kaiser *et al.* 1953) at 3·5 and 4·5 microns due to intervalence band transitions $h\nu_{13}$ and $h\nu_{23}$ (see Fig. 6). In the room temperature measurements the specimens were sufficiently opaque to avoid multiple internal reflection effects. However in the case of the results at 77°K, the measured rotations have been reduced by 13% at wavelengths where the specimen was transparent, to allow for multiple reflections.

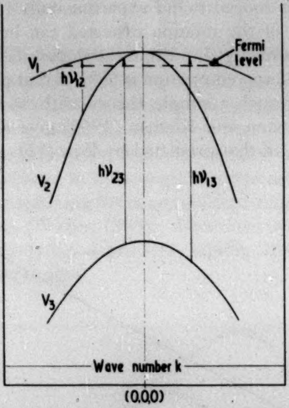

Fig. 6. Transitions causing complex absorption spectra beyond the main absorption edge in p-type germanium.

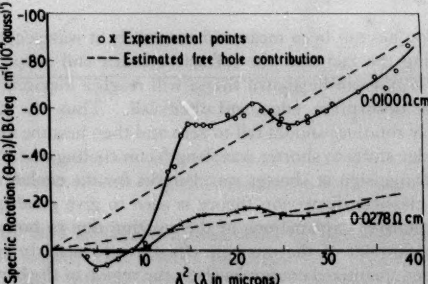

Fig. 7. Faraday rotation in excess of the intrinsic contribution in p-type germanium at 300°K.

In order to eliminate the bound carrier rotation associated with transitions between the valence and conduction bands, the rotation in intrinsic germanium (the measurements of which are described in § 6) was subtracted from the rotation obtained in each p-type specimen. Figs 7 and 8 show the resulting rotations plotted against wavelength squared. In each case the rotation is a complicated function of wavelength but is of the sign expected for a rotation due to free holes, i.e. is in the *opposite* sense to that of the current in the coils which produce the magnetic field.

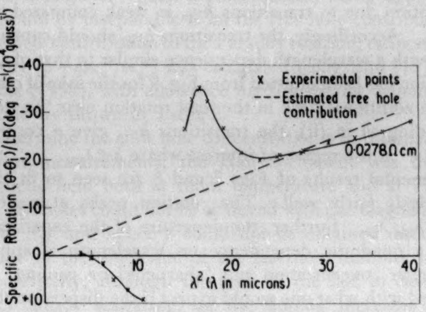

Fig. 8. Faraday rotation in excess of the intrinsic contribution in p-type germanium at 77°K.

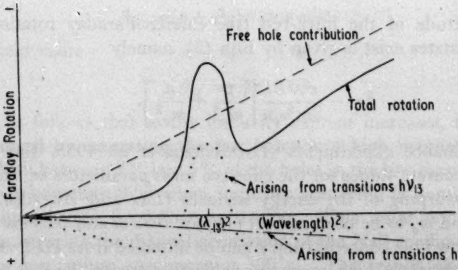

Fig. 9. Theoretical wavelength dependence of the infra-red Faraday rotation in excess of the intrinsic contribution in p-type germanium.

The rotation shown in Figs 7 and 8 is interpreted as arising from free holes and intervalence band transitions. It is suggested that the theoretical wavelength dependence of the rotation in p-type germanium in excess of that in intrinsic germanium should be of the form shown by the continuous line of Fig. 9. The broken lines show the various contributions:

(i) The free hole contribution which will be proportional to wavelength squared.

(ii) The contribution arising from the dispersion associated with the transition $h\nu_{13}$. The wavelength dependence of this contribution has been taken as that of the dispersion associated with a classical oscillator centred at the frequency ν_{13}. In §6, this technique has been shown to give reasonable results when applied to the valence to conduction band transitions in germanium. It follows that, well below the resonant wavelength λ_{13}, the rotation is directly proportional to λ^2 whilst at wavelengths long compared with λ_{13}, the rotation is inversely proportional to λ^2. The sign of this contribution has been taken to be the same as that of the rotation due to valence to conduction band transitions in germanium.

(iii) Absorption due to transitions $h\nu_{23}$ is weak compared with that due to transitions $h\nu_{13}$. Accordingly, the transitions $h\nu_{23}$ should contribute a relatively small rotation with a wavelength dependence similar to that of (ii) above. This small contribution has been omitted from Fig. 9 for the sake of clarity. However, it may cause an additional peak in the total rotation near the wavelength λ_{23}.

(iv) Proceeding as in (ii), the transitions $h\nu_{12}$ give a contribution roughly proportional to λ^2 in the region of interest where $\lambda \ll \lambda_{12}$.

The experimental results of Figs 7 and 8 are seen to fit the above simple qualitative analysis fairly well. The rotation peaks at wavelengths not far removed from λ_{13}, λ_{23}. Further, the departure of the experimentally observed rotation from a quadratic dependence on wavelength is approximately proportional to carrier concentration and 'sharpens' on cooling. These features are also in accord with what one would expect if the dispersion due to transitions h_{12}, $h\nu_{23}$ could be approximated by that of a classical oscillator.

§ 8. THE RELATIVE POPULATION OF THE FAST AND SLOW HOLE STATES IN p-TYPE GE

The magnitude of the infra-red free carrier Faraday rotation when two occupied hole states exist is given by Eqn (5), namely

$$\theta = -\frac{e^3\lambda^2 Bl}{2\pi c^3\epsilon_0 n}\left[\frac{p}{m_p^{\,2}}+\frac{q}{m_q^{\,2}}\right]. \qquad \ldots\ldots(13)$$

Cyclotron resonance experiments (Dresselhaus *et al.* 1955, Lax *et al.* 1956) have yielded accurate values for the effective mass parameters m_p and m_q. With allowance for warping of the energy surfaces (Lax and Zwerdling 1960), the values of m_p and m_q to be used in Eqn (13) are $0{\cdot}35\,m$ and $0{\cdot}044\,m$ respectively.

Now the slow hole concentration p can be obtained from Hall effect measurements. At sufficiently high magnetic fields to saturate the fast holes but not the slow holes (i.e. when $\mu_q H \gg 1 \gg \mu_r H$ where μ_q and μ_p are the mobilities of the fast and slow holes respectively) the Hall coefficient is given to a good approximation by

$$A_{\mathrm{H}}' = \frac{r}{pe}.$$

Thus a determination of the infra-red free carrier Faraday rotation allows q to be calculated on inserting the values of p, m_p and m_q into Eqn (13). Since the fast holes contribute much more than the slow holes to the free hole Faraday rotation (see §2), this is a potentially accurate method of measuring the relative population q/p of the two occupied hole states.

However, beyond the absorption edge of p-type germanium, the Faraday rotation is not simply proportional to wavelength squared and is composed of contributions due to free holes and intervalence band transitions as discussed in §7. Thus isolation of the free hole contribution required is difficult. Nevertheless, since the interband transitions should produce a negative rotation in the middle of the band (i.e. near λ_{13}, λ_{23}) and a positive rotation outside it, a straight line giving the free hole contribution may be drawn fairly accurately as shown in Figs 7 and 8. It is assumed here that the contribution to the rotation due to transitions $h\nu_{12}$ is negligible. Such a contribution, being approximately proportional to λ^2, would be inseparable from the free hole contribution.

From the free hole contribution to the Faraday rotation, estimated as described above, the quantity $[p+qm_p{}^2/m_q{}^2]$ was calculated using Eqn (13). The data of Salzberg and Villa (1958), with allowance for free carrier dispersion, was taken for n. The results are shown in Table 2.

In order to determine the slow hole concentration p in the specimens used for the Faraday effect measurements, the Hall coefficient was determined as a function of magnetic field both at room temperature and at 77°K. However, saturation of the fast holes could not be achieved with the magnetic field available and consequently $A_H{}'$ and hence p could not be obtained directly. This was thought to be due to the low value of the fast hole mobility in these impure materials. Theoretically, although the ratio of the fast to slow hole mobility $a=m_p/m_q=8$ for lattice scattering, as the doping increases 'a' falls until $a=(m_p/m_q)^{1/2}=2\cdot8$ for impurity scattering (Brooks 1955). Further, the slow hole mobility itself falls as the doping increases.

Now as the magnetic field increases, the Hall coefficient is expected to fall from the low field value of

$$A_{H0}=(p+a^2q)r/(p+aq)^2e \qquad \ldots\ldots(14)$$

to the high field value

$$A_H{}'=r/pe. \qquad \ldots\ldots(15)$$

Since $aq \ll p$, it follows that as the impurity content increases, the fall in Hall coefficient caused by saturating the fast holes in a high magnetic field should decrease. With between 2% and 5% of the holes in the low mass state, $A_H{}'/A_{H0}$ should be approximately 0·95 when impurity scattering is dominant compared with approximately 0·5 for lattice scattering. This point was tested experimentally by measuring the magnetic variation of the Hall coefficient in variously doped p-type germanium specimens at 300°K. The results of these measurements are shown in Fig. 10. It is seen that $A_H{}'/A_{H0}$ is 0·65 for the purest material but as the impurity content increases the change in Hall coefficient on saturating the fast holes decreases. Although actual saturation of the fast holes could not be achieved in the 0·01 Ω cm and 0·0278 Ω cm materials which were used in the Faraday work, it was estimated from the results of Fig. 10 and the theoretical value of $A_H{}'/A_{H0}$ for impurity scattering, that $A_H{}'$ was $0\cdot90A_{H0}$ for the 0·0278 Ω cm at 300°K and $0\cdot95A_{H0}$ at 77°K. For the 0·01 Ω cm material $A_H{}'$ was taken to be $0\cdot95\,A_{H0}$. Clearly $A_H{}'$ is close to A_{H0} in these impure materials, so that errors involved in finding $A_H{}'$ from A_{H0} must be small. Table 2 gives the values obtained in this way for $A_H{}'$ and also the values of p calculated using equation (15) and taking r to be 1·1.

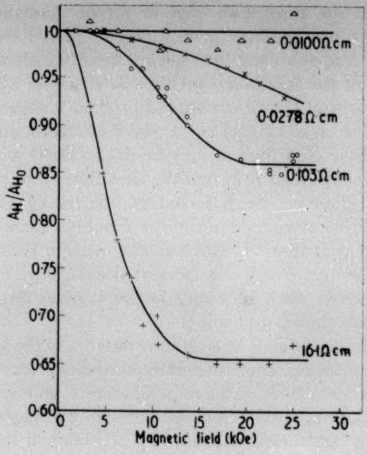

Fig. 10. Magnetic variation of the Hall coefficient in p-type germanium at 300°K.

Table 2. The Relative Population of Light and Heavy Hole States in p-type Germanium calculated from Measurements of the Faraday Rotation and Hall Coefficient

(1)	(2)	(3)	(4)	(5)	(6)	(7)
0·0100	300	$7{\cdot}5\times10^{18}$	5·4	5·1	$1{\cdot}35\times10^{18}$	0·07
0·0278	300	$2{\cdot}1\times10^{18}$	20·0	18·0	$3{\cdot}8\times10^{17}$	0·07
0·0278	77	$2{\cdot}6\times10^{18}$	24·3	23·1	$3{\cdot}0\times10^{17}$	0·12

(1) Specimen resistivity at 300°K (Ω cm); (2) temperature (°K); (3) $p+(m_p/m_q)^2q$ from Faraday rotation (cm^{-3}); (4) A_{H0} (cm^3 coulomb^{-1}); (5) A_H' (cm^3 coulomb^{-1}); (6) p (cm^{-3}); (7) q/p.

The last column of Table 2 gives the ratio of the fast to slow hole concentration obtained by combining columns three and six of the table. Both specimens give $q/p=7\%$ at room temperature. This value is rather large compared with the theoretical estimate of $(m_q/m_p)^{3/2}$ which amounts to about $4\frac{1}{2}\%$, and it appears to increase even further on cooling to 77°K. Galvanomagnetic (Willardson *et al.* 1954) and photomagnetic (Walton and Moss 1959b) experiments have yielded $q/p=2\%$ which is somewhat less than the theoretical estimate.

The values obtained for q/p from the present Faraday and Hall effect experiments are tentative since the interpretation of the Faraday rotation is difficult due to the rotations associated with intervalence band transitions. In the analysis of the results, rotations arising from transitions $h\nu_{12}$ were assumed negligible. However if this contribution to the total rotation is appreciable and of the sign indicated in Fig. 9, the values deduced for q/p are too small! It is possible that the wrong sign has been attributed to the contribution by transitions $h\nu_{12}$. For example, the rotation arising from transitions between the valence and conduction band of InSb is of the correct wavelength dependence but the opposite sign to that of a classical oscillator (Smith *et al.* 1959, Brown and Lax 1959). This difference of sign for the bound carrier contribution is accounted for by the large negative g-factor of the conduction band electron in InSb (Roth *et al.* 1959). Thus it is possible that too large a value of the free hole rotation has been estimated from the experimental data and consequently too large a value of q/p obtained.

In other materials, where absorption bands due to intervalence transitions may lie at more convenient wavelengths, it may well be possible to get accurate values of the relative population of the light and heavy hole states by Faraday and Hall effect measurements as described in this paper.

ACKNOWLEDGMENTS

The authors are indebted to Dr. E. W. J. Mitchell, Reading University, for helpful discussions and to Miss D. Webber and Mr. D. Newberry for assistance with the experiments. Single crystal germanium was kindly supplied by Dr. A. F. Gibson of the Royal Radar Establishment, Mr. S. E. Bradshaw of The General Electric Co. Ltd., and Mr. R. L. Rouse of Associated Electrical Instruments Ltd.

Thermally Stimulated Emission and Conductivity Peaks in the Case of Temperature Dependent Trapping Cross Sections

By P. N. KEATING

Associated Electrical Industries Limited, Harlow Research Laboratory, Essex

MS. received 15*th June* 1961

Abstract. The original theory of thermally stimulated emission is extended to include the effect of a temperature dependent trapping cross section. A method is proposed whereby the ionization energy and temperature dependent capture cross section of a set of identical trapping states may be determined from the half-width and shape of a thermally stimulated emission peak obtained from a single experiment. The method is also applicable to thermally stimulated current peaks if the free electron lifetime varies only slowly with temperature.

§ 1. INTRODUCTION

In recent years investigation of the fundamental properties of phosphors and photoconductors has intensified and methods of studying trapping states and recombination centres have thus gained in importance. The measurements of thermally stimulated emission and current are powerful methods of investigating the properties of trapping centres in these materials.

Since the original theory of Randall and Wilkins (1945), a number of theoretical treatments have been published and several methods of analysis of the two types of peak exist; these methods are discussed in detail in § 6. In the earlier theories, the escape frequency factor (given by the product $N_c S v$ where N_c is the effective density of states in the conduction band, S is the trapping cross section and v is the electron thermal velocity) has been considered as temperature independent; recently Bube (1960) and subsequently Haering and Adams (1960) have considered S to be temperature independent whilst N_c and v vary as $T^{3/2}$ and $T^{1/2}$ respectively.

According to one theoretical model (Lax 1960), S can vary with temperature more rapidly than T^{-3} whilst Bemski (1958) has shown experimentally that the capture of a charge carrier by an oppositely charged gold centre in silicon can have a cross section which varies as T^{-4}. Thus, in general, the assumption that the capture cross section of a trap does not vary with temperature is invalid and the theory which follows is intended to indicate how the temperature dependence of S will affect peaks of thermally stimulated emission or conductivity. The theory is employed to derive a method of analysis of such peaks which will give the ionization energy and temperature dependent cross section of a trapping level.

§ 2. BASIC THEORY

The theory to be described is an extension of the work of Randall and Wilkins (1945) and a brief outline of the basic theory will first be given. The model upon which the theoretical analysis is based consists of a number of discrete trapping levels from which electrons may be thermally excited into the conduction band; recombination of free electrons takes place at deep centres. It is assumed that:

(i) Peaks from different trapping levels do not overlap. Although this is not true in many cases, the peaks may be separated by suitable experimental techniques, e.g. by varying the heating rate or by thermal quenching of the low temperature peak (Hoogenstraaten 1958).

(ii) Transitions directly between trapping states and other centres are negligible.

(iii) The recombination lifetime is so short that $dn_c/dt \ll n_c/\tau$, where n_c is the concentration of electrons in the conduction band. This is almost always a valid assumption for phosphors and photoconductors.

The rate of change of the electron concentration n in a trapping level with an ionization energy E is:

$$\frac{dn}{dt} = -nN_cSv \exp\left(\frac{-E}{kT}\right) + An_c(N-n) \qquad \ldots\ldots(1)$$

where N is the number of states in the level and A is a measure of the retrapping probability.

The rate of change of the electron concentration in the conduction band is

$$\frac{dn_c}{dt} = -\frac{n_c}{\tau} - \frac{dn}{dt}$$

and thus

$$\frac{dn_c}{dT} = -\frac{n_c}{\beta\tau} - \frac{dn}{dT}$$

if $\beta = dT/dt$.

Now since $dn_c/dt \ll n_c/\tau$, as assumed above, then $n_c \simeq -\beta\tau dn/dT$.

Hereafter the theory will be discussed with reference to the emission intensity I but with slight modification it is equally applicable to the conductivity case since the stimulated conductivity is, if μ is the electron mobility,

$$\sigma = n_c e\mu = -e\mu\beta\tau\frac{dn}{dT} = \tau e\mu I$$

since

$$I = \frac{n_c}{\tau} = -\beta\frac{dn}{dT}. \qquad \ldots\ldots(2)$$

It has been assumed that retrapping effects are negligible and it will be shown later that this is a reasonable approximation in most cases. The solution of Eqn (1), with the second term negligible compared with the first, then gives

$$n = n_0 \exp\left\{-\int_{T_0}^{T} \frac{N_cSv}{\beta} \exp\left(-\frac{E}{kT}\right) dT\right\}$$

and thus

$$I = n_0 N_cSv \exp\left\{-\frac{E}{kT} - \int_{T_0}^{T} \frac{N_cSv}{\beta} \exp\left(-\frac{E}{kT}\right) dT\right\}. \qquad \ldots\ldots(3)$$

§ 3. FURTHER ANALYSIS

The trapping cross section S will be taken to be related to temperature by a simple power law as T^{-a} and, for simplicity of analysis, N_cSv is taken to be BT^b

so that $a=2-b$. Thus, from Eqn (3),

$$\ln\left(\frac{I}{I_0}\right)=b\ln T-\frac{E}{kT}-\frac{B}{\beta}\int_{T_0}^{T}T^b\exp\left(-\frac{E}{kT}\right)dT \qquad \ldots\ldots(4)$$

where $I_0=n_0B$ and is temperature independent. A linear temperature increase has been assumed, i.e. $\beta=$ constant.

Differentiation of $\ln(I/I_0)$ with respect to T yields, at the peak temperature T_g,

$$\frac{B}{\beta}=\left(\frac{b}{T_g{}^{b+1}}+\frac{E}{kT_g{}^{b+2}}\right)\exp\left(\frac{E}{kT_g}\right). \qquad \ldots\ldots(5)$$

The integral in Eqn (4) may be evaluated, to a good approximation, by an asymptotic series which gives

$$\int_{T_0}^{T}T^b\exp\left(-\frac{E}{kT}\right)dT\simeq\frac{kT^{b+2}}{E}(1-\Delta)\exp\left(-\frac{E}{kT}\right)$$

where $\Delta=(b+2)kT/E$.

The error involved is less than 3% if $E/kT_g>10$.

Thus Eqn (4) becomes

$$-\ln\left(\frac{I}{I_0}\right)=\frac{E}{kT}-b\ln T+\left(\frac{T}{T_g}\right)^{b+2}\left(1+\frac{bkT_g}{E}\right)(1-\Delta)\exp\left(\frac{E}{kT_g}-\frac{E}{kT}\right). \qquad \ldots\ldots(6)$$

This equation is now applied to the two cases when $I=I_g/2$, i.e. at temperatures T_1, T_2 $(T_1<T_2)$ and is simplified by writing

$$\frac{T_g-T_1}{T_g}=\alpha_1; \quad \frac{T_2-T_g}{T_g}=\alpha_2.$$

Hence

$$\left(1+\frac{bkT_g}{E}\right)(1-\Delta)+\ln 2=-\psi-b\ln(1+x)$$
$$+(1+x)^{b+2}\left(1+bk\frac{T_g}{E}\right)(1-\Delta)\exp(\psi) \qquad \ldots\ldots(7)$$

where x is either $-\alpha_1$ or α_2 and

$$\psi=\frac{E}{kT_g}\left(\frac{x}{1+x}\right).$$

Since $\Delta\ll 1$ for $E/kT>10$, $(b+2)kT_1/E$ and $(b+2)kT_2/E$, have been taken equal to $\Delta=(b+2)kT_g/E$.

Equation (7) has been solved numerically for α_1 and α_2 for values of $b=0$, $+2$, -2 and E/kT_g between 10 and 35, i.e. for values liable to be encountered experimentally. The results are summarized in Figs 1 and 2; analysis of these curves shows that E/kT_g can be accurately related to $\alpha(=\alpha_1+\alpha_2)$ for particular values of the ratio $\alpha_2/\alpha_1=\gamma$ by an equation which is linear in α:

$$\frac{kT_g}{E}=\alpha(1{\cdot}2\gamma-0{\cdot}54)+5{\cdot}5\times10^{-3}-\left(\frac{\gamma-0{\cdot}75}{2}\right)^2. \qquad \ldots\ldots(8)$$

This equation is an accurate description of the variation of kT_g/E with α and γ for values of E/kT_g between 10 and 35 and γ between 0·75 and 0·9 and its validity should extend some way beyond the limits of this range.

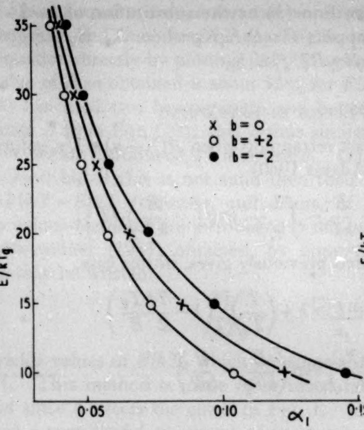

Fig. 1. Variation of E/kT_g as a function of α_1, for $b=0$, $+2$, -2.

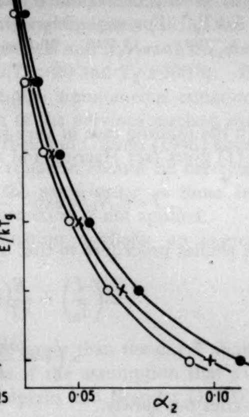

Fig. 2. Variation of E/kT_g as a function of α_2, for $b=0$, $+2$, -2.

§ 4. DETERMINATION OF E, a, S FROM EXPERIMENTAL PEAKS

In order to evaluate the ionization energy and $S=CT^{-a}$, where C is a constant, it is necessary to measure four quantities, the peak temperature T_g, the half-width T_2-T_1, the parameter γ which is $(T_2-T_g)/(T_g-T_1)$, and the heating rate β.

(i) E may be evaluated by substituting α, γ and T_g in Eqn (8).

(ii) The data given in Figs 1 and 2 are replotted in Fig. 3 to enable a to be deduced from the values of E/kT_g and γ.

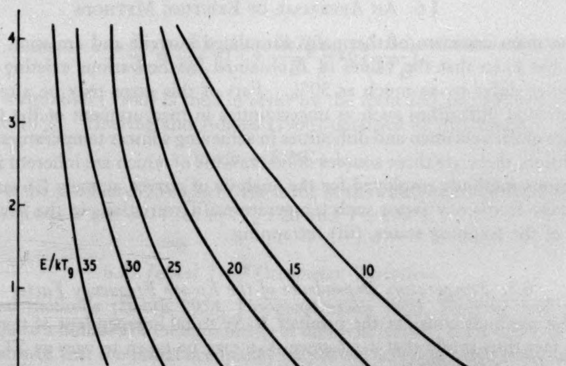

Fig. 3. Variation of a as a function of γ for a number of values of E/kT_g.

(iii) B may be evaluated from Eqn (5) by the substitution of $b=2-a$, T_g and E/kT_g. For negligible retrapping $C=B/K_1K_2$ where K_1, K_2 are given by $N_c=K_1T^{3/2}$, $v=K_2T^{1/2}$. Hence $S=BT^{-a}/K_1K_2$.

§ 5. THE EFFECT OF RETRAPPING

In the limiting case of very fast retrapping when $A(N-n)\gg 1/\tau$, solution of Eqn (1) gives (see Haering and Adams 1960)

$$I=n_0N_cSv\exp\left\{-\frac{E}{kT}-\int_{T_0}^{T}\frac{N_c}{\beta\tau}\exp\left(-\frac{E}{kT}\right)dT\right\}.$$

A similar procedure to that used previously gives, in this case,

$$-\ln\left(\frac{I}{I_0}\right)=\frac{E}{kT}-b\ln T+\left(\frac{T}{T_g}\right)^{7/2}\left(1-\frac{7}{2}\frac{kT_g}{E}\right)$$
$$\times\left(1+\frac{bkT_g}{E}\right)\exp\left(\frac{E}{kT_g}-\frac{E}{kT}\right) \qquad \text{......(9)}$$

if τ varies but slowly.

(This is to be compared with Eqn (6).)

Thus the result for very fast retrapping is identical with that for no retrapping when $b=\frac{3}{2}$ $(a=\frac{1}{2})$ but Eqns (6) and (9) give differing results for other values of b. This difference will be greatest, for the range of values of b considered, when $b=-2$.

As an example, if $E/kT_g=20$ and $b=-2$, use of Eqn (9) and the same procedure as before yields $\alpha_1=0{\cdot}067$, $\alpha_2=0{\cdot}050$, $\gamma=0{\cdot}745$ and $\alpha=0{\cdot}117$. If these two values of γ and α are substituted into Eqn (8), one obtains $E/kT_g=19{\cdot}3$, only $3\frac{1}{2}\%$ different. Whilst it does not necessarily follow that, in intermediate cases, the error is between 0 and $3\frac{1}{2}\%$, it is unlikely that a larger error will be introduced by ignoring the effect of retrapping.

§ 6. AN APPRAISAL OF EXISTING METHODS

The main criticism of thermally stimulated current and emission measurements has been that the values of E obtained by the various existing methods sometimes differ by as much as 50%. Part of this error may be attributed to experimental difficulties such as uncertainties in measurement of the true temperature of the specimen and difficulties in achieving a linear temperature increase. In addition, there are three sources of error, some of which are inherent in each of the various methods employed for the analysis of curves, namely (i) variation of the escape frequency factor with temperature, (ii) variations in the initial occupancy of the trapping states, (iii) retrapping.

6.1. *Temperature Dependence of the Escape Frequency Factor*

Most methods consider the product N_cSv to be independent of temperature and in fact thus imply that $a=2$ since N_cv may be taken to vary as T^2. In this case, $b=0$ and Eqn (5) becomes

$$\frac{B}{\beta}=\frac{E}{kT_g^2}\exp\left(\frac{E}{kT_g}\right). \qquad \text{......(10)}$$

If b is not equal to zero, errors can be introduced into methods which employ this equation and these may be appreciable. Hoogenstraaten (1958) has used this equation directly by plotting $\ln T_g^2/\beta$ against $1/T$ and if $b=-2$ the error in the value of E so obtained is about 12% for $E/kT_g \simeq 20$ and $T_g \simeq 100$°K. Booth (1954) has used two heating rates and hence two simultaneous equations to eliminate B from Eqn (10); this is thus similar to the previous method and the same errors are introduced if b is not zero. Garlick and Gibson (1948) have also taken $b=0$ but if this is not valid then their equation should be corrected to $\ln I = b \ln T - E/kT + \text{constant}$, and errors, of the same order as those in the two previous methods, are introduced if this correction is not applied.

Grossweiner (1953) obtained, by approximation methods, an expression which may be written

$$\frac{E}{kT_g} = 1{\cdot}51 \frac{(1-\alpha_1)}{\alpha_1};$$

this yields values of E/kT_g which are somewhat larger than the curve shown in Fig. 1. This method is made more inaccurate if the assumption that $b=0$ is invalid since b affects the curve in Fig. 1. Halperin and Branner (1960) have derived a very useful treatment of various recombination conditions but their method of analysing the peaks is rendered somewhat inaccurate by a geometrical approximation, originally due to Lushchik (1955). They assume $b=0$ and, for the conditions assumed in §2 above, obtain an expression which may be written

$$\frac{E}{kT_g} = \frac{q(1-\Delta)}{\alpha_2} \qquad \ldots\ldots(11)$$

where q is a quantity related to the shape of the peak (and thus γ) and $\Delta = 2kT/E$. This expression gives somewhat different results from those of the theory proposed in this article, e.g. if $\gamma = 0{\cdot}75$, $q = 1{\cdot}3$ and for $\alpha_2 = 0{\cdot}06$, Eqn (11) gives $E/kT_g = 19{\cdot}5$ instead of 17·9 obtained from Eqn (8)—about 10% difference.

Bube (1960) and Haering and Adams (1960) have taken $N_c v$ to vary as T^2 and have ignored any temperature variation of S. Thus $b=2$ and Eqn (5) becomes

$$\frac{B'}{\beta} = \frac{E}{kT_g} 4\left(1+\frac{2kT_g}{E}\right)\exp\left(\frac{E}{kT_g}\right).$$

Bube's equation (1960) is thus in error by the term $2kT_g/E$ which can easily amount to 10%. Haering and Adams (1960) obtained an expression

$$\ln \sigma/\sigma_0 = E/kT + 1,$$

where σ_0 is the product $N_c S v n_0 e \mu \tau$; the error in the value of E obtained by their method is about 8% if $a=4$ for $E/kT_g \simeq 20$ and $T \simeq 200$°K.

6.2. *Initial Trap Occupancy Variations*

Several methods (Booth 1954, Hoogenstraaten 1958, Haering and Adams 1960) require a number of measurements at different heating rates and it is always tacitly assumed that the initial occupancy (n_0) of the trapping state is the same for each measurement. But in many phosphors and photoconductors the approach to thermal equilibrium is dependent upon the past history of the specimen and it is extremely difficult to ensure that n_0 is the same for each measurement.

6.3. *Retrapping*

The values of E derived by methods using a number of heating rates (i.e. Booth 1954, Hoogenstraaten 1958, Haering and Adams 1960) and that of Garlick and Gibson (1948) are unaffected by retrapping but it may give appreciable errors in other methods. The method due to Bube (1955) has been shown by Haering and Adams (1960) to give values of E in error by about 2% for very fast retrapping with larger errors for less retrapping. Halperin and Branner (1960) have considered specific cases but since it is not possible to determine the extent of retrapping, uncertainty is introduced if it is not negligible. Grossweiner's method (1953) ignores retrapping and uncertainty (about 8% for extreme retrapping) again arises when it is appreciable.

All of the methods can be used to evaluate S but if retrapping is not negligible then the value of S obtained is subject to large errors since Eqn (5) is not valid for this case.

§ 7. CONCLUSION

Provided that the three assumptions made in § 2 are satisfied, the method summarized in § 4 is valid for thermally stimulated emission even when the recombination lifetime varies as a trap empties since I is independent of τ (Eqn (2)). The theory is also valid for thermally stimulated conductivity peaks, provided τ varies only slowly. (It is hoped at a later date to extend the theory to include variations of τ.)

The main advantages of the proposed method are:

(i) The temperature dependence of the trapping cross section is taken into account and, in addition, error in E due to extensive retrapping is small since retrapping is partly corrected for by allowing the effective capture cross section to vary.

(ii) Only one experiment at any one heating rate is necessary for analysis. The values of a and E obtained by the proposed method do not depend on the initial occupancy n_0.

(iii) The main experimental error is in the measurement of temperature difference and this is about half of that introduced into the somewhat similar methods of Grossweiner (1953) and Halperin and Branner (1960).

As in the other methods, S is subject to large errors if retrapping is appreciable since Eqn (5) is not valid in this case. However, if retrapping can be ignored, S can then be evaluated as a function of temperature whereas previous methods give its value only at the particular temperature at which the peak occurs. The value at the peak temperature can easily differ from the room temperature value by a factor 5 if S varies appreciably with temperature and it is of obvious value to be able to determine S at the temperature at which most measurements are made and at which devices are normally used.

Spectroscopic Investigations of Plasma Containment in ZETA

By W. M. BURTON and R. WILSON
Atomic Energy Research Establishment, Harwell, Berkshire

Communicated by R. S. Pease; *MS. received* 17*th April* 1961

Abstract. Observations are made of the time variation of the intensities of spectral lines emitted by small quantities of impurity ions in a deuterium discharge in ZETA. A vacuum ultra-violet monochromator which covers the wavelength range 500–2000 Å is used. The observations are interpreted in terms of temporal ionization distributions determined for a partially contained plasma model. The observations are consistent with the model and it is shown that plasma containment in ZETA is violated by two processes: an escape of plasma to the wall represented by a loss rate coefficient $\lambda(\mathrm{sec}^{-1})$, and an injection of atoms in a neutral or low state of ionization represented by an injection coefficient $\Lambda(\mathrm{sec}^{-1})$. The value of λ is effectively independent of the stabilizing magnetic field strength B_z, whereas the injection coefficient varies considerably with this parameter. Both λ and Λ are closely correlated with ϵ, the energy input per unit mass of gas, and over the range of conditions investigated they show a linear increase with ϵ. The ion containment time $1/\lambda$ is about 100 microseconds at $\epsilon = 3\,\mathrm{kev}/m_\mathrm{p}$ and at this condition most of the energy input is carried to the walls by the escaping plasma. The net effect of the processes of loss and injection controls the variation of plasma line density, and in general this shows a decrease with time or 'pump-out'. This is measured and related to other discharge phenomena.

§ 1. INTRODUCTION

The laboratory production of high temperature plasma has received great impetus over the past decade from experiments aimed at producing controlled thermonuclear reactions. At the moment the great need is to understand the basic physical processes which occur in such a plasma and potentially one of the most powerful methods of achieving this is the observation and interpretation of the radiation emitted. This paper deals with one aspect of this field, namely, the spectral line radiation from impurity ions in a deuterium plasma. Emission from highly ionized impurity ions persists after the initial deuterium ionization phase and should therefore give information concerning the physical conditions when the plasma is fully ionized.

The atomic processes governing the state of ionization within a plasma have been established for astrophysical conditions. If the electron density, electron temperature and dimensions of the plasma are known then one can, in principle, determine the quantitative contribution of the different processes. A similar approach can be made to the study of a high temperature laboratory plasma but two important differences emerge. Firstly, the lifetime of the laboratory plasma is generally short so that the transient phase of the ionization becomes important and must be studied. The second, and more fundamental, difference is that the astrophysicist's assumption of conservation of atoms within his plasma is generally not valid when dealing with the high temperature laboratory plasma. Indeed, one of the primary objectives of thermonuclear research is the conservation of plasma in a suitable magnetic confinement system.

Spectroscopic observations of plasma produced in the laboratory are often interpreted with the assumption that the plasma is fully confined. In the present paper we first describe the ionization processes occurring in such a plasma, and then consider the more realistic case of a partially confined plasma. The non-conservation of atoms is treated empirically. Ions are assumed to escape from the plasma by some loss process represented by a loss-rate coefficient whose reciprocal gives the ion containment time. It is also assumed that some injection process can operate whereby the plasma receives ions, probably from the walls of the confining vessel, in a neutral or low state of ionization.

The mathematical development of this model gives analytical expressions describing the life history of impurity ions in a deuterium plasma, i.e. the temporal frequency distribution of the various states of ionization in terms of the electron density, electron temperature and the parameters describing the processes of loss and gain. The theory is used as the basis for interpreting the observed spectral line transients of impurity ions in the experimental device ZETA. The observations support the model set-up and confirm the existence of the processes of loss and gain in the discharge; indeed, these are the dominant processes governing the ion population in the physical conditions studied.

§ 2. THEORETICAL

2.1. *A Fully Contained Plasma*

We first consider a plasma with neither loss nor injection of atoms. The model is specified by constant uniform electron density n_e and electron temperature T_e, and consists of a deuterium (or hydrogen) plasma containing a small quantity of impurity elements which are present in the neutral state at time $t=0$. The work of Knorr (1958) and McWhirter (1959, 1960) has shown that the dominant atomic processes in a deuterium plasma of the density, temperature and dimensions of ZETA are ionization by electron collision and recombination by radiative capture, as in the solar corona (Woolley and Allen 1948) viz.:

$$\mathrm{X}+\mathrm{e}\longrightarrow \mathrm{X}^{+}+2\mathrm{e}$$
$$\text{and } \mathrm{X}^{+}+\mathrm{e}\longrightarrow \mathrm{X}+h\nu\,.$$

The ionization process for the transition from the nth to the $(n+1)$th state, is described by the coefficient S_n, given by

$$S_n=\sum\langle Q(v)v\rangle,$$

where the cross section $Q(v)$ at velocity v is averaged over a Maxwellian distribution for an electron temperature T_e and the summation is over all electrons in the nth state ion. Similarly, the radiative recombination coefficient α_n for a transition from the nth to the $(n-1)$th state of ionization is given by

$$\alpha_n=\sum\langle q(v)v\rangle,$$

where the summation is this time over all energy levels in the nth state ion.

The equations describing the state of ionization of the impurity elements are

$$\frac{1}{n_e}\frac{dx_n}{dt} = x_{n-1}S_{n-1} - x_n[S_n + \alpha_n] + x_{n+1}\alpha_{n+1}, \qquad \ldots\ldots(1)$$

where x_n represents the proportion of each element in the nth state of ionization at time t. The neutral atom is represented by $n=0$ and the fully stripped ion by $n=Z$ where Z is the atomic number. The instantaneous concentration of any ion in the plasma is then given by $n_0 x_n$ where n_0 is the initial concentration of neutral atoms per unit volume. Analytical solutions of (1) are obtainable with the assumption that during the time period that x_n is varying rapidly, only the adjacent states, $n-1$ and $n+1$, have a time varying population, all states lower than $n-1$ having reached a steady state and all states higher than $n+1$ having yet to be populated. Observations of the intensity variation of spectral lines for an ionic sequence show that this is a close approximation. The solutions are

$$x_n = \beta_n \exp[-n_e S_n' t] - \beta_{n-1}\exp[-n_e S'_{n-1} t] + \gamma_n, \qquad \ldots\ldots(2)$$

where

$$S_n' = S_n + \alpha_n + \alpha_{n+1},$$

$$\beta_n = 1 - \sum_0^n \gamma_n,$$

and γ_n is the steady state value of x_n given by

$$\frac{\gamma_n}{\gamma_{n+1}} = \frac{\alpha_{n+1}}{S_n} \text{ and } \sum_0^Z \gamma_n = 1.$$

These satisfy the following boundary conditions:

$$t=0;\quad x_n=0,\quad x_0=1,$$

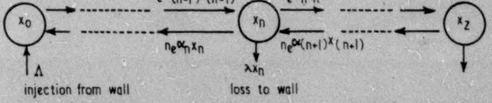
$$t=\infty;\quad x_n=\gamma_n,$$

$$\sum_0^Z x_n = \sum_0^Z \gamma_n = 1.$$

2.2. *A Partially Contained Plasma*

Into the model described above, two new processes are introduced: (*a*) a loss of ions from the plasma at a rate $\lambda x_n n_0$, where the loss rate coefficient $\lambda(\text{sec}^{-1})$ represents an inverse containment time, and (*b*) an injection of atoms from the wall at a rate Λn_0, where the injection coefficient $\Lambda(\text{sec}^{-1})$ represents an inverse time for injecting into the plasma the initial concentration n_0.

The model can be represented schematically as follows where the concentrations are all expressed as fractions of n_0.



Since the injection is associated with the walls of the confining vessel, the injected material will be 'cold' and is indicated in the diagram as being in the neutral state, although it is sufficient to suppose that the injected atoms are in a lower state of ionization than those considered. It is assumed that the coefficients λ and Λ are constant in time and apply, not only to the impurity elements, but also to the parent deuterium plasma. Consequently, the chemical composition of the plasma remains unchanged although its density may vary with time. Spatial uniformity and constant T_e are still assumed.

The differential equations describing this system can be written as

$$\frac{1}{n_e}\frac{dx_n}{dt}=x_{n-1}S_{n-1}-x_n\left[S_n+\alpha_n+\frac{\lambda}{n_e}\right]+x_{n+1}\alpha_{n+1} \qquad \ldots\ldots(3)$$

These are similar to the Eqns (1) describing the fully contained model, but the boundary conditions are quite different and n_e is no longer a constant but becomes a time-varying function depending on λ and Λ. Since we are dealing with a small concentration of impurity ions in a deuterium plasma, we can neglect the contribution of the impurities to the electron density and equate n_e to the number density of the deuterons. Further, as we are interested in the higher stages of ionization of the impurities, we can ignore the initial deuterium ionization phase and assume, as before, that the deuterium is fully ionized throughout. Putting n_0 equal to the initial deuterium number density, we therefore obtain the following equation in n_e:

$$\frac{dn_e}{dt}=n_0\Lambda-\lambda n_e, \qquad \ldots\ldots(4)$$

which is easily solved to give

$$n_e=n_0\left[\left(1-\frac{\Lambda}{\lambda}\right)e^{-\lambda t}+\frac{\Lambda}{\lambda}\right]. \qquad \ldots\ldots(5)$$

Substitution for n_e in Eqns (3) gives a set of differential equations for which analytical solutions are derived with the same approximations as used above. They are:

$$\begin{aligned}x_n=e^{-\lambda t}\Bigg[&\beta_n\left(1-\frac{\Lambda}{n_0\Lambda S_n'/\lambda+\lambda}\right)\exp\left\{-\frac{n_0S_n'}{\lambda}\left(1-\frac{\Lambda}{\lambda}\right)(1-e^{-\lambda t})-\frac{\Lambda}{\lambda}n_0S_n't\right\}\\&-\beta_{n-1}\left(1-\frac{\Lambda}{n_0\Lambda S'_{n-1}/\lambda+\lambda}\right)\exp\left\{-\frac{n_0S'_{n-1}}{\lambda}\left(1-\frac{\Lambda}{\lambda}\right)\right.\\&\left.\times(1-e^{-\lambda t})-\frac{\Lambda}{\lambda}n_0S'_{n-1}t\right\}+\gamma_n\Bigg]+\Gamma_n, \qquad \ldots\ldots(6)\end{aligned}$$

where Γ_n is the steady state value of x_n given by

$$\Gamma_n=\Lambda\left[\frac{\beta_n}{n_0\Lambda S_n'/\lambda+\lambda}-\frac{\beta_{n-1}}{n_0\Lambda S'_{n-1}/\lambda+\lambda}+\frac{\gamma_n}{\lambda}\right].$$

The solutions satisfy the following boundary conditions:

$$t=0; \quad x_n=0, \quad x_0=1$$

$$t=\infty; \quad x_n=\Gamma_n$$

$$\sum_0^Z x_n=\left(1-\frac{\Lambda}{\lambda}\right)e^{-\lambda t}+\frac{\Lambda}{\lambda}.$$

The expressions (6) are quite general and reduce to the fully contained case (2) when λ and Λ tend to zero.

2.3. *Relation to Observed Spectral Line Intensities*

The observable quantity is I_n, the intensity of a spectral line emitted by the nth ion as a function of time. To relate I_n to x_n requires a solution of the equation of radiative transfer for Doppler broadened spectral lines emitted from the model plasma. The problem is identical with that for solar prominences (Ambartsumyan 1958) and the solution can be expressed in the form

$$I_n = n_0 x_n{}^* d\epsilon\left(1 - \frac{\tau_0}{2!\sqrt{2}} + \frac{\tau_0{}^2}{3!\sqrt{3}} - \ldots\ldots\right),$$

where d is the diameter of the plasma, $x_n{}^*$ is the fraction of x_n populating the lower level of the transition, and ϵ is the atomic line emission coefficient. The optical depth τ_0 at the frequency of the line centre is given by

$$\tau_0 = \frac{\pi^{1/2}e^2}{mc}\,\frac{n_0 x_n{}^* df}{\Delta\nu_{\mathrm{D}}},$$

where f is the oscillator strength of the spectral line and $\Delta\nu_{\mathrm{D}}$ is its Doppler width in frequency units.

The simplest relation between I_n and x_n is the proportionality which exists when the plasma is optically thin at the frequency of the observed spectral line, i.e. when the higher terms in the expression for I_n are negligible. The condition for this is $\tau_0 \ll 2!\sqrt{2}$ which is satisfied for the resonance lines to be observed. An upper limit to τ_0 can be estimated by putting $x_n{}^* = 1$, and then, using the observed values for the other parameters we get $\tau_0 \leqslant 0{\cdot}2$.

Since τ_0 is small the excitation processes governing the emission line coefficient ϵ are analogous to those dominating ionization, viz. electron collisional excitation and radiative decay. For constant T_{e} we therefore have $\epsilon \propto n_{\mathrm{e}}$ and also $x_n \propto x_n{}^*$. Hence the expression for the observed intensity of a spectral line as a function of time is given by

$$I_n = C_n n_{\mathrm{e}} x_n, \qquad \ldots\ldots(7)$$

where n_{e} and x_n are given by Eqns (5) and (6) respectively, and C_n is a constant for any one spectral line.

Practical considerations make it convenient to divide this general expression for I_n into two parts: firstly, that part of the distribution resulting from the atoms initially present at $t=0$ and referred to as the 'initial transient'; secondly, that part of the distribution resulting from the injected atoms and referred to as the 'injection tail'. The expression for the initial transient is

$$I_n(t) = C_n n_0\left[\left(1-\frac{\Lambda}{\lambda}\right)\mathrm{e}^{-\lambda t}+\frac{\Lambda}{\lambda}\right]\mathrm{e}^{-\lambda t}\left[\beta_n \exp\left\{-\frac{n_0 S_n{}'}{\lambda}\left(1-\frac{\Lambda}{\lambda}\right)(1-\mathrm{e}^{-\lambda t})-\frac{\Lambda}{\lambda}n_0 S_n{}'t\right\}\right.$$
$$\left.-\beta_{n-1}\exp\left\{-\frac{n_0 S'{}_{n-1}}{\lambda}\left(1-\frac{\Lambda}{\lambda}\right)\left(1-\mathrm{e}^{\lambda t}\right)-\frac{\Lambda}{\lambda}n_0 S'{}_{n-1}t\right\}+\gamma_n\right]. \quad \ldots\ldots(8)$$

In the case of the injection tail, we are mainly interested in the steady state value and therefore omit the time varying part of the function to give

$$I_n(\Gamma) = C_n n_0 \frac{\Lambda}{\lambda}\left[\frac{\Lambda\beta_n}{n_0\Lambda S_n{}'/\lambda+\lambda} - \frac{\Lambda\beta_{n-1}}{n_0\Lambda S'{}_{n-1}\,\lambda+\lambda} + \frac{\Lambda}{\lambda}\gamma_n\right]. \quad \ldots\ldots(9)$$

2.4. *The Coefficients of Injection and Loss*

Our main concern in this investigation is the determination of the injection Λ and loss rate λ coefficients and we set out here the expressions for these parameters in terms of the observable quantities R_n and Δt_n. The intensity ratio R_n is given by

$$R_n = \frac{I_n(\Gamma)}{I_n(t_{\mathrm{P}})}, \qquad \ldots\ldots(10)$$

where $I_n(\Gamma)$ is the intensity of the injection tail, given by Eqn (9), and $I_n(t_P)$ is the peak intensity of the initial transient $I_n(t)$ given by Eqn (8). The 'transient lifetime' Δt_n is given by

$$\Delta t_n = \frac{\int_0^\infty I_n(t)dt}{I_n(t_P)}, \qquad \ldots\ldots(11)$$

which is approximately equal to the time duration of the initial transient measured at an ordinate $I_n(t_P)/e$. The parameters $I_n(\Gamma)$, $I_n(t_P)$ and Δt_n are depicted in Fig. 1 which is reproduced from an actual oscillogram.

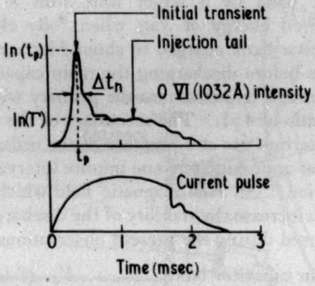


Fig. 1. Typical spectral line intensity and current waveforms showing measured parameters ($P = \frac{1}{2}\mu$ D$_2$, $V_C = 10$ kv, $B_z = 800$ gauss).

When the intensity level in the injection tail is small, i.e. $I_n(\Gamma) \ll I_n(t_P)$, the quantities R_n and Δt_n can be obtained unambiguously from the observed intensity–time distributions. When $I_n(\Gamma)$ becomes large R_n can still be estimated, albeit less accurately, but the initial transient becomes masked by the injection tail. However, it will be shown in § 4 that Δt_n can still be measured under these conditions by using a small quantity of argon, added as a trace element. The injection of argon is very small and therefore reveals the initial transient only (see Fig. 4).

An analysis of Eqns (9), (10) and (11) gives the following approximate expression for the injection coefficient:

$$\Lambda = \frac{2 + 5\Lambda/\lambda + 5(\Lambda/\lambda)^2}{12(\Lambda/\lambda)^2} \frac{R_n}{\Delta t_n}. \qquad \ldots\ldots(12)$$

The value of the transient lifetime Δt_n depends on n_e, T_e, Λ and λ, and since we know n_e in terms of Λ and λ (Eqn (5)), three unknowns remain. Hence, an independent measurement of T_e would enable us, in principle, to estimate Λ and λ from Eqns (11) and (12). This would not be very satisfactory since it depends on poorly known atomic cross sections and instead we consider the form of Δt_n when n is large. As n increases the ionization rate decreases rapidly, so for any significant value of λ there must be an ionization stage at which the loss rate exceeds the ionization rate, i.e. $\lambda > n_e S_n$. When this occurs an analysis of Eqn (11) shows that Δt_n reaches a constant value which is independent of n_e and T_e and is given approximately by

$$\lim_{n \to Z} \Delta t_n \longrightarrow \left(1 + \frac{\Lambda}{\lambda}\right) \frac{e}{2\lambda}, \qquad \ldots\ldots(13)$$

where e is the base of natural logarithms. Thus the asymptotic value of Δt_n when n is large is a function of Λ and λ only. Substitution of the observable quantities R_n and the limiting value of Δt_n in Eqns (12) and (13) allows the determination of Λ and λ without knowledge of the electron temperature or the cross sections of the ionization and recombination processes.

§ 3. EXPERIMENTAL

The plasma studied was produced in the toroidal gas discharge apparatus ZETA 1A which has been described elsewhere by Butt *et al.* (1958) and by Mitchell *et al.* (1959). Since that time modifications have been carried out to replace the 1600 μF capacitor bank by a larger unit with a capacity of 11 000 μF which provides a stored energy of 3 MJ when fully charged to 24 kV. The original 1600 μF capacitor bank charged to about 5 kV is now used as a pre-heat bank to ionize the gas before discharging the main capacitor bank. The main bank is discharged through ignitrons into the primary winding of a pulse transformer with a turns ratio of 4 : 1. The secondary of the transformer is a single turn discharge in deuterium gas at a pressure of the order of one micron. The discharge is operated at approximately one minute intervals with a current pulse of about 3 msec duration. An axial magnetic field which can be varied up to 1600 gauss was used to increase the stability of the discharge. The range of ZETA operating conditions used during the present observations is summarized below.

Voltage on main capacitor bank	V_c	(7 to 15 kV)
Axial magnetic field	B_z	(200 to 1600 gauss)
Current (peak value)	I	(200 to 600 kA)
Deuterium gas pressure	P	($\frac{1}{4}$ to 2 μm Hg)

The model which was developed in § 2 to describe the life history of impurity ions in a deuterium plasma can only be applied after the deuterium has been fully ionized. Under these conditions most impurity atoms will be multiply ionized. The resonance lines of such ions generally occur with high intensity at wavelengths below 2000 Å in the vacuum ultra-violet region of the spectrum. A vacuum ultra-violet monochromator fitted with a photoelectric detection system was used to select particular lines in the ZETA emission spectrum and to observe the time variation of the intensity of each line throughout the ZETA current pulse. A plan-view diagram of the apparatus is shown in Fig. 2.

The monochromator was coupled to ZETA through a vacuum valve at a port providing a radial view of the plasma at the torus centre axis. A vacuum system on the monochromator enabled the pressure to be reduced to about 10^{-5} mm Hg before the valve to the torus was opened. The path of the observed light was entirely *in vacuo* and it was reflected at near-normal incidence by a concave diffraction grating which was blazed to give a high intensity first-order spectrum at a wavelength of 1500 Å. The grating was a one metre radius aluminized replica (Bausch and Lomb Type No. 372). The emergent first-order wavelength could be varied throughout the range 300–5000 Å by a drive mechanism which rotated the grating and simultaneously displaced it in order to maintain adequate focus†. The exit slit was set to pass the required bandwidth of about 1 Å.

The radiation leaving the exit slit illuminated a thin film of sodium salicylate coated on the inside of a quartz window. This fluorescent surface converted the incident radiation into visible blue light which passed through the window and was detected by a photomultiplier tube (E.M.I. Type: 6256A) placed outside the vacuum system. To limit electrical interference the photomultiplier tube was shielded with 2 cm copper and a balanced output circuit was used to reject in-phase signals. The balanced output signal was displayed on a double-beam oscilloscope (Cawkell Type SC46) and recorded photographically simultaneously with the ZETA current waveform. A remote control motor drive synchro-indicator unit enabled the wavelength setting to be adjusted and displayed.

Spectral lines were easily resolved giving signals which were free from electrical interference in spite of the close proximity of the photomultiplier tube to the ZETA primary winding. Experiments were carried out to check that the gain of the detection system did not change significantly during the ZETA pulse, when large stray magnetic fields occur. This was confirmed by observing the signals produced by a separate light source throughout the ZETA pulse. Measurements were made to determine the linearity of the detection system. The light intensity of a laboratory discharge tube was varied by aperture stops reducing the intensity in the ratio 2 : 1 and the monochromator photomultiplier output signal was found to be proportional (±5%) to the incident light intensity. This proportionality was no longer observed if the output signal exceeded 1·5 volts, and in all subsequent measurements the photomultiplier e.h.t. was adjusted so that the peak output signal was close to 1 volt.

To enable the observation of rapid fluctuations in the light intensity the time constants of the circuit were chosen so that no serious distortion was produced on pulses with durations between 10 msec and 10 μsec. The decay time of the fluorescent sodium salicylate coating is much shorter than the circuit time constant which determined the high-frequency response.

The spectral region covered by the monochromator in this work had previously been photographed using a vacuum spectrograph of similar dispersion (Harding *et al.* 1958). The ZETA spectrum at these wavelengths consists mainly of intense resonance lines of ions of impurity elements including carbon, nitrogen and oxygen which occur at concentrations of about 1%. In addition to these normal impurity ions, a small quantity of argon was usually added to provide an artificial impurity or 'trace' element. The amount of argon added was normally one per cent of the deuterium pressure. This was found to give an adequate signal-to-noise ratio ($\simeq 50:1$) and not appreciably to alter the ZETA discharge characteristics. For the subsequent measurements one line of each of the ions to be studied was selected by consideration of intensity and freedom from interfering lines. The lines selected are listed in Table 1.

The experimental results were obtained by selecting the appropriate spectral line of each ion and photographing the intensity and current waveforms for five consecutive ZETA discharges. This was repeated for each ion and for each discharge condition to be studied. Final results were based on the average measurements from each group of five discharges. The transient lifetime values Δt_n were quite reproducible ($\pm 20\%$) but the amplitude measurements $I_n(t_P)$ and $I_n(\Gamma)$ showed greater variation ($\pm 50\%$). These variations make the major contribution to the errors in the final results given in § 5.

Calibration markers were displayed on the oscilloscope immediately following each discharge to facilitate measurement of the waveforms. Amplitude calibration was given by a 1 volt square-wave signal, and timing markers at 100 μsec and 1 msec intervals were produced by a crystal controlled timing pulse generator. The oscillograms were displayed on a projector and the required measurements of the spectral line intensity transients were determined by direct comparison with the calibration markers.

§ 4. CONFIRMATION OF INJECTION AND LOSS PROCESSES

The equations derived in § 2 can only be applied to the ZETA plasma after the initial deuterium ionization phase, which is completed when the intensity of the Lyman α line decreases following its peak value (McWhirter 1959). Fig. 3 shows the observed intensity–time variation of DL_α and the resonance lines of the lithium-like impurity ions C IV, N V and O VI. The lines of these ions all reach peak intensity after the deuterium ionization phase is effectively completed, and the criterion was adopted that only ions of state IV and above would be included in the results analysed.

The discharge condition to which the waveforms shown in Fig. 3 refer was selected because of the low level of injection. This enables the initial transient to be observed clearly. The theory given in § 2 predicts that the initial transient will show a rapid rise to a peak value followed by a decrease. This is supported by the observations shown in Fig. 3.

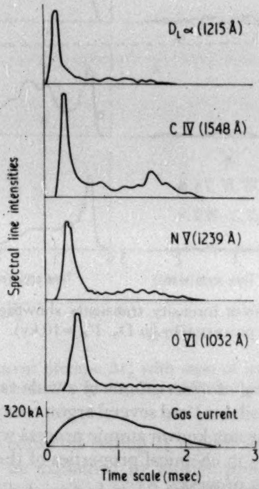

Fig. 3. **Spectral line intensity transients of deuterium and the lithium-like impurity ions ($P = \frac{1}{2}\mu$ D$_2$, $V_C = 10$ kv, $B_z = 1100$ gauss).**

The injection coefficient Λ is given in terms of the observed quantities by Eqn (12). Determined for any ion, it gives the injection rate for that particular element in terms of its initial concentration in the plasma. The value of Λ obtained should therefore be the same for all ions of any one element. This is supported by the observations. The results for a mean of several measurements of the oxygen ionization sequence expressed as a ratio Λ(O IV) : Λ(O V) : Λ(O VI) is 1·0 : 0·9 : 1·2. This result, which is obtained for several discharge conditions, cannot be explained by atomic processes alone, i.e. by using Eqns (2) for a fully confined plasma.

A further proof that the observed tails in the intensity–time distributions are dynamic steady states caused by the injection of material in a low stage of ionization is afforded by a comparison between observations for those impurities normally present in the plasma (carbon, nitrogen, oxygen, etc.), and deliberately introduced trace elements such as argon which are normally absent. Such a comparison is shown in Fig. 4 which reproduces observed intensity transients of an Av line (λ827 Å) and an Ovi line (λ1032 Å) at three different values of B_z. The outstanding feature of the comparison is the presence of a tail in the case of the Ovi transients and its almost complete absence in the case of Av. The Ovi emission persists as an injection tail after the initial transient (which can be identified in the traces) whereas the Av observations show the initial transient only. This result is typical of observations of a wide range of impurity ions (e.g. carbon, nitrogen, oxygen, silicon) and several argon trace ions (iv to viii inclusive), and cannot be explained by any known atomic process within the plasma but must be related to the difference in chemical properties of the elements concerned and the nature of the injection process.

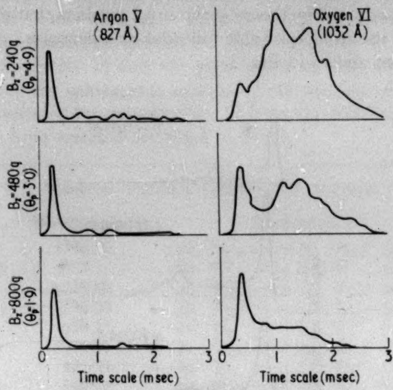

Fig. 4. Argon v and oxygen vi intensity transients showing the effect of an injection process ($P=\frac{1}{2}\mu$ D_2, $V_C=10$ kv).

Two further points are illustrated by Fig. 4. Firstly, the level of injection is a function of the axial magnetic field B_z, decreasing as B_z increases. Secondly, the intensity in the tail varies through the current pulse, indicating that the injection varies with time. All of these points are dealt with more fully in § 5 below.

The observational test to be applied to establish the existence of a loss process is apparent from a consideration of the transient lifetime Δt_n given by Eqn (11). In a fully confined plasma Δt_n increases rapidly with ionization stage n, becoming infinite (in a plasma of infinite lifetime) for an ionization stage which is heavily populated in the steady state. The existence of a loss process places a 'ceiling' on Δt_n set by the loss rate coefficient λ as expressed in Eqn (13). This is a very specific prediction which is fully supported by the observations, as illustrated by the typical results displayed in Fig. 5. This shows a plot of Δt_n for the argon and oxygen sequences for a selected discharge condition. The abscissa is in terms of t_P, the time at which the initial transient peaks, so that both sequences can be plotted on a common scale.

A high injection will obscure the initial transient from which Δt_n is measured (see Fig. 4). The practical importance of using argon trace ions is now very apparent, since they show only the initial transient and this allows the measurement of Δt_n and therefore of λ under all conditions of injection. The discharge condition used for Fig. 5 has been selected with high B_z so that the injection is low, enabling Δt_n to be measured for the oxygen sequence as well as for the argon sequence.

The diagram illustrates the existence of a ceiling on Δt_n since the higher stages of ionization all have the same transient lifetime. Further, a common ceiling applies to both the oxygen and argon ions indicating that λ is independent of ion mass and charge and can therefore be inferred from these results for the main plasma constituent, i.e. deuterium.

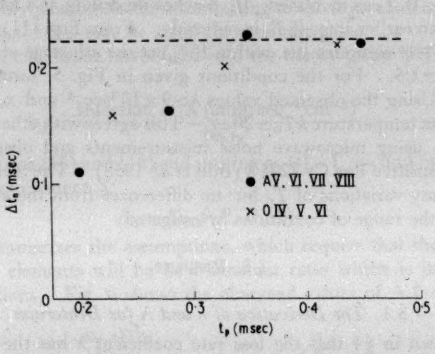

Fig. 5. Variation of transient lifetime Δt_n with state of ionization showing the effect of a loss process ($P=\frac{1}{2}\mu$ D$_2$, $V_c=10$ kv, $B_z=800$ gauss).

The existence of a common ceiling is typical of a wide range of discharge conditions and cannot be explained by atomic processes alone. For the fully contained plasma model described in § 2 the Δt_n values for successive stages of an ionization sequence would increase rapidly. Using the cross sections for electron collisional ionization S_n and radiative recombination α_n given by Elwert (1952), these Δt_n values can be calculated. The values calculated for the sequence argon v–viii in a fully contained plasma at constant temperature $kT_e=20$ ev (estimated below) are as follows:

Ion	Av	Avi	Avii	Aviii
Δt_n(msec)	0·11	0·57	4·9	33

The results shown in Fig. 5 deviate grossly from these values, and the observed limiting value of Δt_n therefore shows the existence of a loss process.

The coefficients of loss and injection are estimated using expressions (12) and (13) without knowing the electron temperature, and the effect of this parameter will now be considered. It was shown that the shape of the initial transient and therefore Δt_n becomes independent of T_e when $\lambda > n_e S_n$. However, the ordinate scale of the distribution does depend on T_e as can be seen from the expression for x_p, the peak population in the nth stage of ionization:

$$x_p=\frac{n_e(\beta_{n-1}S'_{n-1}-\beta_n S_n')}{e\lambda}. \qquad \ldots\ldots (14)$$

This is derived from Eqns (7) and (8) for the case of constant electron density, i.e. $\Lambda=\lambda$. The dependence of x_p on T_e is expressed by the temperature sensitive parameters β and S'. Hence the ion populations decrease rapidly in successive stages of ionization, although the shape and therefore the value of Δt_n remains constant. Obviously, any estimate of T_e based on ionization distributions derived from atomic processes alone will not be valid in a partially contained plasma.

However, the electron temperature can be estimated approximately from the results shown in Fig. 5. Although the level of the ceiling on Δt_n is controlled by the containment time only, the ionization stage at which it is reached is determined by T_e. If T_e is increased, Δt_n reaches its ceiling at a later stage of ionization, and at an earlier stage if T_e is reduced. From Eqn (11) it can be shown that Δt_n effectively saturates (i.e. within 10%) at the nth stage of ionization when $n_e(S_{n-1}-S_n)\simeq\lambda/5$. For the conditions given in Fig. 5, saturation occurs at about A VII. Using the observed values $\lambda\simeq 9\times10^3\,\text{sec}^{-1}$ and $n_e\simeq10^{14}\,\text{cm}^{-3}$ we find the electron temperature $kT_e\simeq 20$ ev. This agrees with other determinations of T_e in ZETA using microwave noise measurements and observations of the temperature-sensitive line C V 2271 Å (Butt *et al.* 1958). The method is too crude to determine any variations of T_e but no differences from the above value were detected over the range of conditions investigated.

§ 5. RESULTS

5.1. *The Derivation of λ and Λ for Deuterium*

It was shown in § 4 that the loss rate coefficient λ has the same value for sequences of argon and oxygen ions which cover an appreciable range in charge and mass. Although this range does not embrace the values of charge and mass for the deuteron, it is reasonable to assume that the value of λ deduced from observations of impurity ions is representative of the deuterons and therefore of the entire plasma.

The injection coefficient Λ was derived for the impurity elements normally present in the plasma, i.e. carbon, nitrogen and oxygen. The value of Λ for deuterium ions, which emit no spectral lines, must then be inferred from the measured injection of these elements. This is done on the basis of the following assumptions. The rate of injection of atoms of any particular element X is assumed to be proportional to the concentration of that element in the adsorbed gas layer on the wall of the discharge tube. This wall concentration is assumed to be related, in turn, to the initial concentration of the element in the gas $(n_0)_X$. In addition the rate of injection will depend on discharge conditions, and these assumptions are expressed as follows:

$$\text{Injection of X (atom sec}^{-1}\,\text{cm}^{-3}) = g_X(t)K_X(n_0)_X f(P, B_z, I) \qquad \ldots\ldots(15)$$

where K_X is some equilibrium adsorption factor which is a constant for each element, and $f(P, B_z, I)$ is a function, common to all elements, which is dependent on the discharge conditions only. The factor $g_X(t)$ is included to allow for the time required to establish equilibrium between the gas and the adsorbed layer. When a chemical element is first added to the gas $g_X(t$ small) is low but it will gradually increase to reach a limiting value of unity when equilibrium is established. For deuterium and the impurity elements which have been present in the discharge tube for a long period, this equilibrium is assumed to be established and for this case we will put $g_X(t \text{ large}) = 1$.

The absence of an injection tail for argon ions which was shown in Fig. 4 is interpreted as a failure to reach equilibrium during the relatively short time for which argon had been present, so that $g_X(t) \ll 1$. Extended observations of argon ions showed the development of injection tails with $R_n \simeq 0{\cdot}1$ after several hundred discharges. This suggests that the equilibrium time for elements present at about the 1% level is of the order of a few thousand discharges. This time is longer than would be expected if surface adsorption were the only important process. A further possible factor contributing to the low argon injection is that the adsorption factor K_X may be small for the inert gases.

The injection coefficient introduced into the theory given in § 2 was defined by the relation

$$\Lambda_X = \frac{\text{Injection of X (atom sec}^{-1}\text{ cm}^{-3})}{(n_0)_X}. \qquad \ldots\ldots(16)$$

Comparing Eqns (15) and (16) and putting $g_X(t) = 1$, we find for the injection coefficient for any element X

$$\Lambda_X = K_X f(P, B_z, I). \qquad \ldots\ldots(17)$$

This relation summarizes the assumptions, which require that the injection coefficients for all elements will be in a constant ratio which is independent of discharge conditions. Fig. 6 shows the observed values of Λ for the impurity elements carbon, nitrogen and oxygen, measured with varying values of one discharge parameter, viz. B_z. The values of Λ for the different elements are plotted, not against B_z, but in terms of the magnetic parameter θ (Lees and Rusbridge 1959) which is defined as $\theta = 2I/aB_z$ where I is the current, a is the discharge tube radius, and B_z is the initial value of the axial magnetic field. Physically, θ represents the compression produced by the magnetic pinch forces for an idealized system. The values of θ_p and Λ in Fig. 6 refer to peak current. Although the observed values of Λ vary considerably with θ_p, the ratios of Λ for different elements remain constant within the accuracy of the measurements. The same result is obtained for all discharge conditions investigated, including

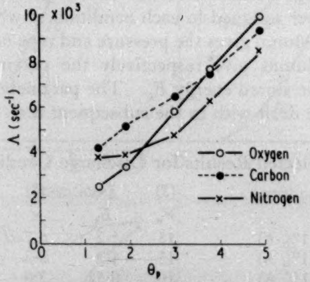

Fig. 6. Variation of injection coefficient with θ_p for different impurity elements ($P = \frac{1}{2}\mu$ D$_2$, $V_c = 10$ kv).

variation of gas pressure and current. This provides direct experimental support for Eqn (17).

The deuterium injection coefficient can therefore be expressed by the relation

$$\Lambda_D = K_D f(P, B_z, I) = (K_D/K_X)\Lambda_X.$$

The observed results from which Λ_D is to be calculated are the values of Λ for carbon, nitrogen and oxygen, and we replace Λ_X by Λ_{CNO}, the measured average value of Λ_C, Λ_N and Λ_O for the six lines observed (Table 1). The calculated value of Λ_D is consequently given by the product of Λ_{CNO} and some numerical constant, i.e.

$$\Lambda_D = \sigma\Lambda_{CNO}. \qquad \ldots\ldots(18)$$

Observations which verify predictions based on Eqn (18) are given in § 5.3 below, and these show that the numerical value of σ is of the order of unity. This is as would be expected if the value of σ, i.e. K_D/K_{CNO}, were determined by physical adsorption of a monolayer, since this would require that $K_D \simeq K_C \simeq K_N \simeq K_O$. Some support for this is given by the observation that $\Lambda_C \simeq \Lambda_N \simeq \Lambda_O$ for each of the discharge conditions shown in Fig. 6.

The derivation of the loss rate and injection coefficients for deuterium from observations of impurity ions enables the remainder of the results to be expressed in terms of the parameters λ and Λ which can now be taken as representative of the entire plasma.

5.2. *Variation of λ and Λ with Discharge Conditions*

All of the discharge conditions observed are listed in Table 2. The first column gives a number assigned to each condition to which we can refer in the text, and the second column gives the pressure and type of gas in the torus. The third and fourth columns give respectively the potential V_c applied to the capacitor bank and the stored energy E_s. The parameters tabulated in the final three columns will be dealt with in the subsequent text.

Table 2. Selected Results for Discharge Conditions Observed

(1) No.	(2) Gas	(3) V_c	(4) E_s	(5) ϵ	(6) λ	(7) N_c

(1) Discharge condition; (2) gas; (3) V_C(kv), capacitor bank voltage; (4) E_S(MJ), energy stored in capacitor bank; (5) ϵ(kev/m_p), energy input per unit mass of gas; (6) λ(sec^{-1}), observed loss rate coefficient; (7) N_C(cm^{-1}), critical line density at discontinuity in current waveform.

The values of loss rate coefficient λ and injection coefficient Λ measured at peak current are plotted against θ_p in Fig. 7 for four selected discharge conditions, i.e. (1), (2), (3) and (4) of Table 2. The variation in θ_p is obtained by varying the axial magnetic field B_z. It will be noticed that the general character of these plots is the same for each condition, except for a change in the scale of the ordinate. The loss rate coefficient λ does not vary appreciably with θ_p and, within the experimental accuracy, can be regarded as constant. The injection coefficient Λ varies linearly with θ_p, becoming equal to λ at about $\theta_p = 5$. These characteristics are true of all the discharge conditions investigated. We can therefore represent each discharge condition by a single measured value—the mean value of λ for all values of θ_p. Then for each condition, we have

$$\text{Loss rate coefficient} \quad = \lambda \quad (\text{constant with } \theta_p)$$

$$\text{Injection coefficient } \Lambda = 0{\cdot}2\lambda\theta_p \text{ for } 1{\cdot}2 < \theta_p < 5.$$

The upper limit on θ_p is an experimental one above which the discharge becomes grossly unstable, and the lower limit on θ_p represents a minimum in Λ at $\theta_p \simeq 1{\cdot}2$ as is shown by discharge condition 3 in Fig. 7. This effect is reproducible and is observed whenever θ_p falls below 1·2.

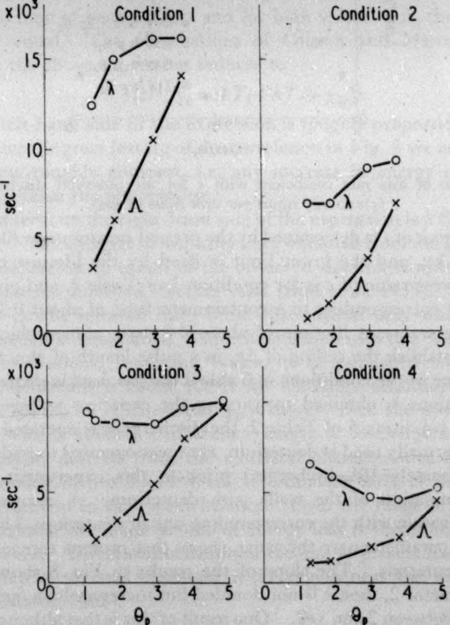

Fig. 7. Variation of injection and loss rate coefficients (Λ and λ) with θ_p for different discharge conditions, numbered as in Table 2. 1: $\frac{1}{2}\mu$ D_2, 15 kv; 2: 1 μ D_2, 15 kv; 3: $\frac{1}{2}\mu$ D_2, 10 kv; 4: 1 μ D_2, 10 kv.

The values of λ representing each discharge condition are tabulated in column (6) of Table 2, where the standard errors are derived solely from the experimental scatter. Given in column (5) are the values of the parameter ϵ, defined as the energy put into the discharge per unit mass of gas, expressed in kev/m_p, where m_p is the proton mass. The energy put into the discharge, which is less than that stored in the capacitor bank, is derived from the electrical characteristics (Butt 1960, private communication) and is given by $\int VI\,dt$, where V is the volts per turn and I the gas current.

The parameter ϵ is tabulated because of its correlation with the loss rate coefficient λ, as is shown by the plot of these parameters in Fig. 8. The relationship between λ and ϵ is linear over the range of conditions observed and the scatter of the points is consistent with the error of measurement.

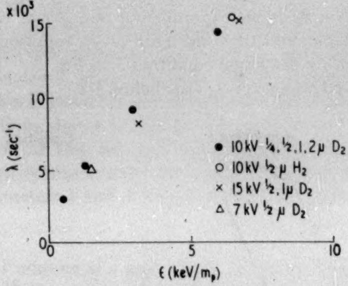

Fig. 8. Variation of loss rate coefficient with ϵ for all observed discharge conditions (ϵ = energy input per unit mass of gas).

The upper limit of ϵ is determined by the present maximum available capacitor voltage $V_c = 15$ kv, and the lower limit is fixed by the lifetime of the plasma itself. The lowest value of ϵ is for condition 7 of Table 2, and gives a value of $\lambda = 3 \times 10^3\,\text{sec}^{-1}$ corresponding to a containment time of about 0·3 msec. This gives a limiting transient lifetime of about 0·8 msec, above which it becomes impossible to establish the ceiling of Δt_n in a pulse length of about 3 msec.

In all but one of the conditions in Table 2 the gas used is deuterium and the range in conditions is obtained by varying the capacitor voltage and the gas pressure. For condition 5 of Table 2, the discharge was operated in hydrogen. Since the gas normally used is deuterium, ZETA was operated in hydrogen for two weeks (approximately 10^4 discharges) prior to this experiment to eliminate possible contamination of the walls with deuterium. A comparison of this hydrogen observation with the corresponding one in deuterium, 3 in Table 2, for which all other parameters are the same, shows that protons escape almost twice as rapidly as deuterons. The slope of the results in Fig. 8 shows that if ϵ is increased by a factor 2, then λ is not doubled but increases by a factor 1·7 which is intermediate between 2 and $\sqrt{2}$. One result of this is that although λ decreases with increasing pressure, the actual loss rate of ions from the plasma remains roughly constant, and in fact increases slightly.

The linear relationship between λ and ϵ appears, on extrapolation, to intercept the λ axis on the positive side. This is clearly inadmissible on energy considerations, and the curve must pass through the origin or make a positive intercept with the ϵ axis.

It is of fundamental interest to consider the energy required to maintain the observed system of injection and loss of particles in the plasma. Gibson and Mason (1961) have shown that the energy lost in the form of radiation is about 20% of the energy input over the range of conditions investigated here. It is easy to show that the rest of the energy can be accounted for by particle loss to the walls.

An energy balance can be carried out by comparing the power input with the power output derived from observed quantities. Thus the power balance equation, per unit length of the discharge, is given by

$$\Omega I^2 = R + N_0\left(\frac{\Lambda}{\lambda}\right)\left[kT_i + kT_e + \chi_D\right]\lambda,$$

where Ω is the effective discharge resistance per unit length, I is the current, R is the radiated power, N_0 is the initial line density, kT_i is the energy of the ions, kT_e the energy of the electrons and χ_D the deuterium ionization potential. The energy in the impurity atoms is neglected, and it is assumed that the values of λ and Λ observed for ions also applies to the electrons. If we consider this power balance for the time of peak current and for high values of θ_p then λ and Λ are approximately equal. The observations of Gibson and Mason (1961) give $R \simeq 0{\cdot}2\Omega I^2$, so the above expression reduces to

$$0{\cdot}8\Omega I^2/N_0 = [kT_i + kT_e + \chi_D]\lambda.$$

Since the left-hand side of the expression is roughly proportional to ϵ we see that to reproduce the gross feature of the correlation in Fig. 8 we need to keep the bracketed terms roughly constant, i.e. any increase in energy input does not substantially increase the temperature.

The largest term on the right-hand side of the expression is kT_i, the energy of the deuterons. The energies of impurity ions, obtained from the Doppler widths of spectral lines, are far in excess of the observed electron temperatures and are of the order of a few hundred electron volts (Butt *et al.* 1958). The energy of the deuterons can be inferred from these observations only when the detailed heating mechanism is understood. An investigation into this is proceeding and preliminary observations (Jones and Wilson, to be published) indicate that the energy of the deuterons is about 100 ev for discharge condition 3 of Table 2. Putting $kT_i \simeq 100$ ev, $kT_e \simeq 20$ ev and $\chi_D = 13{\cdot}6$ ev, then the power loss due to escape of particles is about 5×10^4 w cm^{-1} length of discharge at peak current. The power input, derived from the electrical characteristics by Butt (1960, private communication), is 8×10^4 w cm^{-1}. Allowing 20% of this for radiation gives good agreement in the power balance. Over the range of discharge conditions investigated, the major source of energy loss is therefore due to plasma reaching the walls. Direct confirmation of the loss of plasma has been obtained by the detection of thermal electrons in the region near the wall of the torus (Gibson and Mason 1962).

5.3. *Variation of Plasma Line Density with Time*

The effect of discharge conditions on the loss and injection coefficients measured at peak current is described in the previous section. We will now consider how these processes control the variation of plasma density during a single discharge, and this necessitates the determination of any temporal variation of the respective coefficients.

The values of the loss rate coefficient λ given above were obtained from observations made over the time interval that the ionic sequence A V to A VIII appeared. This time interval varies according to the discharge conditions, but generally it is the period from the end of the deuterium ionization phase to the region of peak current. There is no significant variation in λ over this time period and it is therefore assumed that the measured value of λ applies throughout the current pulse.

The measurements of Λ given above refer specifically to the time of peak current. It was pointed out earlier that the spectral line intensity in the injection tail varies considerably with time, as can be seen from the observations of O VI given in Fig. 4. In determining whether this variation is due to a variation of injection, we apply the test used in § 4 when it was shown that the injection coefficients Λ determined at peak current from Eqn (12) for the ionic sequence O IV, O V and O VI, gave the same value within the experimental error. This test was also applied at a time after peak current when the spectral line intensity in the tail had dropped to about 25% of its peak value. The mean of several measurements, normalized to O IV, give $\Lambda(\mathrm{O\,IV}):\Lambda(\mathrm{O\,V}):\Lambda(\mathrm{O\,VI}) = 1{\cdot}0:1{\cdot}0:1{\cdot}2$. The time variation of spectral line intensity in the tail is therefore taken as an injection variation.

The variation of Λ with time is slow compared with $\tau_c = 1/\lambda$. Hence the assumption of constant Λ, made in the original equations, is valid, and to determine the variation of plasma density with time, it is legitimate to replace Λ in Eqn (5) with $\Lambda(t)$, the observed time variation of the injection coefficient. Further, the time variation in plasma density will be dominated by the slow variation in $\Lambda(t)$ and we can therefore equate the $\exp(-\lambda t)$ term to zero for $t > 1/\lambda$. Replacing the number density ($n\,\mathrm{cm}^{-3}$) by the density per unit length of discharge ($N\,\mathrm{cm}^{-1}$), then this line density at time t is given by

$$\begin{aligned} N(t) &= N_i(t) = N_e(t) \\ &= N_0 \qquad (\text{for } t = 0) \\ &= \sigma N_0 \Lambda(t)/\lambda \ (\text{for } t > 1/\lambda) \qquad \ldots\ldots (19) \end{aligned}$$

where N_0 is the initial line density and σ is the constant given in Eqn (18) which relates the injection coefficients of deuterium and the observed impurity ions. The assumptions on which the application of Eqn (19) depend, i.e. that $\sigma \simeq 1$, and that T_e and λ are constant through the pulse, cannot be verified directly. However, since the existence of loss and injection processes has been established, qualitative predictions, based on results derived from Eqn (19), will be correct. Further, quantitative predictions can be tested against other types of observation, and it will be seen in what follows that these assumptions are confirmed.

The calculated values of $N(t)$ at intervals during single pulses at different values of θ_p in discharge condition 3 of Table 2, are shown in Fig. 9 together with the corresponding current waveforms. The points at which $N(t)$ is measured have been linked by a smooth curve; the broken curves denote the region of interpolation between the earliest measured position and the initial line density.

The general feaures of the $N(t)$ curves are similar. The line density falls to a minimum, then rises to a maximum in the region of peak current which is followed by a general decrease. This is the result of a loss rate on which is superimposed a slowly varying injection rate. The injection observed during a current pulse shows that Λ is roughly proportional to the current. The minimum in $N(t)$ is therefore caused by an initial loss which is eventually counteracted by the increase in $\Lambda(t)$, and the final decrease in line density is due to the reduced injection after peak current. In general, the loss rate is greater than the injection rate and the combined effect is to produce a decrease of plasma density with time. This net plasma loss has been named 'pump-out' by Bernstein *et al.* (1957).

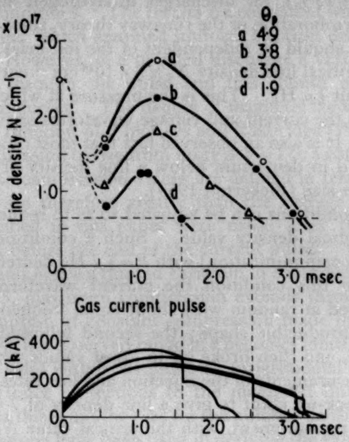

Fig. 9. Measured pump-out during the ZETA pulse ($P=\frac{1}{2}\,\mu\ D_2$, $V_C=10$ kv).

An important result of the present work is shown in Fig. 9. It will be noticed that when the line density drops to a critical value ($N_C \simeq 6\times10^{16}\,\mathrm{cm}^{-1}$) there is a sudden drop in the current. The presence of this phenomenon in the current waveform has been known since the earliest operations of ZETA and is accompanied by a sharp burst of X-rays. Using the present result that the discontinuity occurs at a critical line density, Gibson and Mason (1961) have shown that the phenomenon is consistent with a runaway process. The plasma density decreases until the electron drift velocity becomes comparable with the thermal velocity, when the electrons gain energy rapidly from the electric field and strike the walls of the containing vessel to produce the observed X-rays. Quantitative measurements of the energy of the observed X-rays support this interpretation.

The critical line density has been measured for all conditions that the discontinuity is observed and the results are given, for each discharge condition, in Table 2. The standard error at the foot of the column is an internal one. No value is given for condition 7 as the phenomenon is not observed. This is because the high initial pressure of $2\,\mu$ Hg prevents the density from falling to the critical value. In all cases other than condition 6 the values of N_C are the same within the error of measurement. The accuracy is insufficient to determine whether there is any small variation with pressure or condenser bank voltage. However, the low value of N_C for condition 6 is significant, and is due to the relatively large amount of argon (5%) which had to be used at this low pressure ($\frac{1}{4}\,\mu$ Hg) for the argon lines to be observed. It has been known for some time that the discontinuity in the current waveform can be inhibited, and indeed removed completely, by adding impurities to the gas. Thus the presence of the phenomenon is used as an indication that the discharge is 'clean' and conditioned.

The measured values of critical line density are the same, within the experimental accuracy (±15%), for discharges in hydrogen and deuterium. This provides further corroboration of the runaway theory, since this requires that the critical line density should be independent of the ion mass.

The observed critical line density $N_c \simeq 6 \times 10^{16}\,\mathrm{cm}^{-1}$ corresponds to an initial gas pressure of about $\frac{1}{8}\,\mu$ Hg. This is the pressure at which the discharge gives breakdown trouble, the current and voltage waveforms showing sharp transients (Butt *et al.* 1958). It is also an observed fact that most pinched discharges have not been maintained in deuterium below a line density of about $5 \times 10^{16}\,\mathrm{cm}^{-1}$, independent of tube size (Bickerton 1959).

The discharge conditions can be adjusted so as to reduce the minima shown in Fig. 9 to the critical density value. Such a condition has been observed (Ward 1960, private communication) with $P = \frac{1}{4}\,\mu$ Hg deuterium, $V_c = 15$ kv, and $B_z = 1200$ gauss. In this condition the current waveform had two different forms which occurred at random with about equal frequency. The first had a normal, smooth, reproducible shape; the second followed the first to a point before peak current, and then broke off to lower values with a jagged unreproducible form. Measurements of the injection and loss rates were made at a time just prior to the break-off point to give a line density of $7 \times 10^{16}\,\mathrm{cm}^{-1}$, agreeing within the error of measurement, with the critical value N_c derived above. It should be stressed that only a minimum in the pump-out curve can explain this result. If the injection is sufficient to keep the minimum just above the critical value, the discharge will recover and we get the normal type of current waveform; however if the minimum drops below the critical value then an abnormal current waveform results. The curves shown in Fig. 9 refer to θ_p values greater than 1·9. The discontinuity in the current waveform is not observed at low θ_p values, and the nature of the discharge appears to change below about $\theta_p = 1{\cdot}3$. This value corresponds to the point of minimum injection shown in condition 3 of Fig. 7. All of the pump-out calculations were made for conditions in which θ_p was greater than this value.

A direct measure of the electron density at one point on the predicted density curve has been obtained by an 8·7 mm microwave transmission experiment (Wort 1960, private communication). The electron densities in ZETA are generally too high for transmission at this wavelength, but the observations predict that n_e will drop to about $10^{13}\,\mathrm{cm}^{-3}$ at the onset of the discontinuity in the current waveform. This density is below the critical value ($1{\cdot}5 \times 10^{13}\,\mathrm{cm}^{-3}$) for transmission of 8·7 mm microwaves. Observations were made for the case $\theta_p = 1{\cdot}9$ in Fig. 9, which showed an onset of transmission at about 0·1 msec prior to the discontinuity. This indicated a density of $1{\cdot}5 \times 10^{13}\,\mathrm{cm}^{-3}$ at this time, which is to be compared with the value of $1{\cdot}3 \times 10^{13}\,\mathrm{cm}^{-3}$ predicted by the present work. The agreement shown by these figures may be somewhat better than the uncertainties justify, but the experiment affords a direct quantitative confirmation by an entirely different technique of the pump-out calculations. This result, together with the establishment of an energy balance and the explanation of the current waveform discontinuity, supports the main conclusions of this paper. The interpretation of the processes occurring in ZETA in terms of the partially contained plasma model described above is therefore adequately confirmed.

§ 6. Discussion

The work described above has established the existence of loss and injection processes in ZETA and has also determined the general dependence of these processes on discharge conditions. The results are consistent with the simple plasma model described earlier which assumed uniform electron density in a plasma of fixed dimensions. However, in a pinched discharge a variable degree of compression can occur through the pulse and this should be considered when calculating pump-out curves. The degree of magnetic compression in ZETA has been measured as a function of θ by Lees and Rusbridge (1959). Their results show the radial compression to rise from unity at $\theta = 1$ to a constant value of about two for $\theta > 2$. These compression values are defined in terms of the maximum measured field and are therefore greater than the average compression. The measurements described in this paper were made after the initial deuterium ionization phase and before the end of the current pulse. They therefore cover a limited range in θ and hence a limited variation in compressed plasma diameter. When θ_p exceeds 2·5, maximum compression extends throughout the observed range and the assumption of constant compression made in the model is valid. For lower values of θ_p, the observed range in θ becomes more restricted so that the assumption is again valid within the limits of experimental error (see results for $\theta_p = 1{\cdot}9$, Fig. 9). Hence corrections to the measured line density ($N_e\,\mathrm{cm}^{-1}$) are not necessary, but this is not the case for the number density ($n_e\,\mathrm{cm}^{-3}$), and the appropriate compressions have been used in deriving the values of n_e given in the text.

Pump-out has been shown to occur in the Stellarator (Bernstein *et al.* 1957, Spitzer 1958, Ellis *et al.* 1960 a) by direct observation of the electron density measured with a microwave interferometer. This technique cannot be used with ZETA because the electron density is generally too high for transmission of available microwave frequencies. The electron density in the Stellarator shows an initial rise due to the ionization phase, followed by an exponential decrease due to particle loss. Later observations (Ellis *et al.* 1960 b) show that the loss process also occurs during the ionization phase. These results indicate that the loss rate coefficient is constant throughout the ohmic heating pulse, as was assumed in the present ZETA work.

Direct observations of electron density measure the combined effect of the injection and loss processes, whereas the present method measures them separately. The Stellarator workers use the same expression for dn_e/dt as given in Eqn (4) but with the added assumption that the injection is proportional to the loss rate λn_e and to the initial gas pressure. In ZETA these assumptions are clearly invalid, but the observed pump-out curves are quite different in the two devices. Further, these assumptions explain the exponential decay of electron density observed in the Stellarator.

The observed containment times in ZETA and in the Stellarator are of the same order of magnitude ($\simeq 0{\cdot}1$ msec) and are much shorter than would be expected from classical collisional diffusion theory. Although the two devices use different containment systems, it would not be surprising if the enhanced diffusion of plasma across the confining magnetic fields resulted from the same fundamental process. A possible mechanism has been suggested by Spitzer (1960).

The nature of the injection process is also unknown, but two possible mechanisms—thermal evaporation and unipolar arcs—have been described by

Robson and Hancox (1959). If the heat loading on the discharge tube wall during a current pulse causes the evaporation of only a part of an adsorbed gas layer, then this could account for the observed magnitude and composition of the injected material. If unipolar arcs are the cause of injection, then approximate calculations show that the observed magnitude of the injection could be explained if 10% of the energy input goes into unipolar arcs.

The observations of plasma containment in ZETA show that the loss rate coefficient is roughly independent of the axial magnetic field when this is varied so as to change θ_p from 1 to 5. This is a surprising result since we would have expected some relationship between the loss of plasma across the magnetic field and the configuration of that field. The injection coefficient, however, varies considerably with the axial field, being roughly linear with θ_p but showing a minimum at $\theta_p \simeq 1{\cdot}2$. When the discharge conditions are changed by varying the current and the pressure and atomic weight of the gas, it is shown that λ is correlated with a single parameter ϵ, the energy input per unit mass of gas. This parameter scales roughly as the square of the Alfvén velocity; however, the apparent scaling of λ with $v_A{}^2$ does not extend to variations in v_A caused by varying the axial magnetic field. Further work is required to provide theoretical explanations for the observed properties of the loss and injection processes.

ACKNOWLEDGMENTS

We are grateful for the co-operation of the Zeta Operations Group and for the help of Mr. B. C. Fawcett and Mr. J. G. Firth. The investigation has benefited from many helpful discussions with Mr. R. S. Pease and with other colleagues in the Controlled Thermonuclear Reactions Division.

Interferometric Measurements of the Electron Density in a Shock Heated Deuterium Plasma

By J. K. WRIGHT, R. D. MEDFORD, A. G. HUNT and J. D. HERBERT
Atomic Weapons Research Establishment, Foulness, Southend-on-Sea, Essex

MS. received 11*th May* 1961, *in revised form* 11*th July* 1961

Abstract. The first results are reported of experiments new to plasma research, namely time-resolved interferometry in the optical region. It is shown how the electron density distribution of a fast cylindrical pinched discharge may be measured and how the physical conditions in the discharge may be deduced from such measurements.

---

§ 1. INTRODUCTION

THE experiments in which Alpher and White (1958) and later Ascoli-Bartoli *et al.* (1960) successfully measured electron densities of the order of 10^{17} per cm^3 have shown that the optical interferometer is a powerful tool for the measurement of high density plasmas. Previously microwave transmission methods have been used to measure the electron density of deuterium plasma, but it was found that the highest measurable density was about 10^{13} per cm^3 due to experimental difficulties (Harding *et al.* 1958).

In this paper we describe an experiment to determine the spatial distribution of electrons in an electromagnetically driven electrodeless deuterium discharge (Wright, Eeles and Herbert 1959) using a time-resolved interferometric technique.

§ 2. TRANSMISSION OF ELECTROMAGNETIC WAVES THROUGH A PLASMA

The wave equation for an electromagnetic wave in a plasma is, with certain simplifications, given by Spitzer (1956) as

$$\frac{\partial^2 E_y}{\partial x^2} - \frac{4\pi n_e e^2 E_y}{m_e c^2} = \frac{1}{c^2}\frac{\partial^2 E_y}{\partial t^2} \qquad \ldots\ldots(1)$$

where the 'plasma frequency'

$$\omega_p = \left(\frac{4\pi n_e e^2}{m_e}\right)^{1/2} \qquad \ldots\ldots(2)$$

and n_e is the number of electrons per cm^3, m_e the electron mass and e the electronic charge (e.s.u.). A possible solution is

$$E_y = E\exp\{i(\beta x + \omega t)\}$$

where

$$\beta \simeq \frac{\omega}{c}\left(1 - \frac{\omega_p^2}{2\omega^2}\right)$$

and $f_p = \omega_p/2\pi = 8{\cdot}97 \times 10^3 n_e^{1/2}$ from Eqn (2).

If the transmitted wavelength is $\lambda = 2\pi c/\omega$ we obtain

$$\beta = \frac{\omega}{c}(1 - 4{\cdot}5 \times 10^{-14} n_e \lambda^2).$$

Thus the phase refractivity is $-4{\cdot}5 \times 10^{-14} n_e \lambda^2$. ......(3)

Therefore if a light beam from an interferometer is transmitted through x cm of plasma there will be

$$\Delta N = 4{\cdot}5 n_e 10^{-14} x\lambda \text{ wavelengths shift,} \qquad \ldots\ldots(4)$$

i.e. for monochromatic light of wavelength about 5×10^{-5} cm there will be approximately one-fifth of a wavelength shift when the light is transmitted through plasma having a number density of 10^{17} and length 1 cm.

§ 3. EXPERIMENTAL METHOD

A Mach–Zehnder interferometer (Ladenburg and Bershader 1955) is set up to give a pattern of vertical interference fringes across the full width of a cylindrical electrodeless discharge. An image of this is focused on to the horizontal slit of a high speed rotating mirror streak camera and photographed on a fixed length of film. At a suitable part of the camera sweep a high voltage capacitor is discharged into the single copper turn used to form the electrodeless discharge, whilst monochromatic light from a spark discharge is passed through the discharge tube. The result is a streak picture (radius–time curve) of the fringe shift with the self-luminous electrodeless discharge superimposed. More of the experimental detail is given below and a schematic diagram of the optical layout is shown in Fig. 3.

In the Mach–Zehnder interferometer one pair of glass plates is inserted into the working section and the compensating pair is used to give control over the position and the spacing of the fringes, in addition to the other mirror adjustments. It was found that microscope slides split lengthwise and with one half in each beam could be selected to give fringes with little distortion; in this way such pairs were used to provide windows for the discharge tube and the corresponding compensating glasses.

The instrument was finally adjusted to provide a vertical fringe pattern across a diameter of the discharge tube. At this stage of the experiment 10–15 fringes were set up to cover approximately one-half of the diameter.

Fig. 1. Electrodeless discharge tube.

A cylindrical discharge tube 2 inches in diameter and 1·5 inches long was made in ½ inch Perspex; a recessed horizontal slit was cut in each face to accommodate the half microscope slide and these were secured in place with vacuum grease. A ½ inch pipe let into one face led off to a high vacuum pumping unit and gas filling system (see Fig. 1). A single turn coil 3·5 cm wide was wrapped around the centre section and connected to an 8 μF low inductance condenser consisting of 8 units each of 1 μF and 1 mμH self inductance connected in parallel. Low inductance connections between the units and the model were made with flat copper strips, 6 inches wide, separated by 0·004 inch Melinex insulation. The condensers were discharged into the coil via a low inductance explosive type switch. To ensure reliable breakdown of the deuterium gas on the first half cycle of the discharge it was necessary to pre-ionize with a Tesla coil.

The streak camera includes three photomultiplier units which give out pulses at appropriate parts of the sweep. The first pulse is used to initiate the whole firing sequence through a series of pulse delay units, i.e. the oscilloscopes monitoring the event are triggered and the spark light source is pulsed 1 μsec before the explosive switch is fired. The other two photomultiplier pulses are recorded on a slow sweep single stroke time base and enable the streaking speed of the camera to be determined. Fig. 2 is a schematic diagram of the synchronizing and firing circuit.

A special high intensity short duration light source was developed from a 'trigatron' valve (pressurized triggered spark gap filled with argon and small percentages of oxygen and nitrogen). A 1 μF condenser charged to 10 kv and discharged across the gap gave a spark of 5–10 μsec duration and adequate intensity for recording on HPS film. A part of the emitted spectrum was selected with a narrow band interference filter to provide nearly monochromatic light of bandwidth 70 ångströms centred on a wavelength of 4670 ångströms.

Fig. 2. Synchronizing and firing circuits.

This interference filter was placed adjacent to the spark light source so as not to attenuate the light from the electrodeless discharge.

The streak camera was focused on to a reduced image of the fringe pattern produced by a supplementary lens placed between the Mach–Zehnder interferometer and the camera. This was necessary to give a suitable image size on the recording film. An iris diaphragm placed between the supplementary lens and the exit lens of the Mach–Zehnder interferometer was used to control the amount of light from the discharge entering the camera lens without altering the amount of light from the fringes. By controlling the diaphragm aperture the relative intensities of the discharge and fringe light could be varied over a range sufficient for the present experiment. If the discharge light had been too intense for the diaphragm to give sufficient control, the narrow band interference filter could have been moved from its position close to the spark light to the iris to give a further reduction in the discharge light. A schematic diagram of the optical layout is given in Fig. 3.

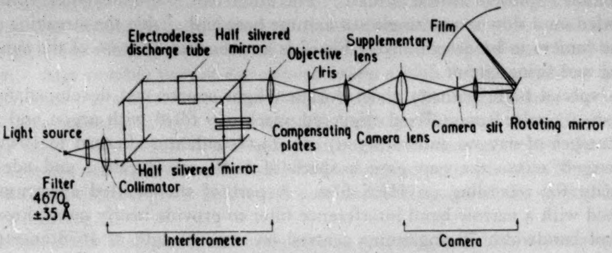

Fig. 3. Layout of optical components.

§ 4. RESULTS

Figures 4, 5 and 6 (Plate) show streak pictures of fringes superimposed on the discharge obtained when the discharge was in deuterium at ambient pressures of 1, 0·5 and 0·3 mm Hg respectively. Fig. 7 (Plate) is a streak picture of the discharge in deuterium at 1 mm Hg without the superimposed fringes. The directions in which the fringes move with increasing electron density are shown by the direction of the arrow at the right of the photograph. The direction of the time axis is from right to left in each photograph.

In each figure the first and second half cycles of the electrodeless discharge are shown. It will be noticed that the fringes are parallel before the first pinch of the discharge is initiated. When the deuterium gas is sufficiently pre-ionized a converging cylindrical shock is formed on the first half cycle of the discharge and when the shock front intersects a fringe the fringe is shifted by an amount proportional to the electron density behind the shock front. Shortly afterwards the current sheet (Wright, Eeles and Herbert 1959) intersects the displaced fringe and the fringe shifts back in the opposite direction to its normal position. Between the first and second half cycle of the discharge the fringes are very nearly parallel again and on the second half cycle the process is repeated.

It will be noticed that the shock formed on the first half cycle of the discharge does not converge on to the axis of the discharge tube because of the trapped magnetic field (Wright, Eeles and Herbert 1959, Medford *et al.* 1960) and the fringes passing close to the axis are undeflected, except in Fig. 4 where the central fringe has a slight kink. The reason for this exception is obvious when Fig. 7 is examined since at this particular gas pressure there is a bright central core of gas inside the self-luminous shell on the axis of the shock tube. The reason for the presence of the bright central core emerges from an analysis of the fringe patterns and will be discussed in §5.

§ 5. ANALYSIS OF THE RESULTS

5.1. *Measurement of Percentage of Deuterium Ionized and Swept up*

If we put the values of $x=3{\cdot}5$ and $\lambda=4{\cdot}67\times10^{-5}$ cm into Eqn (4) we obtain

$$\Delta N=7{\cdot}35n_e10^{-18}. \qquad \ldots\ldots(5)$$

This, of course, assumes that along lines parallel to the discharge tube axis n_e is constant and that there are no boundary layer effects.

Ideally fringe shifts should be measured using a microdensitometer but since, in this case, the fringe shifts are large we were able to measure the values of ΔN with a pencil and rule. Values of ΔN measured from Figs 1, 2 and 3 were converted into electron densities by using Eqn (5). From the electron densities obtained it was possible to integrate the number of electrons behind the shock front at any time, and this gave the fraction of the available deuterium swept up and ionized by the shock. We have done this for selected times during the first half cycle of the discharge and the results are given in Table 1. It is seen from this table that, as predicted by strong shock theory, (Wright 1960, Niblett, unpublished), the fraction of gas ionized increases with reduced ambient pressure and thus with increasing shock speed, and the quantities are in good agreement with theory during the initial period of implosion.

Table 1. Percentage of Gas Swept up and Ionized

Ambient pressure 1 mm		Ambient pressure 0·5 mm		Ambient pressure 0·3 mm	
Time (μsec)	Ionization (%)	Time (μsec)	Ionization (%)	Time (μsec)	Ionization (%)
0·30	17·5	0·26	37	0·43	48
0·41	17	0·35	36	0·53	60
0·52	24·5	0·41	43	0·60	78·5
0·75	20	0·66	57	0·64	85
Theory	13·0	—	30	—	47·0

From Table 1 we see that Fig. 7 corresponds to about 20% ionization behind the shock front. We conclude from this that the bright central core is a result of the trapped magnetic field holding back the ionized particles and allowing the non-ionized particles to implode on to the axis, where the increase of temperature behind the reflected shock causes ionization and the appearance of the bright central core.

5.2. *Calculation of Plasma Resistivity and Electron Temperature at the Current Sheet*

In an idealized shock model we would have expected the electron density to have a step increase to the values given by Wright (1960) and Niblett (unpublished) immediately behind the shock front and a step decrease to zero behind the current sheet. But in our experiment we have not reached sufficiently high shock speeds to give a temperature high enough for the conductivity of the plasma to exclude the driving and the trapped magnetic fields from the plasma. The magnetic fields have obviously penetrated measurable distances into the plasma during the implosion phase and altered the electron distribution.

The relation between the magnetic field strength H in the plasma and the electron number density can be derived from the following equations:

$$\frac{\partial \mathbf{H}}{\partial t} = \operatorname{curl}(\mathbf{V} \wedge \mathbf{H}) + \frac{\eta}{4\pi}\nabla^2 \mathbf{H} \qquad \ldots\ldots(6)$$

$$\rho\frac{d\mathbf{V}}{dt} = -\nabla\left(p + \frac{H^2}{8\pi}\right) \qquad \ldots\ldots(7)$$

where $\mathbf{V}$ is the velocity, p the plasma pressure ρ the plasma density and η the plasma resistivity. Eqn (6) requires η to be constant—not strictly true in our experiment. If the plasma moves with constant velocity $\mathbf{V}$ and if we approximate to the cylindrical electrodeless configuration with a plane geometry, for times taken up to a value where it is felt that errors due to the use of plane geometry become important, the equations become:

$$\frac{\partial H}{\partial t} + \frac{\partial (VH)}{\partial x} = \frac{\eta}{4\pi}\frac{\partial^2 H}{\partial x^2} \qquad \ldots\ldots(8)$$

$$2n_e kT + \frac{H^2}{8\pi} = \text{constant}, \qquad \ldots\ldots(9)$$

and if we put $x = x_1 + Vt$ in Eqn (8), we obtain

$$\frac{\partial H}{\partial t} = \frac{\eta}{4\pi}\frac{\partial^2 \mathbf{H}}{\partial x_1^2}. \qquad \ldots\ldots(10)$$

Solving this for the boundary conditions

$$H(x_1, t) \to 0 \text{ as } x_1 \to \infty$$

and $$H(x_1, t) \to H_0 \text{ as } x_1 \to 0$$

we obtain

$$H(x, t) = H_0 \operatorname{erf_c}\left(\frac{x - Vt}{2(\eta t/4\pi)^{1/2}}\right), \qquad \ldots\ldots(11)$$

and if we change back into cylindrical coordinates we get

$$H(r, t) = H_0 \operatorname{erf_c}\left(\frac{a - r}{(\eta t/\pi)^{1/2}}\right), \qquad \ldots\ldots(12)$$

where a is the radius of the current sheet at time t, and $H = H_0$ at the current sheet. From Eqn (9) and the boundary conditions for H together with the condition that when $H = 0$, n_e is a maximum n_m, say, and when $H = H_0$, $n_e = 0$ and assuming that T is constant with respect to time and radius, we obtain

$$n_e(r, t) = n_m\left\{1 - \operatorname{erf_c}^2\left(\frac{a - r}{(\eta t/\pi)^{1/2}}\right)\right\}. \qquad \ldots\ldots(13)$$

From the interference fringe patterns it is possible to obtain the variation of electron number density n_e with radius for a fixed value of t, and by using Eqn (13) a fit can be made to the error function curve thus enabling the resistivity η to be computed. The maximum number of experimental points available for curve fitting at any fixed time is only three because the number of fringes is small and only values of η calculated from three experimental points are given. The values of η calculated are given in Table 2 together with the associated values of electron temperature given by Spitzer's formula

Table 2. Plasma Resistivity and Electron Temperature calculated from Fringe Shifts

Ambient pressure	1 mm		0·5 mm		0·3 mm	
Shock speed	2·6 cm μsec^{-1}		3·1 cm μsec^{-1}		3·5 cm μsec^{-1}

Time (μsec)	η (e.m.u.)	T_e (°K)	η (e.m.u.)	T_e (°K)	η (e.m.u.)	T_e (°K)
0·32			2·63.10^{6}	6·0.10^{4}		
0·34			2·86.10^{6}	5·6.10^{4}		
0·40					1·4.10^{6}	9·0.10^{4}
0·45	0·94.10^{6}	1·2.10^{5}	0·74.10^{6}	1·67.10^{5}		
0·47	3·14.10^{6}	5·2.10^{4}				
0·48	2·27.10^{6}	6·5.10^{4}				
0·49	3·27.10^{6}	5·1.10^{4}				
0·50			0·86.10^{6}	1·26.10^{5}		

$$\eta = 3{\cdot}80\times 10^{12} Z \ln(\Lambda)\, T^{-3/2}\ \text{e.m.u.}, \qquad \ldots\ldots(14)$$

where $\ln(\Lambda) = 10$ and $Z = 1$ for deuterium. Also included in Table 2 are the values of temperatures calculated from the measured shock speed and the Rankine–Hugoniot equations excluding the effect of the magnetic fields (see Wright 1960).

It will be noticed that the values of temperature calculated from the interference fringe patterns are generally higher than the temperatures calculated from the shock velocity. This effect has been observed in helium by McLean, Griem, Faneuff and Kolb (1960) and by Wiese, Berg and Griem (1960) in hydrogen and helium. These authors interpret the heating effect as being due to the fact that gas ahead of the shock has been preheated by precursor radiation, but in this case the reason may be that the plasma is still low enough in temperature for Joule heating to be effective (see Wesson 1960).

The following approximate calculation gives the increase in temperature ΔT_e when Joule heating is taken into account.

The 'skin depth' at time $t = \delta \simeq 2(\eta t/\pi)^{1/2}$ cm. ......(15)

Therefore the resistance of the skin to azimuthal current is

$$R = \frac{\eta}{10^{9}}\,\frac{2\pi a}{3{\cdot}5\delta}\,\Omega\,; \qquad \ldots\ldots(16)$$

the Joule heat is then

$$J = 100 I^2 \frac{\eta}{10^9} \frac{2\pi a}{3{\cdot}5\delta} t \text{ joules} \qquad \ldots\ldots(17)$$

If H_0 is the magnetic field strength external to the plasma, then from Eqn (9) we obtain

$$\frac{H_0^2}{8\pi} = \frac{H^2}{8\pi} + 2nkT = 2n_m kT, \qquad \ldots\ldots(18)$$

and since H_0 is produced by a single turn coil

$$H_0 = \frac{4\pi I}{3{\cdot}5}, \qquad \ldots\ldots(19)$$

therefore

$$J = 3{\cdot}5 n_{\mathrm{m}} k T a (\pi\eta t)^{1/2} 10^{-7} \text{ joules} \qquad \ldots\ldots(20)$$

Equating this to $\frac{3}{2} n\, k\Delta T$ erg, where $n \simeq n_{\mathrm{m}}/2$, gives

$$\frac{\Delta T}{T} \simeq \frac{4}{3} 3{\cdot}5 a (\pi\eta t)^{1/2}. \qquad \ldots\ldots(21)$$

If we take values at $t = \frac{1}{2}\,\mu$sec then, from the experimental results, $\eta = 10^6$ e.m.u. and $a = 1{\cdot}5$ cm, hence

$$\frac{\Delta T_{\mathrm{e}}}{T_{\mathrm{e}}} \text{ is of the order of 10,} \qquad \ldots\ldots(22)$$

and from Table 2 we see that, in general, this is the correct order of magnitude. The accuracy of the value of temperature obtained from the interference fringe patterns would, or course, be improved if the number of fringes were increased.

5.3. *Equilibrium Ionization behind the Shock Front*

It is apparent from an examination of the fringe patterns that the electron number density behind the shock front takes a finite time to reach a maximum. A measure of this rise in time should give information about the ionization process immediately behind the shock front. We are concerned with a strong shock moving at the order of 3 cm μsec^{-1} into cold deuterium. The first action will be to heat and dissociate the deuterium leaving us with deuterium atoms at a temperature T corresponding to an energy of the order of 3 to 6 ev depending on the actual value of the shock speed. At these low temperatures the atom–atom ionization cross section is very small, but the electron–atom ionization cross sections are appreciable. Petschek (1955) has pointed out that under these conditions the electrons take an appreciable time to heat up. The following approximate calculation gives the time constant for the electron multiplication in the early stages of the process when recombination can be ignored.

If the electronic and atomic masses are m and M respectively, the electron gains a fraction $4m/M$ of the energy of the atom at each collision. Hence if it loses an energy I every time it ionizes an atom, the electron makes on average $MI/6kTm$ elastic collisions with atoms before it is capable of effecting an ionization. The average electron velocity is of the order $(3kT/2m)^{1/2}$ assuming its energy is, on average, half the energy of the atoms. Hence the time constant for multiplication of electrons is of the order

$$\tau = \frac{MI/6kTm}{N\sigma(3kT/2m)^{1/2}}$$

$$\tau = 0{\cdot}14\,\frac{MI}{N\sigma(kT)^{3/2}m^{1/2}}. \qquad \ldots\ldots (23)$$

In this formula N is the number of atoms per cm^3 just behind the shock front and will be of the order of 15 times the number of deuterium molecules per cm^3 just ahead of the shock front. σ is the electron–atom elastic scattering cross section at low energies and will be of the order of 25×10^{-16} cm^{-2}. This is the total elastic cross section—the cross section for appreciable energy exchange will be somewhat less than this. To compensate for this we have taken the lower value of $T(3 \times 10^4$ ev) in working out the time constants in Table 3. The agreement with the experimental values is better than could be expected from such a crude treatment.

Table 3. Time Constants for Multiplication of Electrons behind the Shock Front

Ambient pressure 1 mm		Ambient pressure 0·5 mm		Ambient pressure 0·3 mm	
Measured	Calculated	Measured	Calculated	Measured	Calculated
0·04 μsec	0·02 μsec	0·06 μsec	0·04 μsec	0·09 μsec	0·06 μsec

§ 6. CONCLUSIONS

We have found that the optical interferometer technique is one of the most satisfactory tools for the investigation of high density, high temperature plasmas. Using the technique we have measured the spatial distribution of electron density with time and obtained the percentage of deuterium that has been ionized and swept up by the shock. From the fringe patterns we have inferred the penetration depth of magnetic field into the plasma and calculated the electron temperature. The electron temperatures obtained were higher than the temperatures predicted by the Rankine–Hugoniot equations and we have shown how the temperature difference can be caused by Joule heating of the plasma skin.

An approximate theory of the approach to equilibrium ionization behind the shock front has been given and found to agree with the measured time for the increase of electron density behind the front.

It has been particularly satisfying to use a diagnostic technique that has not been subject to electromagnetic interference and enables some of the plasma parameters to be measured without the introduction of large perturbation effects. The disadvantages of the technique, as used in this experiment, are that all effects are integrated along the optical path and boundary effects are not taken into account.

ACKNOWLEDGMENTS

We wish to thank Mr. K. Mead for his help in setting up the Mach–Zehnder interferometer and also Mr. H. E. Bulless for his invaluable assistance in the experiment. We are indebted to the Director of Atomic Weapons Research Establishment for permission to publish this paper.

A Low Temperature Adiabatic Calorimeter for Condensed Substances. Thermodynamic Properties of Argon

By P. FLUBACHER†‡, A. J. LEADBETTER†§ and J. A. MORRISON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Communicated by M. Blackman; *MS. received 25th May* 1961

Abstract. An adiabatic calorimeter has been constructed for the study of properties of condensed substances in the temperature range 2° to 300°K. Two resistance thermometers were used, one of platinum for $T > 11$°K and one of carbon for $T < 11$°K. The carbon thermometer was calibrated on the thermodynamic temperature scale by using the calorimeter vessel as a gas thermometer; subsequent absolute shifts of its resistance on cycling between room temperature and liquid helium temperatures were taken into account by calibrations against the platinum thermometer.

The heat capacities of solid and liquid argon have been measured between 2° and 86°K with estimated accuracies to $\pm 2\%$ at the lowest temperatures, increasing to $\pm 0{\cdot}2\%$ for $T > 20$°K but decreasing to $\pm 0{\cdot}5\%$ at the highest temperatures. In conjunction with these measurements, vapour pressures were measured in the temperature range 66° to 86°K.

The heat of fusion was found to be $284{\cdot}5 \pm 0{\cdot}4$ cal mole^{-1}, the triple point temperature 83·810°K and the triple point pressure $516{\cdot}86 \pm 0{\cdot}02$ mm Hg. The amount of impurity in the specimen of argon was estimated to be 3 parts per million from a study of the melting range.

Direct measurement of the heat of vaporization of the liquid gave the result $1563{\cdot}6 \pm 4{\cdot}6$ cal mole^{-1} at 85·67°K, which corresponds to $1555{\cdot}0 \pm 4{\cdot}6$ cal mole^{-1} at the normal boiling point.

§ 1. Introduction

Because of their simple crystal structure and supposed simple interatomic forces, the solids of the inert gas elements have been widely studied from the theoretical point of view. Also, many of their properties have been measured experimentally. Unhappily, much of the theory contains approximations whose consequences are difficult to judge, and much of the experimental information is incomplete. Definitive comparisons between theory and experiment are, therefore, still to be made.

One object of the present work was to provide more complete and more accurate information on the thermodynamic properties of some of the inert gas solids. In part, the work was stimulated by concurrent theoretical calculations by Horton and Leech (1962, to be published), who have obtained accurate numerical values for thermodynamic properties corresponding to models of the inert gas solids based on the Mie–Lennard-Jones potential. The calorimetric method which has been developed can, however, be used quite generally for measurements on condensed substances in the temperature range between 2°K and room temperature. It has, for example, been used to measure heat capacities of ice at low temperatures (Flubacher, Leadbetter and Morrison 1960).

§ Present address: Department of Physical and Inorganic Chemistry, The University, Bristol.

In § 2 of this paper we describe the calorimeter assembly, the techniques used to determine the different quantities and the important matter of the temperature scale. In § 3 the results of measurements on argon are given. These include the heat capacities of the solid and liquid, heats of fusion and of vaporization and vapour pressures of the solid and liquid. Where possible, comparisons are made with results published by others. Some of the numerical values given here differ slightly from ones contained in a preliminary report (Flubacher, Leadbetter and Morrison 1961). The differences are due to small arithmetical errors which have now been corrected. Equivalent results for krypton are given in the following paper together with a detailed analysis of the properties of solid argon and solid krypton.

§ 2. EXPERIMENTAL

2.1. *The Calorimeter Assembly*

Different types of calorimeters have been developed for heat capacity and other measurements on condensed substances over a wide temperature range below room temperature (see Sturtevant (1949) for a general discussion and references). However, only infrequently have they been used for measurements below solid hydrogen temperatures (i.e. $T < 11$°K). Generally, measurements in this range are made with somewhat different techniques (see, for example, Hill and Lounasmaa 1959). For our present purposes it was important to obtain the thermodynamic data from temperatures well below 11°K, and also it was desirable to avoid using two calorimeter assemblies. The assembly which we shall now describe accomplishes these objects. It can be used for continuous measurements between 2°K and room temperature. Essentially, it is a conventional adiabatic low temperature calorimeter assembly to which has been added a liquid helium stage.

In basic design the cryostat is similar to one described previously (Morrison, Patterson and Dugdale 1955). Liquid helium is made in the apparatus by means of a Simon expansion bomb (Pickard and Simon 1948), and the cooling of the calorimeter and adiabatic shield below 11°K is accomplished by conduction of heat along the electrical leads, which make thermal contact with the bomb. A photograph of the interior of the cryostat is shown in Fig. 1. The helium bomb C and the adiabatic shield A are hung below the liquid hydrogen container D on nylon cords. In operation, the cryostat is closed by two concentrically arranged metal cans sealed with Wood's metal at X.

The electrical leads into the cryostat are of 36 a.w.g. copper except for inserts of constantan (15 cm of 30 a.w.g.) between C and D and between A and the calorimeter vessel (see below). The junctions between the copper and constantan, although insulated, are brought into good thermal contact with D and C at Y.

The calorimeter filling tube B (1 mm outer diameter, 0·1 mm wall thickness, German silver) is provided with a heater over its entire length from the top of the shield A to the point where it emerges from the top of the cryostat. It is also attached to D through a thermal shunt (10 cm of 28 a.w.g. copper, wound with

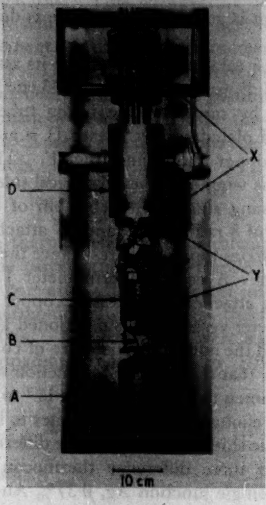

Fig. 1. A photograph of the interior of the cryostat. (For identification of parts, see text.)

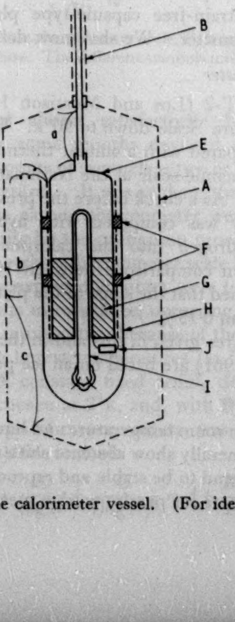

Fig. 2. A sectional view of the calorimeter vessel. (For identification of parts, see text.)

a heating element) whose purpose is to provide a path for heat to be taken from the tube during the experiments at the very low temperatures. The temperature of the point where the shunt is attached to the tube is determined with a thermocouple.

A sectional view of the calorimeter vessel and its associated parts is shown in Fig. 2. The vessel itself, E, (internal volume ~43 cm^3) is made of gold, 0·3 mm thick. It is suspended by means of the filling tube B within the adiabatic shield A. An outer gold plated copper sheath H is attached to the vessel with Wood's metal through copper reinforcing rings F. The calorimeter heater (36 a.w.g. manganin, 160 Ω) is wound on the cylindrical side of the calorimeter vessel between the top reinforcing ring and the bottom of the vessel. Heat is distributed inside by means of 8 radial gold vanes G attached to the side and to the re-entrant well, which carries a platinum resistance thermometer I cast in with a thin film of paraffin wax. A carbon thermometer J (Allen Bradley, ½ watt, nominal value ~10 Ω) is attached by means of copper lead wires wound several times around the calorimeter vessel. As is mentioned above, lead wires between the calorimeter vessel and the adiabatic shield are of constantan. Their lengths (~20 cm) were so chosen that the thermal conduction would be high enough for the calorimeter and specimen to be cooled from 11° to 2°K in a reasonable time (5 hours or less), yet low enough for the calorimeter to be not unduly sensitive to the control of the adiabatic shield. Temperature differences within the adiabatic shield are detected with three difference thermocouples: *a*, triple junction chromel–constantan; *b*, single junction Ag, 0·37% Au–Au, 2·4% Co; *c*, single junction chromel–constantan.

2.2. *Temperature Scale*

As is indicated in the previous section, the calorimeter assembly contains two thermometers, a strain-free capsule-type platinum thermometer and a carbon resistance thermometer. We shall now describe their calibrations.

2.2.1. *Platinum thermometer*

This thermometer, T-2 (Los and Morrison 1951), was calibrated on the International Temperature Scale down to 90°K. In the temperature range 11° to 90°K it was intercompared with a similar thermometer which had been calibrated on the thermodynamic scale at the National Bureau of Standards (Hoge and Brickwedde 1939). As a check before the present experiments were undertaken, the thermometer was compared with hydrogen vapour pressures by condensing normal hydrogen into the calorimeter vessel. The maximum deviation found in seven comparisons between 14·8° and 20·5°K was 0·006°. It could also be determined that the slope of the platinum thermometer scale was not in error by more than 0·15%.

All of the temperatures given in this and in the following paper (Beaumont, Chihara and Morrison 1961) are based on an ice point of 273·15°K.

2.2.2. *Carbon thermometer*

When cycled between room temperature and liquid air temperatures or lower, carbon thermometers generally show absolute shifts in resistance. If kept below 90°K the thermometers tend to be stable and reproducible. In order, therefore, to use carbon thermometers for precise work a means of calibrating them *in situ* needs to be provided, and this is often done by incorporating vapour pressure thermometers into the apparatus. This, however, is not without disadvantages for calorimetry at very low temperatures because heat leaks are increased.

In the present arrangement the carbon thermometer, which was used as the working thermometer for $T < 11$ °K, could be calibrated easily in the temperature range 11° to 20°K by direct comparison with the platinum thermometer. Since the comparison could be made with high precision, the procedure first tried was to use it to determine for each series of experiments the constants in the Clement and Quinnell (1952) formula

$$\log R + \frac{K}{\log R} = A + \frac{B}{T}, \qquad \ldots\ldots (1)$$

and so to obtain a carbon thermometer scale for calculating temperatures down to 2°K. Deviations of the carbon thermometer scale from the thermodynamic scale were determined by converting the calorimeter into a gas thermometer and comparing the carbon thermometer with the gas thermometer at a number of points between 2° and 20°K. The deviations were surprisingly small, being a maximum of 0·06° and apparently reproducible to ±0·01°.

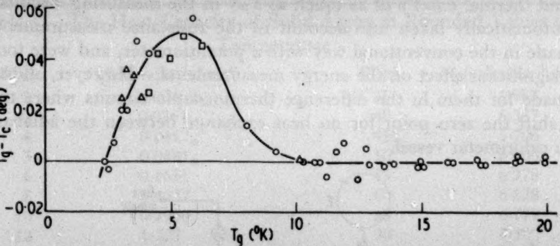

Fig. 3. The deviation of the carbon thermometer scale T_c from the gas thermometer scale T_g as a function of temperature. The different symbols indicate different gas thermometer fillings.

This initial method was almost satisfactory. However, heat capacity measurements repeated after some months deviated systematically from the original ones below 9°K by amounts of as much as two or three times the expected accuracy at the lowest temperatures. It was evident, therefore, that the absolute shifts in the resistance of the carbon thermometer were not being taken into account completely satisfactorily by the calibration procedure. In other words, it became necessary to fix the carbon thermometer scale in some better fashion at the low temperature end if the expected accuracy were to be achieved.

An examination of the shifts in resistance, occurring over a period of a year, showed that at 2°K they were unimportant because of the very large temperature coefficient of resistance at the lowest temperatures (in fact, the maximum shift was equivalent to 0·01°). A constant fixed point, determined with the gas thermometer, was therefore chosen at 2°K, and, with fixed points between 11° and 20° obtained for each series of measurements, was used to calculate a new carbon thermometer scale with the formula

$$\log R + \frac{K}{\log R} + \frac{C}{(\log R)^2} = A + \frac{B}{T}. \qquad \ldots\ldots (2)$$

The deviations of this scale from the thermodynamic scale are shown in Fig. 3. With this modification, the systematic deviations between different sets of heat capacity results either completely disappeared, or at the very least became less than the probable accuracy at all temperatures.

2.3. *Heat Capacity Measurements*

For all of the heat capacity measurements the calorimeter was operated adiabatically. At the lowest temperatures, temperature increments of about 0·5° were used, and these were increased to about $2\frac{1}{2}$° at the higher temperatures. Equilibrium times after heating varied from a few seconds at 2°K to 10 to 15 minutes for $T > 50$°K. When vapour pressures became significant, the calorimeter system was operated with the top of the adiabatic shield slightly warmer (up to 0·05°) than the calorimeter vessel. Tests for condensation in the filling tube were also made periodically by increasing the amount of heat applied to the filling tube and watching for changes in the temperature of the calorimeter vessel and in the pressure.

Under some circumstances, strong temperature gradients in the cryostat produced thermal e.m.f's of as much as 3 μV in the measuring circuits. These were automatically taken into account in the resistance measurements, which were made in the conventional way with a potentiometer, and were too small to have a significant effect on the energy measurements. However, allowance had to be made for them in the difference thermocouple circuits where their effect was to shift the zero point for no heat exchange between the adiabatic shield and the calorimeter vessel.

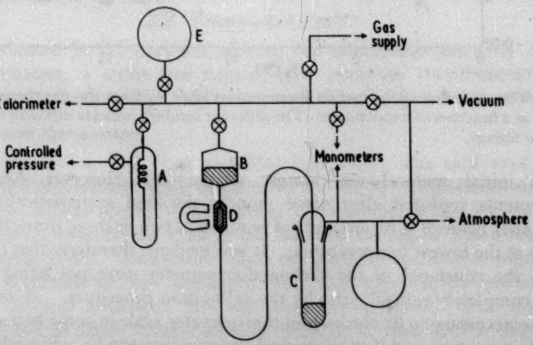

Fig. 4. The calorimeter filling system with additions for measurement of heats of vaporization. (For identification of parts, see text.)

2.4. *Measurement of Heat of Vaporization*

Heats of vaporization were determined at constant temperature by putting energy into the calorimeter and simultaneously withdrawing vapour into an external system to which the calorimeter was attached. A sketch of the experimental arrangement is shown in Fig. 4. During the vaporization, mercury was withdrawn from the reservoir B into a weighed receiver C under a manually regulated pressure head, at such a rate that the pressure of argon vapour indicated by the quartz spiral differential manometer A (sensitivity ~5 mm displacement per mm Hg) remained substantially constant. Flow of mercury between the reservoir and the receiver could be accurately started or stopped by means of an iron-loaded check valve D operated by means of a magnet. Since the volume of vapour removed was determined directly from a weight of mercury, good accuracy was obtainable with quite small volumes (20 to 50 cm^3).

All pressures were measured with a mercury manometer (not illustrated). Heights of the mercury in the two arms were determined from a calibrated steel scale mounted between them, using a comparator which could be read to 0·01 mm. Appropriate corrections were made for capillary depression.

§ 3. THERMODYNAMIC PROPERTIES OF ARGON

3.1. *Heat Capacities of the Solid and Liquid*

The argon used in the experiments was obtained from the Linde Company and was of a 'spectroscopically pure' grade. The actual specimens were measured out to an accuracy better than 0·1%, using the calibrated volume E (see Fig. 4) of the external system, and then condensed into the calorimeter vessel.

Table 1. The Heat Capacity of Solid Argon at Rounded Values of Temperature

T(°K)	C_p(cal mole^{-1} deg^{-1})	T(°K)	C_p(cal mole^{-1} deg^{-1})
2	$0{\cdot}00468_8$	35	4·983
3	$0{\cdot}0161_1$	40	5·387
4	$0{\cdot}0417_9$	45	5·706
5	$0{\cdot}0881_3$	50	6·006
6	0·1651	55	6·278
8	0·4237	60	6·528
10	0·7900	65	6·779
12	1·227	70	7·100
15	1·940	75	7·488
20	2·990	80	7·928
25	3·828	83	8·327
30	4·463		

The primary experimental results are given in the Appendix and smoothed values of the heat capacity of the solid in Table 1. Strictly speaking, what was measured was the heat capacity of the solid or liquid in equilibrium with saturated vapour, which is commonly denoted by C_{sat}. This quantity is related to C_p, the heat capacity at constant pressure, by

$$C_{\mathrm{sat}} - C_p = \left[\left(\frac{\partial H}{\partial P}\right)_T - V\right]\left(\frac{\partial P}{\partial T}\right)_{\mathrm{sat}}. \qquad \ldots\ldots(3)$$

When numerical values were inserted in Eqn (3) it was found that $C_{\mathrm{sat}} - C_p$ was less than 0·1% of C even at the highest temperatures. The difference $C_{\mathrm{sat}} - C_p$ has therefore been neglected and the results tabulated as C_p, which is the more familiar quantity. The thermochemical calorie (=4·184 abs.J) is used throughout.

Above 60°K corrections were necessary for the vaporization of argon which occurred during the heat capacity measurements. The free volume in the calorimeter vessel was calculated using densities of solid argon given by Dobbs, Figgins, Jones, Piercey and Riley (1956) and 1·43 g cm^{-3} for the density of liquid argon†. Gas imperfection corrections were made using virial coefficients determined by Staveley (1959, private communication) and Kerr (1957).

It is important to assess the accuracy of the experimental heat capacities but it is difficult to make completely satisfactory estimates. For temperatures below 60°K a major limiting factor is the knowledge of the temperature scale. As is indicated in §2.2 the scale used down to 11°K is one from the National Bureau of Standards (Hoge and Brickwedde 1939) which would appear to be reliable to ±0·02° at worst (Moessen, Aston and Ascah 1954). Resulting inaccuracies in the heat capacities should not exceed about 0·1%. The accuracy of the results at still lower temperatures depends upon the gas thermometry done in conjunction with the heat capacity experiments and is also affected by other factors such as the decreasing sensitivity of the difference thermocouple. Considering these we estimate that the results at the lowest temperatures are accurate to ±2% at worst.

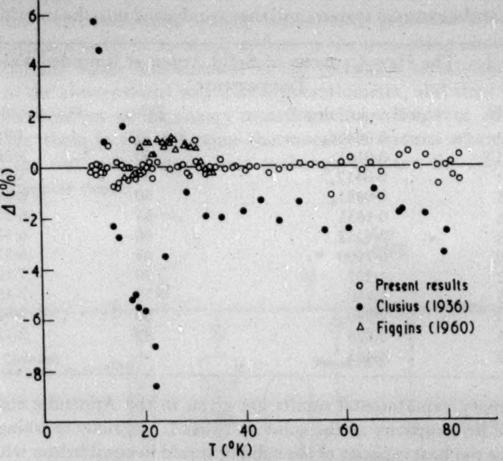

Fig. 5. A comparison of heat capacity results for solid argon.

$$\Delta\% = \frac{C_{\mathrm{p\,(obs)}} - C_{\mathrm{p\,(smooth)}}}{C_{\mathrm{p\,(smooth)}}} \times 100,$$

where $C_{\mathrm{p\,(smooth)}}$ is given in Table 1.

Additional factors must be taken into account for $T > 60$°K, where the absolute values of the heat capacities depend upon knowledge of the densities of the solid and liquid and of the virial coefficients of argon. We have made estimates of the uncertainties in these quantities and conclude that the heat capacities in the region of the triple point should be reliable to ±0·5%.

---

† Recent measurements of van Itterbeek and Verbeke (1960) indicate that the density of the liquid is about 1·40 g cm^{-3} at 86°K. The difference of 2% is not significant in the calculation of the free volumes.

To sum up: we estimate the accuracy of the present measurements to be ±2% at the lowest temperatures, increasing to ±0·2% for $T > 20$°K but then decreasing above 60°K to about ±0·5% at the highest temperatures.

Because of its bearing upon the question of accuracy, it is useful to compare the present results with those from other measurements. This is done in Fig. 5 where all of the available results in the region $T > 10$°K are plotted as differences from a smooth curve represented by the values given in Table 1. On the whole, the deviations are not large, being 2% or less for all of the results except for those of Clusius (1936) below 25°K. The agreement between the present values and all of those determined by Figgins (1960) in the range 16° to 34°K is just about within the combined estimated accuracies (±0·7%) for both sets. Other measurements of the heat capacity of solid argon between 1·5° and 20°K have been made by Anderson (1960). These will be discussed in the following paper (Beaumont, Chihara and Morrison 1961).

3.2. *Vapour Pressures of the Solid and Liquid*

The vapour pressures of the solid and liquid which were measured in conjunction with the heat capacity determinations are tabulated in the second column of Table 2. The pressures are in terms of a mercury column at 0°c and under standard gravity. The precision of the pressure measurements is estimated to be $\pm 0{\cdot}03$ mm but the accuracy is probably somewhat less than this.

The vapour pressure results were fitted to equations of the form

$$\log p(\mathrm{mm}) = A - \frac{B}{T} \qquad \ldots\ldots(4)$$

by the method of least squares and the resulting coefficients A and B are given in Table 3, where they are compared with values reported by others. The deviations of the actual vapour pressures from the corresponding equations are listed in the last column of Table 2. In doing the least squares analysis, no distinction was made between different series of measurements and all values were given the same weight. The large number of significant figures for A and B is necessary in order to give p to better than 0·05 mm at the higher pressures.

Table 3. Vapour Pressure Equations for Solid and Liquid Argon

A and B are coefficients of the equation $\log p = A - \frac{B}{T}$

Observers	A	B
Solid		
Present	7·65590	414·272
Freeman and Halsey (1956)	7·7353	420·9
Clark *et al.* (1951)	7·54454	404·84
Liquid		
Present	6·89537	350·484
Freeman and Halsey (1956)	6·9224	352·8
Clark *et al.* (1951)	6·84451	346

It is evident from the magnitudes of the coefficients in Table 3 that the present results lie in between those of Freeman and Halsey (1956) and of Clark *et al.* (1951). The differences are appreciable: for example, at 80°K, Freeman and Halsey's equation yields a pressure lower than ours by 2·3 mm and the equation of Clark *et al.* a pressure higher by 4·6 mm. There is no simple explanation for the differences other than to say that they must arise from undetected experimental difficulties. Such difficulties were minimized in the present work because the apparent heat capacity was very sensitive to distillation of the argon out of or into the calorimeter vessel.

3.3. *Heat of Fusion*

The measurements of the heat of fusion are summarized in Table 4, and the average result compared with that obtained by Clusius (1936). In the first

Table 4. The Heat of Fusion of Argon

Amount melted (mole)	Temperature range (°K)	Heat of fusion (cal mole^{-1})
0·1534	83·639–84·299	284·4

Michels *et al.* (1957)	83·809 ± 0·001	—
Freeman and Halsey (1956)	83·77	514·1
Clark *et al.* (1951)	83·78	515·7
Clusius and Staveley (1941)	—	516·85 ± 0·02
Clusius and Weigand (1940)	83·78 ± 0·02	—
Frank and Clusius (1939)	—	516·8 ± 0·2

measurement, the fusion was done in stages and measurements of the equilibrium temperature and pressure made in between. The results are given in Table 5. The triple point of pure argon, given as 83·810°K, was estimated from a plot of the equilibrium temperature against the reciprocal of the fraction melted. The amount of impurity present in the argon was also estimated from the plot and was found to be 3 parts per million. This is in very good agreement with the value of about 1 part per million determined by Lovejoy (1962)† for argon from the same source.

The present result for the triple point temperature of argon is very close to the results of Lovejoy (1962)† and of Michels *et al.* (1957) whose objects were to establish this triple point as a possible thermometric fixed point. The most careful measurements of the triple point pressure which have been made are those of Clusius and Staveley (1941). Our result comes within the limits assigned to theirs.

3.4. *Heat of Vaporization*

The results of four separate measurements of the heat of vaporization are given in Table 6. They are compared with that calculated from the temperature dependence of the vapour pressure of the liquid, and with a value published by Frank and Clusius (1939). In both comparisons the agreement is well within the assigned uncertainties.

† Note to be submitted to *Nature*.

Table 6. The Heat of Vaporization of Argon at $T = 85{\cdot}67$°K

Amount evaporated (mole)	Heat of vaporization (cal mole^{-1})
$1{\cdot}867 \times 10^{-3}$	1570·2

$2{\cdot}151 \times 10^{-3}$	1560·5
average	1563·6 ± 4·6
Calculated from vapour pressures	1555 ± 6
Heat of vaporization at normal boiling point	1555·0 ± 4·6
Frank and Clusius (1939)	1557·5 ± 1·5

§4. SUMMARY

In the foregoing sections we have given the results of measurements of the thermodynamic properties of solid and liquid argon. The results are complete in the sense that they are all that can be obtained from the calorimetric and directly associated techniques. In so far as it has been possible, we have assigned probable accuracies to the various quantities measured.

In the following paper (Beaumont, Chihara and Morrison 1961) similar results will be given for solid and liquid krypton. In addition, the vibrational and other properties of solid argon and solid krypton will be discussed in some detail.

ACKNOWLEDGMENTS

We are indebted to Mr. G. Ensell and Mr. R. Reid for valuable assistance with the construction of the calorimeter assembly. We should also like to thank Dr. H. Chihara for much help with the computations.

Thermodynamic Properties of Krypton. Vibrational and Other Properties of Solid Argon and Solid Krypton

By R. H. BEAUMONT†‡, H. CHIHARA†§ and J. A. MORRISON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Communicated by M. Blackman; MS. received 25th May 1961

Abstract. The calorimetric methods described in the preceding paper have been used to measure thermodynamic properties of solid and liquid krypton. Besides heat capacities and vapour pressures over a range of temperatures, the following were obtained: heat of fusion $= 392\cdot0 \pm 2\cdot3$ cal mole^{-1}, T(tr. pt.) $= 115\cdot77_6$°K, p(tr.pt.) $= 548\cdot7 \pm 0\cdot1$ mm, heat of vaporization at 116·85°K $= 2179\cdot2 \pm 0\cdot9$ cal mole^{-1} and at the normal boiling point $= 2162 \pm 1$ cal mole^{-1}.

A number of properties of solid argon and solid krypton has been derived, in particular, the apparent Debye characteristic temperatures at 0°K and as a function of temperature, the heats of sublimation at 0°K, the static lattice energies and the zero point energies. The results of the thermal measurements on the solids have been correlated with expansivity and compressibility results and certain inconsistencies resolved. The calorimetric results are shown to be internally consistent.

The shapes of curves of $\Theta_D(T)$ against temperature indicate that anharmonic contributions to the vibrational properties of solid argon and solid krypton are appreciable, particularly in the region $T > \Theta_0/10$.

In the region below the melting points, C_p for both argon and krypton increases rather rapidly with temperature. This is interpreted as an effect of formation of vacancies in the solids. Enthalpies of formation are found to be 1280 ± 130 cal mole^{-1} for argon and 1770 ± 200 cal mole^{-1} for krypton. These are about two-thirds of values estimated from theory. An effect of vacancy formation may also be seen in the vapour pressures.

INTRODUCTION

In the first part of this paper we give the results of measurements of the thermodynamic properties of solid and liquid krypton. The results are analogous to those for argon reported in the preceding paper (Flubacher, Leadbetter and Morrison 1961 a). Since the experimental methods used were exactly the same, they require no further description.

§ Now at Department of Chemistry, Osaka University, Osaka, Japan.

The second and longer part of the paper is concerned with vibrational and other properties of solid argon and solid krypton. The experimental results given here and in the preceding paper are analysed and correlated with other information on these solids so as to obtain derived quantities such as the apparent Debye characteristic temperature, $\Theta_D(T)$, at 0°K and as a function of temperature and the zero point properties, namely, heats of sublimation at 0°K, zero point energies and static lattice energies. A rather long section (§2.3) is devoted to the correlation of the thermal properties with existing data on the expansivity and compressibility of solid argon and solid krypton. Here, there are inconsistencies which we have tried to resolve. It would be valuable if our conclusions could be checked by further measurements of expansivities and compressibilities. Because of uncertainties which remain we cannot say very much about the detailed temperature dependence of $\Theta_D(T)$ above 15°K, other than that $\Theta_D(T)$ definitely increases with increasing temperature for both argon and krypton, and that $\Theta_D(T)$ for argon seems to increase more rapidly. Clearly, this behaviour should be ascribed to anharmonicity, but to what extent it is due to zero point energy or to thermal energy cannot be established at present. The fact that the effect seems greater for argon, for which the ratio of zero point energy to lattice energy is greater, suggests that zero point energy is an important factor. The comparison of the experimental properties with those derived from theoretical models corresponding to the inert gas solids is largely left to a theoretical paper by Horton and Leech (1962, to be published).

The heat capacities in the region below the melting point have been analysed so as to obtain estimates of the enthalpies required to form vacancies in solid argon and solid krypton. The results are discussed in §2.5. The enthalpies found from experiment are only about two-thirds of those computed from models. A further investigation of the discrepancy using expansivity data suggests that the relaxation of surrounding atoms into the vacancy is very much larger than has been estimated by theory.

PART 1. THERMODYNAMIC PROPERTIES OF SOLID AND LIQUID KRYPTON

The following three sections contain the experimental results obtained for krypton and brief accounts of relevant corrections. The krypton used was of a grade similar to that of argon and it also was obtained from the Linde Company. The purity was checked during the determination of the triple point (§1.3).

1.1. *Heat Capacities of Solid and Liquid Krypton*

The measured values of the heat capacity are listed in the Appendix and values for the solid at rounded temperatures in Table 1. The accuracies to be assigned to the results are essentially the same as those applicable to the results for argon. There is, however, a slightly greater uncertainty in the results at higher temperatures. The second virial coefficient of gaseous krypton has not been determined experimentally below room temperature. It was therefore necessary to estimate its value at low temperatures by extrapolation of high temperature results (Beattie, Barriault and Brierly 1952, Whalley and Schneider 1955). The extrapolation was made down to 76°K by a method due to Hirschfelder,

Table 1. The Heat Capacity of Solid Krypton at Rounded Values of the Temperature

Curtiss and Bird (1954).† Fortunately, the correction to the heat capacity on account of gas imperfection is rather small, so that the virial coefficients do not need to be known with high accuracy. An uncertainty of 10% in the virial coefficient leads to an uncertainty in the heat capacity of 0·4% at worst. The densities of solid krypton used were those obtained by Figgins and Smith (1960). In correcting the heat capacities of the liquid a single value of the density (2·43 g cm^{-3}) was used.

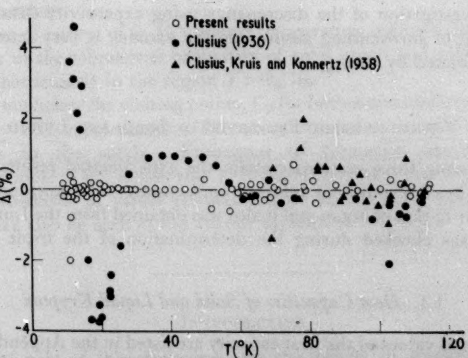

Fig. 1. A comparison of heat capacity results for solid krypton.

$$\Delta(\%) = \frac{C_p(\text{obs}) - C_p(\text{smooth})}{C_p(\text{smooth})} \times 100$$

where C_p(smooth) is given in Table 1.

---

†The quantum-mechanical correction (de Boer and Michels 1938) was small, amounting to only 0·23% at 116°K.

The measured heat capacities of solid krypton in the region $10^\circ < T < T(\text{tr. pt.})$ are compared with earlier results (Clusius 1936, Clusius, Kruis and Konnertz 1938) in Fig. 1. The results are plotted as differences from a smooth curve corresponding to the values given in Table 1. The average deviation of the present results from the smooth curve is less than 0·2%. The other results deviate more strongly, particularly at the lower temperatures.

The heat capacities of solid argon and solid krypton have also been measured between 1·2° and 20°K by Anderson (1960). A comparison of Anderson's results† with ours can be summarized as follows. Over a large part of the temperature region, in particular between 3° and 4°K and above 9°K, the two sets for both argon and krypton agree within their probable accuracies. Between 4° and 9°K Anderson's heat capacities for argon are larger by as much as 4%, and for krypton smaller by as much as 5%. These differences are larger than the estimated accuracy of the present measurements (see §3 (*a*) of Flubacher, Leadbetter and Morrison 1961 a). At the lowest temperatures ($T < 3^\circ$K) Anderson's results are consistently higher than ours by up to 3%.

† We should like to thank Dr. Anderson for sending us the tables from his thesis.

1.2. *Vapour Pressures of the Solid and Liquid*

The vapour pressures of solid and liquid krypton, determined in conjunction with the measurements of the heat capacity, are listed in Table 2. The pressures are of comparable accuracy to those obtained for argon. The results were fitted to the following equations by the method of least squares:

$$\left.\begin{aligned}\text{solid krypton: } \log_{10}p\ (\text{mm}) &= 7{\cdot}70741 - \frac{575{\cdot}267}{T},\\ \text{liquid krypton: } \log_{10}p\ (\text{mm}) &= 6{\cdot}96880 - \frac{489{\cdot}70}{T};\end{aligned}\right\} \quad\ldots\ldots(1)$$

the deviations of the actual pressures from the equations are given in the last column of Table 2. The differences, of course, simply reflect the fact that the heats of sublimation and vaporization are temperature dependent. The constants of Eqns (1) are significantly different from those found by Freeman and Halsey (1956), namely 7·7447 and 579·6 for solid krypton, and 6·9861 and 491·9 for liquid krypton. The difference between the two sets of measurements can also be seen in the estimates of the triple point temperature and pressure of krypton (see Table 4).

1.3. *The Triple Point of Krypton and the Heats of Fusion and Vaporization*

Three determinations of the heat of fusion of krypton were made, and the results are given in Table 3. During the first, the fusion was stopped at intervals for the determination of the triple point pressure and temperature. For this reason the first result may be the least accurate, but on the other hand the amount melted was 40% larger, which would tend to improve the accuracy. In obtaining the average value the three results were given equal weight. The average value agrees well with the result found by Clusius (1936).

Table 3. The Heat of Fusion of Krypton

Amount melted (moles)	Temperature range (°K)	Heat of fusion (cal mole^{-1})
0·1550	115·758–116·240	388·6
0·1105	115·661–116·037	393·5
0·1105	115·626–116·129	394·0
	average	392·0 ± 2·3
	Clusius (1936)	390·7

The triple point temperature corresponding to pure krypton was estimated from a plot of the equilibrium temperatures against the reciprocal of the fraction melted. The relevant data are given in Table 4. The amount of impurity was also estimated and the result was $4{\cdot}_5$ parts per million. The triple point temperature found here, 115·776°K, lies in between the values given by others. Little can be said about this because the different temperature scales are involved in an absolute way. The triple point pressure does not involve the temperature

Table 4. The Triple Point of Krypton

Fraction melted	T(°K)	p (mm Hg)
0·20	115·7748	548·90
0·40	115·7756	548·64
0·60	115·7756	548·60
0·80	115·7761	548·66
	average	548·70 ± 0·10
$T_{\rm tr}$ (pure krypton)	115·776	
Freeman and Halsey (1956)	115·6	538·1
Clusius, Kruis and Konnertz (1938)	115·97 ± 0·05	548·7 ± 1·5
Clusius (1936)	116·0 ± 0·05	549·5 ± 1·0
Keesom, Mazur and Meihuizen (1935)	115·95 ± 0·03	549 ± 1·5

scale and it is interesting to see that our result agrees so well with the values found by Clusius and his colleagues (1936, 1938) and by Keesom, Mazur and Meihuizen (1935). Freeman and Halsey's result is much lower but was probably calculated from a vapour pressure equation.

Table 5. The Heat of Vaporization of Krypton at $T = 116{\cdot}85$ °K

Amount evaporated (moles)	Heat of vaporization (cal mole^{-1})
$7{\cdot}946 \times 10^{-4}$	2178·6
$8{\cdot}167 \times 10^{-4}$	2178·4
$5{\cdot}365 \times 10^{-4}$	2180·5
Average	2179·2 ± 0·9
Calculated from vapour pressures	2186 ± 9
Heat of vaporization at normal boiling point	2162 ± 1
Clusius, Kruis and Konnertz (1938)	2158 ± 3

The results of the direct measurement of the heat of vaporization of krypton are given in Table 5, and the average value agrees with that calculated from the vapour pressures to well within the assigned uncertainties. It is also in accord with the average of much more extensive determinations by Clusius, Kruis and Konnertz (1938).

PART 2. VIBRATIONAL AND OTHER PROPERTIES OF SOLID ARGON AND SOLID KRYPTON

2.1. *General Remarks*

In this second part of the paper our object is to analyse the results of thermal and other measurements on solid argon and solid krypton to see what can be learned about their vibrational properties. For instance, we should like to know to what extent the properties can be described in terms of harmonic vibrations. This is a matter which becomes very important when the experimental results are compared with properties corresponding to models, such as those calculated by Horton and Leech (1962, to be published). Before conclusions about the interatomic forces can be reached from the agreement or lack of agreement between theory and experiment, effects due to anharmonicity must be clearly understood. While some general conclusions about effects of anharmonicity can be drawn, uncertainties in some of the auxiliary data required are just too great, so that a complete detailed analysis of the thermal measurements cannot be justified at present.

2.2. *Zero Point Properties*

2.2.1. *The characteristic temperature at* 0°K. An investigation of the low temperature heat capacities of a number of examples has shown (Barron and Morrison 1957) that the expansion

$$C = aT^3 + bT^5 + cT^7 + \ldots \qquad \ldots\ldots(2)$$

may be expected to describe experimental results in the temperature region $T < \Theta_0/25$. The apparent Debye characteristic temperature at 0°K, Θ_0, may be calculated from the first coefficient, i.e.

$$\Theta_0 = \left(\frac{464{\cdot}5}{a}\right)^{1/3}, \qquad \ldots\ldots(3)$$

where a has the units cal mole^{-1} deg^{-4}. Figs 2 and 3, which are graphs of C_v/T^3 against T^2 for the heat capacity results below 9°K, illustrate the estimation of a for argon and krypton. The temperature $\Theta_0/25$ is approximately 4° for argon and 3° for krypton. Since the lowest temperature of the experiments is 2°K, and since the experimental accuracy is least in this region, it is obvious that we cannot conclude from the experimental results whether or not the expansion (Eqn (1)) applies. If, however, we accept the principle of the expansion, we are led to suggest that the dashed lines in the figures represent reasonable limits on the extrapolation of the results to 0°K. The coefficients a so derived correspond

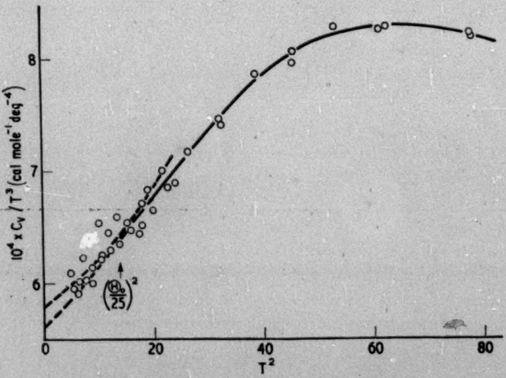

Fig. 2. A graph of C_V/T^3 against T^2 for argon.

V. 19

to $\Theta_0 = 93{\cdot}3 \pm 0{\cdot}6°$ for argon and $\Theta_0 = 71{\cdot}7 \pm 0{\cdot}7°$ for krypton. No attempt has been made to estimate the coefficients b and c. Anderson's heat capacity results (Anderson 1960) yield values of Θ_0 which are about $1\frac{1}{2}\%$ lower.

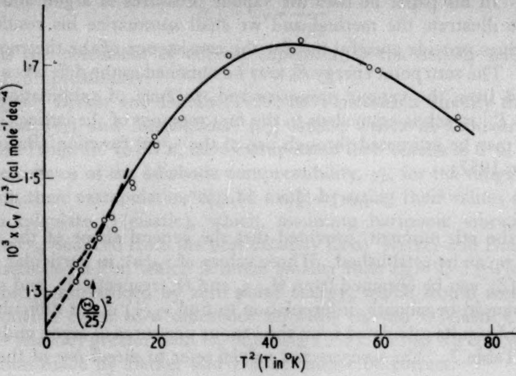

Fig. 3. A graph of C_V/T^3 against T^2 for krypton.

2.2.2. *The heat of sublimation at* 0°K. The thermodynamic properties given in this and in the preceding paper may be used to calculate the heats of sublimation of argon and krypton at 0°K. The relevant thermodynamic expression is a standard one and requires no detailed discussion. It is

$$\Delta H_{\text{sub}}(0°\text{K}) = \Delta H_{\text{sub}}(T) - \int_0^T C_P(\text{gas})\,dT + \int_0^T C_P(\text{solid})\,dT + RPT^2\left(\frac{dB_P}{dT}\right). \quad \ldots\ldots(4)$$

The last term takes account of gas imperfection; the sources of numerical values of the second virial coefficient B_P have been indicated (§1.1 above, and §3.1 of the preceding paper). The results are summarized in Table 6. The estimated uncertainties are also given.

Table 6. Calculation of the Heat of Sublimation at 0°K
(in units of cal mole⁻¹)

	Argon	Krypton
Heat of sublimation at $T = T_{\text{tr}}$	1861 ± 5	2579 ± 3
$\int_0^{T_{\text{tr}}} C_P(\text{S})dT$	391 ± 1	648 ± 2
$-\int_0^{T_{\text{tr}}} C_P(\text{G})dT$	−416	−575
$RPT^2\left(\frac{dB_P}{dT}\right)$ at $T = T_{\text{tr}}$	10 ± 1	14 ± 2
Heat of sublimation at $T = 0°$K	1846 ± 7	2666 ± 7
Dobbs and Jones (1957)	1850 ± 12	—
Whalley and Schneider (1955)	1818 ± 40	2589 ± 50

2.2.3. *The static lattice energy*. Recently, Salter (1962) has shown how vapour pressure data for monatomic solids may be analysed to obtain values of the static lattice energy E_0 and the geometric mean frequency ν_g of the lattice frequency distribution. In his paper he uses the vapour pressures of argon and krypton given here to illustrate the method and we shall summarize his results. The numerical values provide a useful test for the consistency of the thermodynamic information. The zero point energy E_z may be obtained as the difference between E_0, computed from the vapour pressures and the heat of sublimation at 0°K. Alternatively E_z, which is equivalent to the first moment of the lattice frequency distribution, may be estimated through use of the $\nu_D(n)$ function (Barron, Berg and Morrison 1957)

$$\nu_D(n) = \{\tfrac{1}{3}(n+3)\,\mu_n\}^{1/n}, \qquad \ldots\ldots(5)$$

where μ_n is the nth moment, provided that the general shape of the curve of $\nu_D(n)$ against n can be established. Three values of $\nu_D(n)$, in particular $\nu_D(-3)$, $\nu_D(0)$ and $\nu_D(2)$, can be obtained from Θ_0, ν_g and Θ_∞ respectively, and since the $\nu_D(n)$ curve should be smooth, interpolation to find $\nu_D(1)$ is not difficult.

Two sets of results calculated from the vapour pressures of argon and krypton are given in Table 7. The uncorrected values refer to direct use of the vapour pressure data as found experimentally. These give E_z (argon) = 124 ± 17 and E_z (krypton) = 74 ± 22 cal mole^{-1} from E_0, which are to be compared with 158 ± 5 and 117 ± 5 cal mole^{-1} from $\nu_D(n)$ curves (not illustrated) based on estimates of Θ_∞ given in § 2.4. The differences between the independent estimates of E_z, which are clearly outside the limits shown, turn out to be due to an effect of the presence of vacancies in the lattices at higher temperatures. When an allowance is made for the free energy of formation of vacancies (see § 2.5), the corrected results in Table 7 are obtained. These lead to E_z (argon) = 159 ± 17 and E_z (krypton) = 124 ± 22 cal mole^{-1} from E_0 and 171 ± 5 and 134 ± 6 cal mole^{-1} from $\nu_D(n)$ curves. The agreement is now quite satisfactory.

Table 7. The Static Lattice Energy and Geometric Mean Frequency Computed from the Vapour Pressures

	E_0 (cal mole^{-1})		$10^{-12} \times \nu_g(\mathrm{s}^{-1})$	
	Uncorrected	Corrected	Uncorrected	Corrected
Argon	1970 ± 10	2005 ± 10	1·06 ± 0·01	1·15 ± 0·01
Krypton	2740 ± 15	2790 ± 15	0·81 ± 0·01	0·88 ± 0·01

2.3. *The Estimation of* $C_P - C_V$

Before the apparent Debye characteristic temperature, $\Theta_D(T)$, at higher temperatures can be calculated it is necessary to know $C_P - C_V$. Estimates of this quantity as a function of temperature have been made for both solid argon (Clusius 1936, Dobbs and Jones 1957) and solid krypton (Clusius 1936), but a re-examination in the light of more recent experimental and theoretical information turns out to be worth while. The standard expression is

$$C_P - C_V = \frac{\alpha^2 T}{\rho \chi_T} \qquad \ldots\ldots(6)$$

where α is the coefficient of cubical expansion, ρ the density and χ_T is the isothermal compressibility.

2.3.1. *Argon.* Barker and Dobbs (1955) have measured directly the velocities of transverse (v_t) and longitudinal (γ_l) lattice waves in solid argon in the temperature range 65° to 80°K, have extrapolated their results to 0°K, and so have obtained estimates of the adiabatic compressibility, χ_S, for the range 0° to 80°K. A check on their extrapolation can be made by using their values of v_t and v_e at 0°K to calculate Θ (elastic), which, assuming harmonic vibrations should be equal to Θ_0, deduced from the heat capacity data. Barker and Dobbs's results give Θ (elastic) $= 80{\cdot}5$°K, which is much smaller than $\Theta_0 = 93{\cdot}3 \pm 0{\cdot}6$°K (§2.2.1). Anharmonicity introduced by zero point energy, which would seem to be the only reasonable cause of a difference between Θ_0 and Θ (elastic), is believed to make Θ (elastic) greater than Θ_0 (Ludwig 1958), and so we conclude that the extrapolation made by Barker and Dobbs cannot be correct.

Velocities of the lattice waves at 0°K have been calculated from theory by Bernades (1960) and Horton and Leech (1962, to be published). The results ($v_t = 0{\cdot}94 \times 10^4$ cm sec^{-1}; $v_e = 1{\cdot}61 \times 10^4$ cm sec^{-1}) lead to Θ (elastic) $= 92{\cdot}6$°K, which is in better agreement with Θ_0. We have therefore calculated χ_S at 0°K from the theoretical wave velocities and have used it with the experimental compressibilities derived by Barker and Dobbs to obtain χ_S as a function of temperature. Fortuitously, the values of χ_S at intermediate temperatures are rather close to those tabulated by Dobbs and Jones (1957) (Table III in the appendix to their paper); the maximum difference is 2%.

The density of solid argon has been measured between 20°K and the melting point by Dobbs *et al.* (1956) using X-ray diffraction and volumometer techniques. More recently, Henshaw (1958) has reported a single value of the density at 4·2°K, obtained from neutron diffraction experiments, which is about 3% higher than that given by an extrapolation of the results of Dobbs *et al.* (1956). The difference is disturbingly large, and since there do not appear to be any obvious errors in either the X-ray or neutron diffraction experiments, it is necessary to distinguish between their results using other information.

Theoretical work on the inert gas solids (Barron 1955, Horton and Leech 1962, to be published) suggests that the Grüneisen parameter γ should be only slightly temperature dependent. In particular, the indications are that γ for argon should decrease by probably not more than 10 to 20% when the temperature falls below 50°K. γ is given by

$$\gamma = \frac{\alpha}{\rho \chi_S C_P}. \qquad \ldots\ldots(7)$$

We may therefore conveniently test the internal consistency of the quantities on the right-hand side by plotting α/ρ against $\chi_S C_P$. Such a graph is shown in Fig. 4. The points represent smoothed values of α/ρ given by Dobbs *et al.* (1957) at the temperatures 20, 30, 40, 50 and 60°K. The corresponding values of χ_S were taken from the (χ_S, T) relation established as indicated above, and the values of C_P from Table 1 of the preceding paper. The light dashed lines represent

$\gamma = 3{\cdot}0$ and $\gamma = 2{\cdot}7$. The points at 20° and 30°K lie well below the dashed lines but the others come nicely in between. If we rely on the theoretical deductions about γ, we are obliged to discard the points at 20° and 30°K and to say that the solid curve in Fig. 4 is what should be used to fix α/ρ below 40°K†. When this is done one finds that the resulting change in the density below 40°K is small. For example, the density at 0°K becomes $1{\cdot}776\,\mathrm{g\,cm^{-3}}$ compared with $1{\cdot}770\,\mathrm{g\,cm^{-3}}$ given by Dobbs *et al.* (1956). It seems impossible to make the density value found by Henshaw (1958) consistent with the other data.

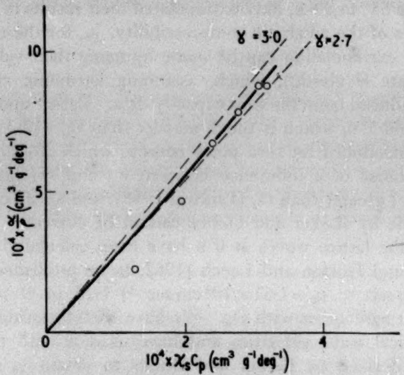

Fig. 4. A graph of α/ρ against $\chi_S C_P$ for argon (see § 2.3.2 of the text).

A summary of the values of α, ρ, χ_S and χ_T used in computing $C_P - C_V$ is given in Table 8. χ_T was calculated from χ_S using

$$\chi_T = \chi_S(1 + \alpha T \gamma). \qquad \ldots\ldots (8)$$

A final check may be made by comparing χ_T so derived at 65° and 77°K with values determined directly by Stewart (1956) using a piston displacement method. The agreement at 65°K is good (<2%) but Stewart's result at 77°K is much higher (>20%). A complicating factor at this higher temperature is that the concentration of thermally created vacancies is appreciable (see §2.5). The general effect of the vacancies would be to enhance the compressibility as determined by displacement under pressure. It is difficult, however, to construct a quantitative argument. Stewart (1956) has considered other possible reasons, such as errors in density measurements, and shown that they are insufficient to account for the observed difference in χ_T.

2.3.2. *Krypton.* Figgins and Smith (1960) have measured the density of solid krypton between 20° and 90°K using X-ray diffraction and between 70° and the melting point using a volumometer technique. From the results they have computed the expansivity for the temperature range 20° to 90°K. Very much less information is available for the compressibility of solid krypton. In fact, there

---

† It will be noted that the measurements at 60°K are represented by two points. One is based on C_P as given in the Table, and the other, which is closer to the ordinate, on C_P corrected for vacancy formation (see § 2.5).

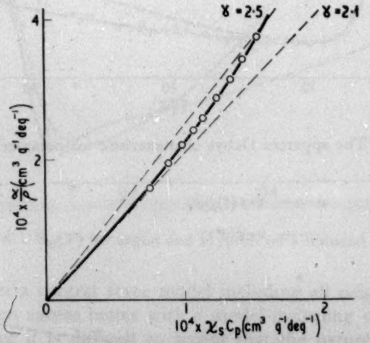

Fig 5. A graph of α/ρ against $\chi_S C_p$ for krypton (see § 2.3.2 of the text).

appears to be but a single experimental value of χ_T at 77°K obtained by Stewart (1955). In order to obtain the compressibility of krypton as a function of temperature our only recourse has been to do a type of corresponding states treatment based on the results for argon and using χ_S at 0°K obtained from theory (Horton and Leech 1962, to be published). (The velocities were equivalent to Θ (elastic) = 72·9°K.) The particular method chosen was to use a graph of $\chi_s(T)/\chi_s(0°\text{K})$ against T/T_m, where T_m is the triple point temperature. It is impossible to fix the accuracy of this procedure but it is useful to note that χ_T at 77°K derived using it agreed with Stewart's result to about 3%.

The test for the consistency of the different properties of solid krypton is shown in Fig. 5, which is a graph of α/ρ against $\chi_s C_p$ corresponding to the temperatures 20, 25, 30, 35, 40, 50, 60, 70 and 80°K. In contrast to the example of argon, none of the values of α/ρ needs to be eliminated. All of the points lie close to the solid curve. The only troubling feature is that the magnitude of γ is smaller than is suggested by the calculations from models (Horton and Leech 1962, to be published). This may, of course, simply be caused by a consistent error in the estimation of the compressibility, but on the other hand it could represent a significant departure of experiment from theory. The second part of Table 8 contains the values of $C_p - C_v$ for krypton and of the quantities used in their calculation.

2.4. *The Temperature Dependence of* $\Theta_D(T)$

Figures 6 and 7 are graphs of $\Theta_D(T)$ as a function of temperature for argon and krypton†. In the calculation of the plotted points, $C_p - C_v$ as given in Table 8

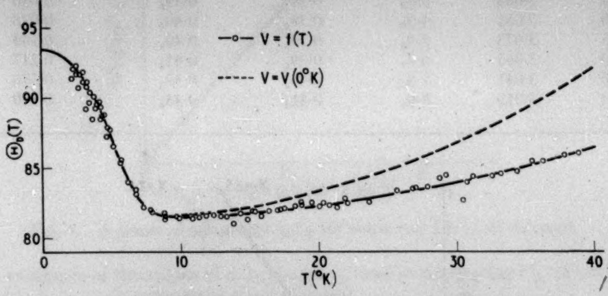

Fig. 6. The apparent Debye characteristic temperature of argon.

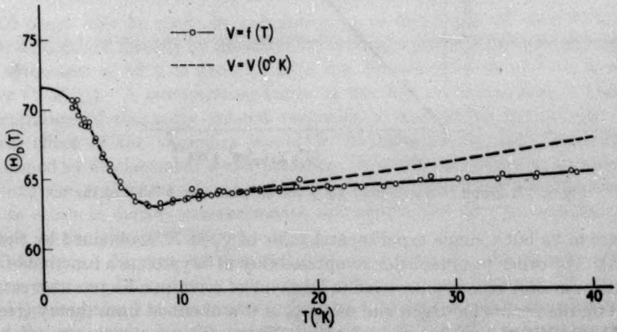

Fig. 7. The apparent Debye characteristic temperature of krypton.

---

† A graph of $\Theta_D(T)$ against T for argon is contained in a preliminary report (Flubacher, Leadbetter and Morrison 1961 b) and its shape is a little different from that of Fig. 6. It was, however, based on a different estimate of $C_p - C_v$.

was used, and therefore $\Theta_D(T)$ corresponds to a volume which is varying with temperature. What is required for comparison with theory is $\Theta_D(T)$ for a fixed volume. Correction of $\Theta_D(T)$ to the volume of the crystal at 0°K has been made using the expression (Barron, Berg and Morrison, 1957)

$$\Theta_D(V_0)=\Theta_D(V_T)\left(\frac{\rho_0}{\rho_T}\right)^{\gamma}, \qquad \ldots\ldots(9)$$

and the results are indicated by the dashed curves in Figs 6 and 7. We do not show $\Theta_D(T)$ above 40°K for two reasons. First, above 40°K, $C_P - C_V$ is becoming a large fraction of C_P ($>11\%$ for argon, $>7\%$ for krypton), and at best we only know its value to 5%. Second, a non-vibrational contribution to the heat capacity, namely that due to vacancy formation, begins to come in.

While the general shape of the $\Theta_D(T)$ curves in Figs 6 and 7 is rather similar, there are differences in detail. The curve for krypton shows a more pronounced minimum in the vicinity of 8°K, and rises less rapidly at the higher temperatures. The latter feature is displayed more clearly in Fig. 8, where the two curves are compared on a reduced basis using Θ_0 (argon) = 93·3°K and Θ_0 (krypton) = 71·7°K. The difference between the two curves in the region $T/\Theta_0 < 0{\cdot}15$ is of interest in connection with a comparison with the calculated curves of Horton and Leech (1962, to be published). It turns out that the curve for krypton agrees most closely with one for a central force model including all neighbour interactions, while that for argon agrees better with a model including only first neighbour interactions. Since it is difficult to accept that the nature of the interatomic forces in the two crystals is different in any fundamental way, one is almost obliged to ascribe the difference in the reduced $\Theta_D(T)$ curves to anharmonic effects. Here it is relevant to note that the ratio of zero point energy to the static lattice energy for argon is nearly twice that for krypton, i.e. 0·085 compared with 0·048.

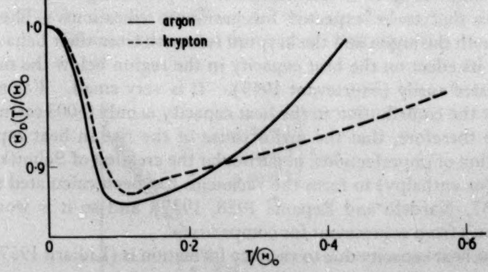

Fig. 8. $\Theta_D(T)$ for argon and krypton on a reduced basis.

The rise in $\Theta_D(T)$ at the higher temperatures must also be attributed to anharmonicity, and again it appears significant that the effect is much greater for argon. At 40°K, the increase of $\Theta_D(T)$ for argon above the minimum value corresponds to a change of about 4% of C_V, which is outside the combined uncertainties of the experimental heat capacities, of the estimation of $C_P - C_V$ and of the use of Eqn (9). The effect is less certain for krypton where the increase in $\Theta_D(T)$ to 40°K amounts to only 1% of C_V, but the chances are great that it is real. This being so, it is interesting to note that the behaviour of $\Theta_D(T)$ of argon and krypton at the higher temperatures is quite the reverse of what has been found for other simple crystals such as some alkali halides and diamond structure elements (Berg and Morrison 1957, Flubacher, Leadbetter and Morrison 1959).

Because of the apparent early onset of anharmonic effects (right from 0°K), it is not worth while at this stage to attempt an analysis of the heat capacities to obtain moments and other properties of the lattice frequency distributions. It is even difficult to make an unambiguous choice of Θ_∞. The best that can be said from inspection of the $\Theta_D(T)$ curves is that Θ_∞ for argon probably lies between 82° and 85°K, and for krypton between 64° and 66°K.

2.5. *The Enthalpy to Form Vacancies in Solid Argon and Solid Krypton*

The heat capacities of both solid argon and solid krypton show marked upward trends in the temperature region below their melting points. At a few tenths of a degree below the melting points, the heat capacities are about 8·5 cal mole^{-1} deg^{-1} (Tables 1 of this paper and of Flubacher, Leadbetter and Morrison 1961 a). This behaviour might be ascribed to one or more of several causes. For example, it might be due to effects of anharmonicity, to premelting induced by impurities or to the thermal formation of imperfections in the lattices. In the previous section we have seen that anharmonicity is having the opposite effect on the heat capacities of argon and krypton up to 40°K at least, i.e. it is producing a decrease of the heat capacity from that to be expected for harmonic vibrations. The amount of impurity in both the argon and the krypton is known from their behaviour during melting, and its effect on the heat capacity in the region below the melting point can be estimated easily (Sturtevant 1949). It is very small. For example, for argon at 80°K the contribution to the heat capacity is only 0·003 cal mole^{-1} deg^{-1}. We conclude therefore, that the major cause of the rise in heat capacity is the thermal creation of imperfections, in particular the creation of Schottky vacancies. The energy (or enthalpy) to form the vacancies has been calculated from theory (Kanzaki 1957, Nardelli and Repanai 1958, 1959), and so it is worth while to obtain estimates from experiment for comparison.

The excess heat capacity due to vacancy formation is (Lidiard 1957)

$$\Delta C_p = \left(\frac{\partial \Delta H}{\partial T}\right)_p = \left(\frac{\partial n_s h_s}{\partial T}\right)_p \qquad \ldots\ldots(10)$$

where n_s, the number of vacancies, is given by

$$n_s = N \exp\left(\frac{s_s}{k}\right) \exp\left(-\frac{h_s}{kT}\right) \qquad \ldots\ldots(11)$$

and N is Avogadro's number, h_s and s_s the enthalpy and entropy of formation. It is obvious that, if $\ln(\Delta C_p \times T^2)$ is plotted against $1/T$, one should get a straight line whose slope is $-h_s/k$.

In order to apply the above, we need only to estimate ΔC_p. This may be done by simply extrapolating a graph of C_p against T smoothly from low temperatures so as to obtain an estimate of the 'normal' heat capacity. We have preferred to use graphs of C_p against $1/T^2$ for this purpose, and the example of argon is shown in Fig. 9. Such a graph foreshortens the high temperature region, and hence makes extrapolation somewhat easier. The broken curves 1, 2, and 3 in Fig. 9 show what seemed to be a reasonable spread of possible extrapolations from the

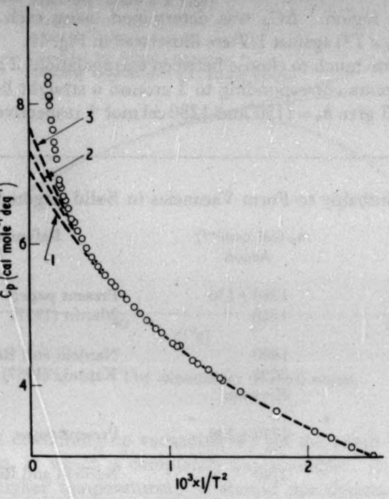

Fig. 9. A graph of C_p against $1/T^2$ for argon. The dashed curves 1, 2 and 3 represent different estimates of the ' normal ' heat capacity.

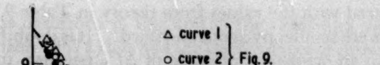

Fig. 10. A graph ln($\Delta C_p \times T^2$) against $1/T$ for argon, based on different estimates of the ' normal ' heat capacity.

low temperature region. ΔC_p was determined using each and the resulting graphs of ln $(\Delta C_p \times T^2)$ against $1/T$ are illustrated in Fig. 10.

There is not too much to choose between extrapolations 2 and 3, although the distribution of points corresponding to 3 around a straight line is better. The slopes for 2 and 3 give $h_s = 1150$ and 1280 cal mol^{-1} respectively. We therefore take the experimental estimate of h_s for argon as 1280 ± 130 cal mole^{-1}. A similar treatment of the data for krypton gives $h_s = 1770 \pm 200$ cal mole^{-1}. These results are compared with the values from theory in Table 9, and we see that the experimental ones are smaller by about one third. It is doubtful that the difference can be ascribed to an erroneous estimate of ΔC_p because, in fact, h_s is not very sensitive to ΔC_p. Also, it should be noted that the value of h_s for argon found by Martin (1957) was obtained using the heat capacity data of Clusius (1936) and a completely different method of extrapolation.

Table 9. The Enthalpy to Form Vacancies in Solid Argon and Solid Krypton

The calculations can be carried further. By using the additional information contained in the intercepts of the lines in Fig. 10, we can obtain explicit expressions for the number of vacancies. These are

$$\frac{n_s}{N} = 30(\pm 20) \exp\left(\frac{-1280(\pm 130)}{RT}\right) \qquad \ldots\ldots(12)$$

for argon, and

$$\frac{n_s}{N} = 30(\pm 20) \exp\left(\frac{-1770(\pm 200)}{RT}\right) \qquad \ldots\ldots(13)$$

for krypton. Having the number of vacancies at any temperature, it is of interest to correlate it with the expansivity, and we shall do this for argon for which expansivities up to the melting point are available (Dobbs *et al.* 1956). At these higher temperatures the densities (and hence the expansivities) were determined by a bulk method, and therefore should be particularly sensitive to the change in volume due to vacancy formation. Indeed, the expansivities of Dobbs *et al.* (1956) show a curl-up in the region $T > 50$°K (solid curve in Fig. 11). If we assume that the volume of a vacancy is equal to the atomic volume (in other words, assume no relaxation of surrounding atoms into the vacancy) and work out α for a

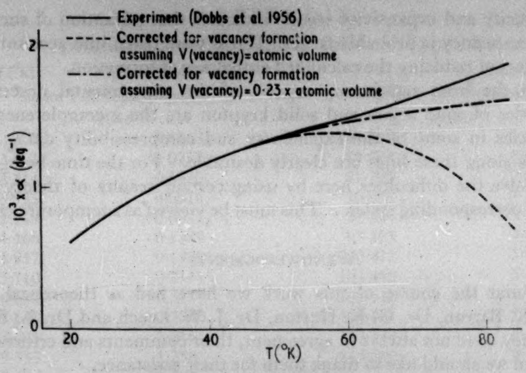

Fig. 11. The expansivity of solid argon.

hypothetical crystal containing no vacancies, we get the result indicated by the dashed curve in Fig. 11 which is completely unreasonable. At worst, α should flatten off at the higher temperatures; it should not decrease. The middle chain curve was calculated assuming that the volume of a vacancy was only 23% of the atomic volume, and this is much more like what should be expected.

SUMMARY

The work which is described in this and in the preceding paper (Flubacher, Leadbetter and Morrison 1961 a) has had the initial object of providing more complete and accurate values of the thermal properties of condensed argon and krypton than have been available heretofore. The experimental results satisfy different tests for internal consistency. For instance, heats of vaporization determined calorimetrically and indirectly from the vapour pressures agree well. Also, zero point energies computed in two ways agree within the uncertainties assigned to the various quantities used.

The latter calculations are of particular interest. In the first place, one of the methods of computation, which uses estimates of certain moments of the lattice frequency distribution, implies harmonic vibrations. The fact that it seems to work suggests that it is not a bad approximation to describe the thermodynamic properties in the low temperature region in terms of an effective harmonic frequency distribution. However, the reduced curves of $\Theta_D(T)$ against temperature (Fig. 8) indicate that anharmonic effects definitely come in at higher temperatures ($T > \Theta_0/10$) and perhaps at all temperatures. A further point about the zero point energy calculations is that they demonstrate the effect of vacancy formation upon the vapour pressures of the solids.

The enthalpies required to form vacancies, determined from the experimental heat capacities for the solids, are quite appreciably smaller than values estimated form theory. The latter are close to the heats of sublimation (compare Tables 6 and 9), and this comes about because energy effects due to relaxation and distortion around a vacancy are taken to be small (Kankazi 1957). However, a comparison of heat capacity and expansivity results indicates that relaxation of surrounding atoms into a vacancy is probably large. If this were taken into account it would have the effect of reducing the calculated enthalpies of formation.

Perhaps the least satisfactory aspects of the experimental description of the properties of solid argon and solid krypton are the incompleteness of and inconsistencies in some of the expansivity and compressibility data. Further experiments along these lines are clearly desirable. For the time being we have tried to resolve the difficulties here by using certain results of theory and the principle of corresponding states. This must be viewed as a temporary expedient.

ACKNOWLEDGMENTS

Throughout the course of this work we have had as theoretical advisers Dr. T. H. K. Barron, Dr. G. K. Horton, Dr. J. W. Leech and Dr. L. S. Salter. Although they were not always in agreement, their comments and criticisms were valuable, and we should like to thank them for their assistance.

The Specific Heat of Hexagonal Metals at Very Low Temperatures

By DOUGLAS L. MARTIN

Division of Pure Physics, National Research Council, Ottawa, Canada

Communicated by N. F. Mott; *MS. received 26th June* 1961

Abstract. The specific heats of cadmium and magnesium have been measured in the temperature range 0·4° to 1·5°K. For cadmium the electronic specific heat coefficient γ is $163{\cdot}6 \pm 2{\cdot}6\,\mu$cal deg^{-2} (g at.)$^{-1}$, the Debye temperature θ is 204 ± 3°K, and the superconducting transition temperature is $0{\cdot}52 \pm 0{\cdot}01$°K. For magnesium γ is $292{\cdot}7 \pm 2{\cdot}5\,\mu$cal deg^{-2} (g at.)$^{-1}$. These results show that a previously reported discrepancy between the elastic and thermal values of θ for the hexagonal metals was due to incorrect interpretation of specific heat data.

---

§ 1. Introduction

Wolcott (1961) recently drew attention to discrepancies between the values of the Debye characteristic temperature θ for the hexagonal metals derived from elastic constant and specific heat measurements respectively. It follows from the lattice theory of specific heats (see, for example, Blackman 1955) that at very low temperatures, when the thermal vibrations are of long wavelength and the lattice behaves essentially as a continuum, these two values of the Debye temperature should be the same for a given substance. Due to the marked anisotropy of the hexagonal lattice it appears that measurements must be made to much lower temperatures than for cubic lattices with similar θ values, in order to be sure that the continuum region has been reached. In the present paper specific heat results on cadmium and magnesium extending down to about 0·4°K are reported. These results suggest that there is no real discrepancy between the elastic and thermal θ values of the hexagonal metals.

§ 2. Experimental

The measurements were made in a ^{3}He cryostat using a technique, described elsewhere (Martin 1961 a), in which the sample is stuck to a 'tray' calorimeter with a film of silicone grease.

The cadmium sample was a piece of Tadanac High Purity Cadmium of nominal purity 99·9999%. Some difficulty was experienced at first due to the breaking of the grease bond to the calorimeter on cooling, presumably due to a large differential contraction. This was overcome by sawing the sample into a number of pieces so that the total differential contraction on a given piece was much reduced. The sample then consisted of four pieces, each about 5 cm long and with a contact area of about 1 cm^2. The pieces were annealed *in vacuo* for one hour at 300°c. The sample weighed 229·768 g.

The magnesium sample was supplied by the Dow Chemical Co. in the form of a rod about 1·3 cm diameter. This material was the same as the Sample No.

728 of Hedgcock, Muir and Wallingford (1960) who quote the following spectrographic analysis: Al $<0{\cdot}001\%$, Ca $<0{\cdot}01\%$, Cu $<0{\cdot}001\%$, Fe $<0{\cdot}001\%$, Mn $<0{\cdot}001\%$, Ni $<0{\cdot}0005\%$, Pb $<0{\cdot}001\%$, Si $<0{\cdot}001\%$, Sn $<0{\cdot}01\%$, Zn $<0{\cdot}001\%$. Hedgcock *et al.* found the residual electrical resistance ratio $R_{4\cdot2}/(R_{\sim300}-R_{4\cdot2})$ to be $3{\cdot}6\times10^{-3}$, indicating rather a high purity. They also found that this material does not show the anomalous resistance—minimum at low temperatures and therefore specific heat anomalies associated with these phenomena (Martin 1961 b) are presumably absent. The magnesium was measured in the same condition as it was received, without any heat treatment. For convenience the calorimeter sample consisted of four pieces of the rod, each about 5 cm long, and weighed 44·300 g.

§ 3. RESULTS

Each sample was measured on two separate occasions, the carbon thermometer on the calorimeter being recalibrated every time it was cooled to low temperatures.

The results have been analysed on the assumption that they may be represented by the equation

$$C=\gamma T+\frac{12\pi^4R}{5}\left(\frac{T}{\theta}\right)^3$$

where C is the specific heat, γ the electronic specific heat coefficient, R the gas constant and θ the Debye temperature. The values of γ and θ were determined from a least squares analysis of the results from which the 95% confidence limits were also obtained.

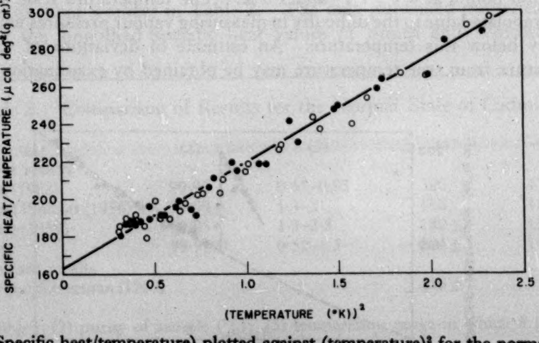

Fig. 1. (Specific heat/temperature) plotted against (temperature)^2 for the normal state of cadmium.

Results for the normal state of cadmium are shown graphically in Fig. 1 and the derived θ and γ values are given in Table 1. Cadmium becomes superconducting at the lower end of the measurement range and details of the superconducting transition are shown in Fig. 2. The exact temperature of the superconducting transition was determined by taking heating curves through the transition region and noting where the change of slope occurred. By taking curves at different heating rates, and extrapolating to zero heating rate, the exact transition temperature may be determined. This was done during both sets of measurements on cadmium with the results of 0·519 ± 0·001°K and $0{\cdot}519_5 \pm 0{\cdot}000_5$°K. The error limits represent the uncertainty on the experimental temperature scale which, as described by Martin (1961 a), is obtained by the use of the three constant interpolation formulae of Clement and Quinnell (1952) with calibration points at 0·7°, 1·1° and 1·5°K. The temperature scale below 0·7°K was extrapolated due to the difficulty in measuring vapour pressures with sufficient accuracy below this temperature. An estimate of deviations of extrapolated temperature from true temperature may be obtained by examination of specific heat results within this region for trends away from results anticipated on the basis of measurements above 0·7°K. On this basis the superconducting transition temperature of cadmium, in the ambient field, is 0·52 ± 0·01°K. The

Table 1. Summary of Specific Heat Results for the Normal State of Cadmium and Magnesium

Cadmium: Atomic weight = 112·41	θ(°K)	γ(μcal deg^{-2} (g at.)$^{-1}$)
First set	204 ± 4	164 ± 4
Second set	204·5 ± 4	163·5 ± 4
All points	204 ± 3	163·6 ± 2·6

Magnesium: Atomic weight = 24·32	θ(°K)	γ(μcal deg^{-2} (g at.)$^{-1}$)
First set	442^{+250}_{-75}	294 ± 4
Second set	444^{+210}_{-70}	292 ± 3
All points	440^{+110}_{-56}	292·7 ± 2·5

Note: Indicated errors are 95% confidence limits.

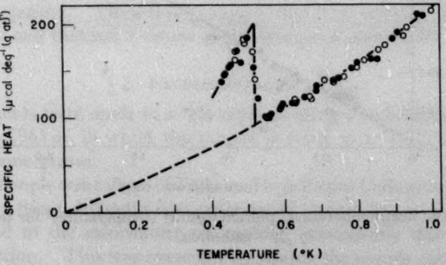

Fig. 2. Details of the superconducting transition for cadmium. The exact position of the transition temperature was determined from heating curves as discussed in the text.

earth's magnetic field was measured just outside the cryostat and found to be 0·33 gauss. Assuming the same field inside the cryostat, the transition temperature of the cadmium sample would be depressed by about 0·003 °K (Smith and Daunt 1952). The transition width, as determined from the heating curves, was less than 0·001 °K.

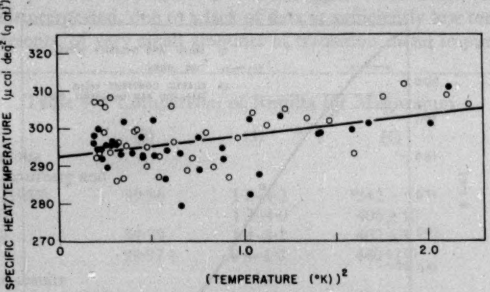

Fig. 3. (Specific heat/temperature) plotted against (temperature)² for magnesium.

Results for magnesium are shown graphically in Fig. 3 and the derived θ and γ values are given in Table 1.

§ 4. Discussion

The θ and γ values determined for the normal state of cadmium are compared with those of other workers in Table 2. The only published numerical data of results are the smoothed specific heat values of Smith and Wolcott (1956). Using the γ value as determined in the present work, values of θ have been calculated from this data and are shown in Fig. 4. If it is assumed that Smith and Wolcott's value at 1·5 °K is in error, then it appears that there is satisfactory agreement between the elastic constant and specific heat values of θ. Examination of the θ against T plot for cadmium (Fig. 4) shows that the minimum occurs at an unusually low reduced temperature, $\theta/20$, and the θ value then rises very rapidly

to the value at 0°K. The necessity for making measurements to very low temperatures, in order to obtain the correct limiting value for θ, is therefore quite obvious. Previous discrepancies between the elastic constant and specific heat values of θ were because accurate specific heat measurements had not been made to sufficiently low temperatures.

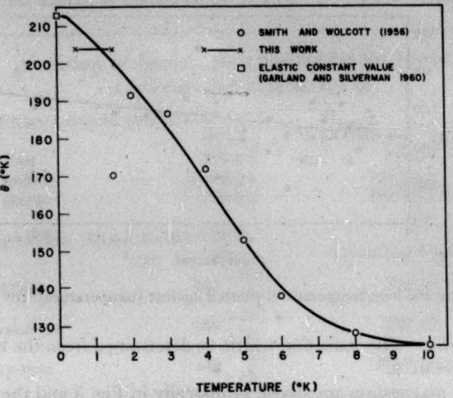

Fig. 4. The Debye temperature of cadmium. The analysis of results for the present work assumes a constant θ value between 0·4 and 1·5°K (see text).

The reported values for the superconducting transition temperature of cadmium cover a wide range, as will be apparent from Table 3. Part of the discrepancy is no doubt due to errors in temperature scales and to the difficulty in ensuring thermal equilibrium at these temperatures. It is also probable that the purity of the sample is an important factor, since it is well known that relatively small amounts of impurity can result in surprisingly large alterations in superconducting transition temperatures (see, for example, Chanin, Lynton and Serin 1959).

(1) Author; (2) purity of sample (%); (3) superconducting transition temperature (°K).

The lattice specific heat of magnesium is so small within the temperature range of the present experiments that an accurate value of θ cannot be obtained. However, the value for γ obtained in the present work is significantly lower than previously reported values (Table 4). This suggests that earlier results have either been misinterpreted, due to a lack of data at sufficiently low temperatures, or else the presence of very small amounts of transition metal impurities might have resulted in an anomalously high specific heat within the liquid helium temperature region (Martin 1961 b). In either event it is obvious that no published thermal θ values can be accepted as correct. Unfortunately no raw specific heat data for magnesium in the region below 4°K has been published and therefore a re-analysis of earlier data, as has been carried out in this paper for cadmium, is not possible. It therefore seems that establishment of a definite agreement between thermal and elastic θ values for magnesium must await re-measurement of pure magnesium in the range 1·5 to 4°K. However, at the present time there is no reason for supposing that any disagreement exists.

The disagreement between the thermal and elastic constant θ values for another hexagonal metal, zinc, has recently been considered by Garland and Silverman (1961). They showed that the higher temperature specific heat data could be re-analysed on the basis of a new γ value, derived from recent specific heat measurements below 1°K, and a much better agreement between the elastic and thermal θ values was then obtained.

§ 5. CONCLUSION

There is no evidence for discrepancies between the elastic and thermal Debye temperatures of the hexagonal metals, provided that specific heat data at sufficiently low temperatures are used to derive the thermal θ values.

The superconducting transition temperature for pure cadmium was found to be 0·52° ± 0·01°K.

ACKNOWLEDGMENTS

The pure magnesium sample was kindly supplied by Dr. F. T. Hedgcock of Ottawa University. I am indebted to Dr. D. K. C. MacDonald for his comments on the manuscript, to Mr. R. L. Snowdon for help with the experimental work, to Miss B. A. Cotton for computing assistance and to Messrs. F. W. Richardson and H. J. Broome for the supply of liquid helium.

The Low Temperature Specific Heat of an Aluminium–Manganese Alloy

By DOUGLAS L. MARTIN
Division of Pure Physics, National Research Council, Ottawa, Canada

MS. received 6th July 1961

Abstract. Aluminium–manganese alloys do not show the resistance-minimum phenomena often found in dilute alloys containing transition metals, but anomalous thermoelectric powers are observed. Alloy systems which do show the resistance minimum also have large specific heat anomalies at low temperatures. It was therefore of interest to see whether specific heat anomalies occurred in the aluminium–manganese system.

Measurements of the specific heat of pure aluminium and of an alloy containing 0·045 atomic % manganese were therefore made in the temperature range 0·4° to 1·5°K. In the normal state the specific heats of the two samples are the same. Thus a specific heat anomaly of the type found in systems showing the resistance minimum does not occur. The superconducting transition temperature of the alloy is about 0·84°K (compared with 1·174 ± 0·002°K for pure aluminium) but the transition remains sharp (width less than 0·001 deg K) and of the second order. The reduced electronic specific heats in the superconducting state $C_{es}/\gamma T_c$, when given in terms of reduced temperature T_c/T, are identical.

---

§ 1. Introduction

The addition of transition metal impurities, in solution, to otherwise pure metals often leads to the resistance-minimum phenomena and associated 'giant' thermoelectric powers (see, for example, review by MacDonald 1956). It is now known that large specific heat anomalies are associated with these phenomena in the following systems: silver–manganese, and copper–manganese (De Nobel and Du Chatenier 1959, Zimmerman and Hoare 1960), copper–iron (Martin and Franck 1960, Franck, Manchester and Martin 1961), copper–cobalt (Crane and Zimmerman 1961), magnesium–manganese (Martin 1961a), copper–chromium, silver–chromium and zinc–manganese (van den Berg, private communication).

Dilute alloys of manganese in aluminium do not show the resistance minimum phenomena (Hedgcock, Muir and Wallingford 1960) but there are anomalous thermoelectric effects (Hedgcock, to be published) similar to those found in systems showing the resistance minimum. It was therefore of some interest to see whether this alloy system showed any specific heat anomalies.

§ 2. Experimental

The measurements were made in a ^{3}He cryostat using a 'tray' type calorimeter (Martin 1961b). The temperature scale was derived from ^{3}He vapour pressures (Sydoriak and Roberts 1957).

The aluminium sample was supplied through the courtesy of Dr. Hay of the

Aluminium Company of Canada, Kingston, Ontario, and had a residual electrical resistance at 4·2°K of $1 \cdot 6 \times 10^{-3}$ of its room temperature resistance, indicating a high purity. Spectrographic analysis of the sample showed the only impurity to be less than 5 parts per million of copper. In order to measure the sample in, as far as possible, the same physical state as the alloy, it was annealed at 560°C for 2 hours and then water quenched. The sample weighed 74·600 g.

The alloy was a piece of the alloy GKO (nominally 0·045 atomic % Mn) of Hedgcock, Muir and Wallingford (1960), kindly supplied by Dr. Hedgcock. After machining to a suitable shape it was annealed at 560°C for 2 hours in a helium atmosphere and then water quenched to prevent precipitation. A test strip had been rolled from each end of the sample and was similarly heat treated. The residual electrical resistances ($R_{4\cdot2}/(R_{293}-R_{4\cdot2})$) of these strips were 0·1313 and 0·1310. Thus the alloy appeared to be satisfactorily homogeneous with a considerable amount of manganese in solution. The sample weighed 67·391 g and the average atomic weight was taken as 26·985.

§ 3. Results

The specific heat results for pure aluminium and the alloy are shown in Fig. 1 as a plot of specific heat against temperature. The superconducting transition temperatures were located by heating through the transition at different rates and extrapolating to zero heating current. In all cases the transition was very

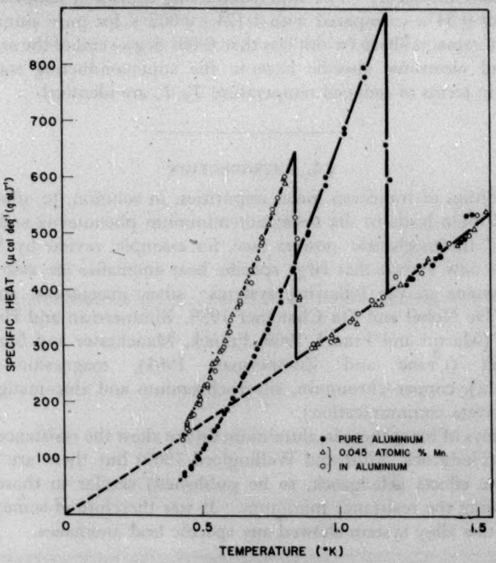

Fig. 1. The specific heats of pure aluminium and of an aluminium–0·045 atomic % magnanese alloy.

sharp, with no latent heat, the transition width being about 0·001 deg K. For pure aluminium the transition temperature was $1{\cdot}171_5 \pm 0{\cdot}002$°K and for two separate measurements on the alloy values of 0·84 and 0·85°K were obtained. The second figure for the alloy was obtained from an experiment in which the usual apparent dependence of transition temperature on heating rate was not observed. The first figure is therefore considered more reliable and the transition temperature of the alloy will be taken as $0{\cdot}84 \pm 0{\cdot}01$°K. Since the measurements were made in the ambient magnetic field a small correction must be made to obtain the zero field transition temperatures. The local magnetic field outside the cryostat was found to be 0·33 gauss. If it is assumed that the magnetic field on the sample is the same, then, from the known variation of transition temperature with applied field (Daunt and Heer 1949), a correction of around 0·002°K must be applied. The corrected transition temperatures are then taken as $1{\cdot}174 \pm 0{\cdot}002$°K for pure aluminium and $0{\cdot}84 \pm 0{\cdot}01$°K for the alloy. (The assumption as to the equality of external and internal field may not be correct since the calorimeter is surrounded by a superconducting lead shield (Martin 1961b) which may affect the internal field (Pippard and Pullan 1952).)

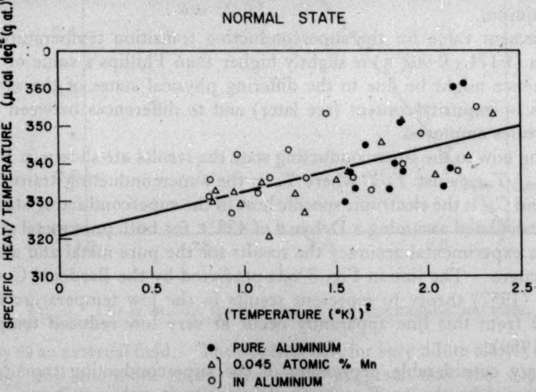

Fig. 2. The normal state specific heat of pure aluminium and an aluminium–0·045 atomic % manganese alloy.

The specific heats in the normal state are shown in Fig. 2 as a plot of specific heat/temperature against the square of the temperature. The line was fitted by a least-squares analysis of the results for the alloy for which the electronic specific heat coefficient γ is $321 \pm 8\,\mu$cal deg^{-2} (g at.)$^{-1}$ and the Debye temperature θ is 343^{+70}_{-40}°K, where the error limits are 95% confidence limits.

§ 4. Discussion

From the results in the normal state, it is clear that there is no specific heat anomaly of the type found in dilute alloys showing a resistance minimum. The residual resistance measurements show that there is a considerable amount of the manganese in solid solution, and other measurements (Collings and Hedgcock, to be published) show that manganese ions in solution in aluminium have a magnetic moment. The conditions are therefore similar to those found in the alloys which do show a resistance minimum and associated large specific heat anomaly. A possible explanation for the difference in behaviour is that the splitting of the ground state degeneracy of the manganese ions is either much greater or much smaller than that which occurs in the other systems and consequently the various anomalies are either swamped by other effects or else lie below the present temperature limit of measurement.

However, the anomalous thermoelectric effects in aluminium–manganese alloys (Hedgcock, to be published) occur in a similar temperature range to those found in systems showing a resistance minimum. Thus it might be that the resistance-minimum phenomena and associated specific heat anomalies do not arise from the process causing the anomalous thermoelectric powers.

The value found for γ for the alloy is in good agreement with the result of Phillips (1959) for pure aluminium. The θ value is rather low but is not known accurately due to the smallness of the lattice specific heat. The present results on pure aluminium are also consistent with Phillips's values but due to the very limited range of measurement no accurate estimates of γ or θ can be made for the pure aluminium.

The present value for the superconducting transition temperature of pure aluminium ($1{\cdot}174 \pm 0{\cdot}002$°K) is slightly higher than Phillips's value of 1·163°K. The difference might be due to the differing physical states of the samples, to differences in impurity content (see later) and to differences between the temperature scales employed.

Turning now to the superconducting state the results are shown in Fig. 3 as a plot of $C_{es}/\gamma T_c$ against T_c/T where T_c is the superconducting transition temperature and C_{es} is the electronic specific heat in the superconducting state (which has been calculated assuming a Debye θ of 428°K for both pure metal and alloy). Within the experimental accuracy the results for the pure metal and alloy lie on the same curve. The line in Fig. 3 was predicted by the Bardeen, Cooper and Schrieffer (1957) theory to represent results in the low temperature limit but departures from this line apparently occur at very low reduced temperatures (Phillips 1959).

The very considerable depression of the superconducting transition temperature caused by the small amount of impurity is rather striking. Previous work with non-transition metal impurities in tin, indium and aluminium (Lynton, Serin and Zucker 1957, Chanin, Lynton and Serin 1959) had shown that for very dilute alloys the superconducting transition temperature is usually depressed, the depression increasing as the impurity content, and therefore residual resistance is increased. However, for more concentrated alloys the superconducting transition temperature may be raised. Work with transition metal impurities (Matthias and Corenzwit 1955, Matthias *et al.* 1959, Müller 1959) had shown that the superconducting transition temperature was often raised on adding the impurity, but no very dilute alloys were investigated. The results of the present experiment suggest that, in the limit of extreme dilution, there is no essential difference in the effects of transition and non-transition metal impurities on the superconducting transition temperature.

The effect of impurities on the superconducting transition temperature has been considered theoretically by Pippard (1957), Herring (1958) and Suhl and Matthias (1959). Both experimental and theoretical evidence shows that the effect cannot be due to the magnetic moment of the impurity ions acting in the same way as an external field. The dependence, for very dilute alloys, on residual resistivity, and therefore mean free path, suggests that the depression of transition temperature is due to an altered electron–phonon interaction. This alteration apparently has a negligibly small effect on the electronic specific heat.

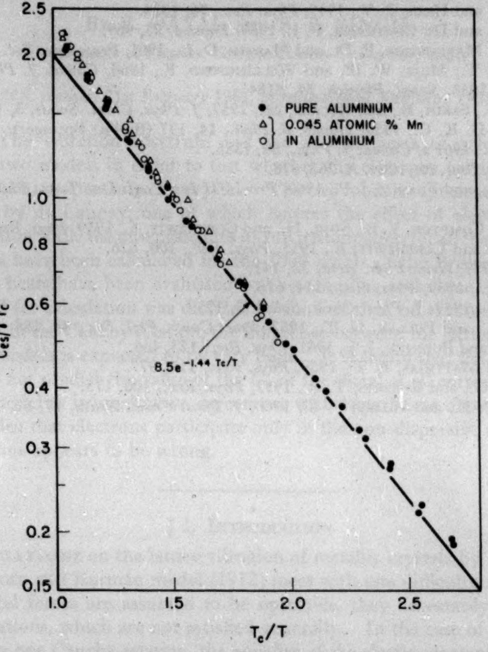

Fig. 3. The electronic specific heat in the superconducting state.

§ 5. Conclusion

For dilute alloys of manganese in aluminium there is no evidence for a specific heat anomaly of the type found in very dilute alloys showing the resistance-minimum phenomena. The presence of 0·045 atomic % manganese in solution in aluminium depresses the superconducting transition temperature by 0·33 deg K.

Note Added in Proof.

Quinn and Budnick (1961) have recently reported that very small amounts of indium, bismuth, or lead dissolved in thallium *raise* the superconducting transition temperature. Thus it appears that the sign of the initial shift of superconducting transition temperature, resulting from the addition of small amounts of impurity, depends on the parent metal.

Participation of the Electron Gas in Lattice Vibrations

By B. DAYAL and S. P. SINGH
Department of Physics, Banaras Hindu University, India

MS. received 21*st February* 1961, *in revised form* 30*th May* 1961

Abstract. The vibration spectrum and the specific heats of gold have been studied by two models in order to test whether the electrons participate in the complete vibration spectrum of a crystal. The two models represent the extreme cases given by de Launay, one of which ignores the effect of electrons on the lattice vibration while the other assumes its full participation for all the frequencies. Frequencies have been calculated for the 1000 points of the Brillouin zone and the specific heats have been evaluated by the sampling technique. The choice of this metal for calculation was dictated by the fact that, on account of the large discrepancy in the Cauchy relation, the difference between the lattice frequencies of the two models is expected to be very high. It is found that the central force model does not predict the value of the C_V of the metal at all correctly, while de Launay's model is in qualitative agreement with experiment above 15°K. De Launay's idea that electrons participate only in the non-dispersive region of the spectrum thus appears to be wrong.

---

§ 1. Introduction

Investigations on the lattice vibration of metallic crystals by means of the usual Born and Kármán model (1912) meet with one difficulty at the outset. If central forces are assumed to be operative, they necessarily lead to the Cauchy relations, which are not satisfied generally. In the case of cubic metals there is only one Cauchy relation, the equality of the elastic constants c_{12} and c_{44}. Experimental data on elastic constants show that usually this is not obeyed even roughly, the values of c_{12} being in many cases as high as two to three times the other constant. In a well-known work, Fuchs (1935, 1936) gave a probable cause of this discrepancy. According to him certain energies such as the energy of the ground state of the valency electron, the Fermi, the exchange and the correlation energies of the conduction electrons, depend only on the atomic volume. The forces on the displaced ions due to them are not central. They contribute to the compressibility but not to those elastic constants, in the corresponding strains of which the volume changes are absent. Fuchs showed that the constants $c_{11}-c_{12}$ and c_{44} are unaffected by the presence of the electron gas, while the individual values of c_{11} and c_{12} which depend on the compressibility are affected by it. If the contribution of the free electrons to the compressibility is removed, the Cauchy relation would be satisfied.

Fuch's work has greatly influenced all the subsequent calculations of the lattice frequencies of metals. Two different lines of approach have been adopted. In one of these, which owes its inspiration to the work of Fine (1939), and has been developed by Leighton (1948) and Bauer (1953), the presence of the free electrons has been entirely ignored. The experimental values of the elastic constants are separated into two parts, one of which is assumed to arise from the central interaction of the ions while the other is due to the electron gas. This division is carried out in such a way that the former satisfies the Cauchy relation and at the same time retains the experimental values of $c_{11}-c_{12}$ and c_{44} unchanged. These adjusted constants of the central interaction are then used to calculate the lattice frequencies. Leighton supports this method with the remark "Fuchs' result was used in the evaluation of the atomic force constants α and γ because the Born–von Kármán boundary condition which is used in the derivation of the secular determinant requires that the volume of the crystal remains constant so that the conduction electrons have no effect on the motion of the lattice".

In the second method, an electron lattice interaction is explicitly introduced in the setting up of the secular determinant. It has been argued that the ionic vibrations may cause local changes in the volume of the electron gas, even though the total crystal volume remains unchanged and these compressions and rarefactions may greatly alter the numerical values of the frequencies. Force models on these lines have been introduced by de Launay (1953, 1956), Leibfried and Brenig (1953) and Bhatia (1955). The latter has calculated the electron–lattice interaction by means of the Thomas–Fermi model of the atom. If the non-central interaction is put equal to zero, Bhatia's force model does not yield the Cauchy relation as one would expect it to do on the basis of Fuch's investigations. On the other hand we get $c_{11}=c_{44}$ in the case of the body-centred metals and a more complicated relation between elastic constants for the face-centred metals.

Leibfried and Brenig derived a Hooke's constant by considering the change brought about by the ionic displacements on Wigner and Seitz's polyhedra, but confined themselves only to the derivation of certain averages of the powers of the frequencies. De Launay has developed a simple phenomenological approach in which the free electrons are assumed to behave like an ordinary gas supporting a compressional but not a shearing stress. They, therefore, influence the numerical values of the frequencies of the longitudinal wave only. Since the waves traversing the crystal are, in general, neither purely longitudinal nor transverse, they are separated into their longitudinal and transverse components. The former is then corrected for the electron gas by the introduction of new force constants.

De Launay (1956) expressly states that his model applies to the long acoustical waves and has left its applicability to the high frequency thermal waves as an open question. He has discussed two extreme cases. The central force model of Fine and Leighton, in which the effect of the electron gas has been ignored, forms one extreme case. The opposite extreme is represented by his own model, applied to the complete vibration spectrum of the crystal. According to him neither extreme was likely to be correct. He has suggested that "by comparing the results of calculations for both extreme cases, with experiment, one may be able to draw conclusions which will give direction towards a better theory". He has discussed the case of copper and is of the opinion that the participation of the electrons in the long-wave non-dispersive region of lattice vibration is complete, while it is negligible or nearly so in the highly dispersive region. The same conclusion has been reached recently by Overton (1960). In his review article Parkinson (1958) has pointed out that recent experimental data on the specific heats of the alkali metals do not support de Launay's conclusion regarding electron participation in the non-dispersive part of the spectrum. The specific heats of all the body-centred metals have been calculated in this laboratory under the assumption that de Launay's model is applicable to the complete vibration spectrum of a crystal. A very good agreement has been obtained between the calculated and the experimental values of the specific heats. The results on lithium have already been published (Dayal and Sharan 1960). This would indicate that de Launay's conclusion is erroneous and that the electrons do participate to the same extent in the full vibration spectrum of the metallic crystals.

In copper as well as in the body-centred cubic metals discussed above, the discrepancy from the Cauchy relation is not very large. The calculated frequencies and specific heats for both the extreme cases of de Launay are not likely to differ by large amounts. It is, therefore, possible to ascribe the deviations from the experimental values in either case to the uncertainties in the elastic and the specific heat data. In order to decide the question of electron participation in the lattice vibrations it is obviously necessary to take up a case where the departure from the Cauchy relation is very pronounced. This is so for gold where the elastic constant c_{12} is nearly three and a half times the value of c_{44}. The authors have, therefore, taken up the case of gold, which is a face-centred lattice, for study. The vibration frequencies and specific heats of this metal have been calculated for both the extreme cases of de Launay and the results are being reported in the present paper. Similar cases of lead, aluminium and silver are under study at present and the results will be reported in due course.

§ 2. CHOICE OF WAVE VECTORS

The wave number vectors **k** of the permitted vibrations are fixed by Born's cyclic conditions, according to which the vibration pattern repeats itself in a large crystal block of $n \times n \times n = n^2$ cells. Suppose $\mathbf{a}_i$ $(i=1, 2, 3)$ are the basic vectors of the unit cell of the direct lattice and $\mathbf{a}_i^*$ those of the reciprocal lattice. The latter are defined by

$$\mathbf{a}_i^* = \frac{\mathbf{a}_j \times \mathbf{a}_k}{V} \qquad \ldots\ldots(1)$$

where V is the volume of the unit cell of the direct lattice. It follows that the wave number vectors **k** of the permitted vibrations are the vectors of a miniature reciprocal lattice whose basic vectors are $\mathbf{a}_i^*/n$ (Blackman 1955). These miniature cells are confined within the first Brillouin zone. It is obvious that the zone will contain n^3 lattice points defining a total of n^3 wave vectors.

The unit cell of the face-centred cubic lattice is rhombohedral. The basic vectors of the direct and reciprocal lattice are (Smith 1948)

$$\mathbf{a}_1 = \tfrac{1}{2}a(0, 1, 1) \qquad \mathbf{a}_2 = \tfrac{1}{2}a(1, 0, 1) \qquad \mathbf{a}_3 = \tfrac{1}{2}a(1, 1, 0) \qquad \ldots\ldots(2)$$

$$\left.\begin{aligned} \mathbf{a}_1^* &= \frac{1}{a}(-1, +1, +1) \\ \mathbf{a}_2^* &= \frac{1}{a}(+1, -1, +1) \\ \mathbf{a}_3^* &= \frac{1}{a}(+1, +1, -1) \end{aligned}\right\} \qquad \ldots\ldots(3)$$

where a is the lattice constant of the cubic cell.

Since the wave number vectors **k** are vectors of the miniature reciprocal lattice they are given by

$$\mathbf{k} = \frac{1}{na}\left[(-p_1+p_2+p_3),\ (p_1-p_2+p_3),\ (p_1+p_2-p_3)\right]$$

$$= \frac{1}{na}\left[p_x, p_y, p_z\right] \qquad \ldots\ldots(4)$$

where the p are all integers. It can be easily seen that p_x, p_y, p_z are either all odd or all even.

The boundaries of the Brillouin zone are defined by $p_x = \pm n$, $p_y = \pm n$, $p_z = \pm n$ and $p_x \pm p_y \pm p_z = \pm 3n/2$. On account of the cubic symmetry a number of points will correspond to the same values of the frequencies. It is sufficient if we consider only those points of the positive octant for which

$$\left.\begin{array}{l} 0 \leqslant p_z \leqslant p_y \leqslant p_x \leqslant n \quad \text{and} \\ p_x + p_y + p_z \leqslant \frac{3}{2}n. \end{array}\right\} \qquad \ldots\ldots(5)$$

Following Kellermann (1940) we have taken n to be ten. There are 48 points defined by (4) and (5) including the origin. These points were also derived by Kellermann, but he missed the point (7, 7, 1), and added an extraneous point (10, 5, 0) (Dayal and Tripathi 1961). The secular determinants have been solved for each of the 47 points and each frequency has been weighted according to the number of similar points associated with it. The weight of the points on the boundaries of the zone has been taken to be half of the number of similar points (Dayal and Singh 1960). In this way we have been able to get exactly 3000 frequencies including the three zero frequencies corresponding to the origin.

§ 3. FREQUENCY SPECTRUM

Frequencies have been calculated for all the representative points of the Brillouin zone for both the extreme cases, whose secular determinants have been taken from de Launay's article (1956). In one of these, the effect of the electrons has been completely ignored while in the second they participate equally well in all the lattice vibrations. There is a misprint in de Launay's article regarding the definition of ξ which should be given by $(\alpha' - \alpha_1)/\alpha_1$. This has been corrected here.

For the computation of the frequencies we have used the following elastic constants for 0°K, which have been taken from de Launay's review (1956) and refer to measurements made by Goens (1940).

$$c_{11} = 1{\cdot}94 \times 10^{12}\ \text{dyn cm}^{-2} \qquad c_{12} = 1{\cdot}62 \times 10^{12}\ \text{dyn cm}^{-2}$$

$$c_{44} = 0{\cdot}455 \times 10^{12}\ \text{dyn cm}^{-2}.$$

These constants do not differ substantially from later measurements of Neighbours and Alers (1958). In fact, the numerical values of $c_{11} - c_{12}$ and c_{44} are almost the same in both sets of measurements. As a result, the use of Neighbours and Alers' data would only affect the longitudinal frequencies of de Launay's model by about one or two per cent. The difference is trivial from the point of view of the results of the present paper.

The lattice constant has been taken to be $4{\cdot}07 \times 10^{-8}$ cm. It is expected that the calculated values of the frequency are correct to 1%. The frequency distribution, i.e. the $g(\nu)$ curves for both the cases are shown in Fig. 1. The curves have not been normalized and the units for $g(\nu)$, though the same for both the curves, are arbitrary.

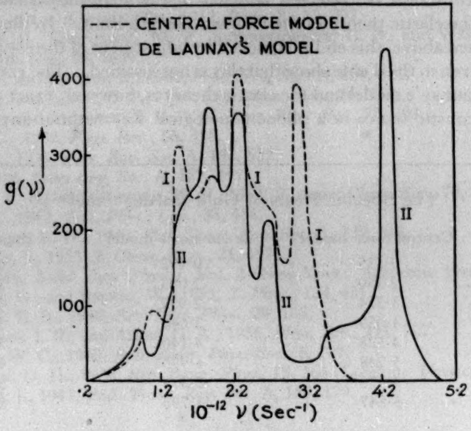

Fig. 1. Frequency distribution curve for gold.

§ 4. EVALUATION OF SPECIFIC HEATS

The specific heats have been calculated by numerical computation by Blackman's sampling technique (Blackman 1937). For this purpose, the vibration spectrum has been divided into intervals of $\Delta\nu = 0{\cdot}2 \times 10^{12}\,\mathrm{sec}^{-1}$. Calculations have not been made below 15°K because the number of frequencies is too small for getting accurate results in this region. The results are shown in the Table and have been compared with the experimental data of Geballe and Giauque (1952). The electronic specific heat has not been subtracted from the experimental results shown in the Table. (θ, T) curves for both the central force and de Launay's models are given in Fig. 2. For presenting θ values below 15°K we have calculated $\theta_0{}^3$ for both the models from the elastic constants by means of Eqns (11.40) and (11.43) of de Launay's review (1956). These give the following extrapolation formulae for θ for the liquid helium region:

Case I $\qquad \theta = 156 - 0{\cdot}064T^2$ ......(6)

Case II $\qquad \theta = 159 - 0{\cdot}075T^2$. ......(7)

These two formulae have been used to extrapolate our calculated (θ, T) curves below 15°K. The experimental values of θ in the range 1–5°K are from the work of Corak *et al.* (1955) and above this range from Geballe and Giauque (1952). It can be seen that the central force model does not show any degree of agreement with the experimental data above 20°K. De Launay's electron gas model shows a much better agreement. The calculated values of θ are, however, about 6–10% lower than the experimental values. This difference is not large and is obviously due to the general inadequacy of the limited Hooke's law interaction in the case of metals.

There is one feature common to all models based on Hooke's law of forces. Their force constants are selected in such a way that they yield the secular equations of the elastic theory in the long wavelength limit. In the central force model discussed above, this end is achieved by adjustment of the elastic constants. The results given in the Table show that this is not justified. The correspondence between de Launay's model and the elastic theory is, however, exact and it applies to the long acoustic waves in a phenomenological way without any reservation.

The Specific Heats of Gold (cal deg^{-1} mol^{-1})

Temp. (°K)	Central force model	de Launay's model	Experimental
15	0·535	0·492	0·354
30	2·380	2·083	1·756
40	3·374	2·972	2·672
50	4·059	3·640	3·396
60	4·528	4·140	3·952
90	5·248	4·990	4·887
120	5·539	5·372	5·296
240	5·847	5·798	5·747

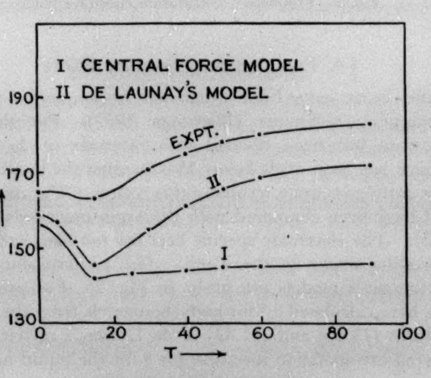

Fig. 2. (*θ*, *T*) curves for gold.

It can be seen from the Table that the specific heats given by de Launay's model are always higher than the experimental values. This shows that the actual lattice frequencies for short waves do not lie between the values given by the two models, but are in fact a few per cent higher than those given by de Launay's theory. We are led to conclude that the electrons participate fully in all the vibrations but their effect on the numerical values of the frequencies is slightly greater than that given by the simple phenomenological theory of de Launay.

The Excitation of the Vibrational Modes of Ethylene in Homo-molecular Collisions

By R. HOLMES and W. TEMPEST
Acoustics Laboratory, Chadwick Physics Laboratory, University of Liverpool

Communicated by H. D. Parbrook; *MS. received* 15*th June* 1961

Abstract. Sound absorption and velocity were measured in ethylene at 500 kc/s and 700 kc/s in the ranges 0·07 to 2 atm and −10 to 80°c. All the vibrational modes relaxed out at approximately 1 Mc/s atm, but the assumption of two relaxation times, for the transfer of energy between translational and vibrational motion, fitted the measurements better than the assumption of a single relaxation time. Assuming that the average relaxation time found by fitting single relaxation curves to the measured points was approximately that of the lowest frequency mode, the value of the force constant β in the exponential intermolecular potential was found to be $6{\cdot}71 \times 10^8\,\mathrm{cm}^{-1}$. This agrees well with the value $4{\cdot}72 \times 10^8\,\mathrm{cm}^{-1}$ calculated from the Lennard-Jones potential.

---

§ 1. Introduction

The mechanism of the excitation of the internal modes of a gas molecule can be conveniently studied, in many cases, by measurements of the sound propagation constants. Several observers have investigated the excitation of the vibrational modes of ethylene in this way.

Richards and Reid (1934) measured the relaxation time for the transfer of energy between vibrational and translational motion at 15, 30 and 45°c and investigated the effects of added hydrogen and deuterium in promoting transitions. McCoubrey, Parke and Ubbelohde (1954), McGrath and Ubbelohde (1954) and Arnold, McCoubrey and Ubbelohde (1958) worked at several temperatures between 0 and 25°c and investigated the effects of other added impurities, particularly hydrocarbons. Corran, Lambert, Salter and Warburton (1958) covered the temperature range between 19 and 300°c and found $\ln P_{10}$ to be proportional to $T^{-1/3}$ (P_{10} is the probability of a transition from the first excited state to the ground state per molecule per encounter and T is the absolute temperature). They used the Cottrell and Ream (1955) analysis of vibrational–translational energy exchange to obtain a value for β (the exponent in the intermolecular potential function $V = V_0 e^{-\beta r}$, where r represents the molecular separation), and obtained a value about four times greater than that obtained from viscosity data. Edmonds and Lamb (1958) estimated the relaxation time at 25°c, assuming a single relaxation mechanism, from some low frequency (1–10 kc/s) tube absorption measurements. Gravitt (1960) measured absorption in the region of the absorption peak using a tube method at three temperatures between −1·5 and 60°c and fitted single relaxation curves to his results to find the relaxation time and the vibrational specific heat.

The estimates of the relaxation time at a given temperature show a considerable spread; for example, at 25°c the values obtained by the above mentioned workers range from 0·2 μsec to 0·39 μsec. This spread may be due to the difficulty of obtaining pure ethylene. All the results published to date are in agreement with the hypothesis of a single relaxation time for vibrational–translational energy transfer, but in most cases only part of the relaxation region has been investigated.

Ethylene has eight vibrational modes with wave numbers between 810 cm^{-1} and 1623 cm^{-1}, a situation which might be expected to give rise to a number of relaxation times close together. This could lead to a broadening of the relaxation peak in the sound absorption curve, which would be easier to detect than the corresponding change in the velocity dispersion curve.

It was therefore decided to make simultaneous absorption and velocity measurements over a wide range of frequency to pressure (f/p) ratios and at several temperatures, the particular objects of the experiments being to reduce the absolute error in the relaxation time measurements and to investigate carefully the possibility of a double or multiple relaxation mechanism. Measurements of the temperature dependence of the relaxation times would give information about the intermolecular force operating in transition-producing encounters.

§ 2. EXPERIMENTAL PROCEDURE

2.1. *Apparatus*

The absorption and velocity of sound were measured at frequencies between 500 kc/s and 700 kc/s using a pulse technique which has been described in detail elsewhere (Parbrook and Tempest 1957, Holmes, Parbrook and Tempest 1960). The apparatus could be operated at gas pressures between 2·1 and 0·07 atm and covered the range of f/p ratios from 0·24 to 10 Mc/s atm. Measurements were made at temperatures between −10° and +80°c.

2.2. *Experimental Accuracy*

Individual absorption measurements were estimated to be accurate to ±2% and velocity measurements to ±0·1%.

2.3. *Gas Supply and Purification*

Two sources of ethylene were used in the course of these experiments. Samples of 99·8% stated purity were obtained from the Esso Petroleum Co. Ltd., and a sample of 99·5% stated purity was supplied by Imperial Chemical Industries Ltd. In both cases the main impurity was stated to be ethane.

It is known that water vapour has a considerable effect on the relaxation time in ethylene (Arnold, McCoubrey and Ubbelohde 1958); the gas was therefore dried by passing it slowly through phosphorus pentoxide and magnesium perchlorate.

Work on ethylene–ethane mixtures (Arnold, McCoubrey and Ubbelohde 1958) has shown that the presence of 5·53% ethane shifts the relaxation time in ethylene from 0·32 μsec to 0·148 μsec, thus 0·2% ethane should shift it by less than 2%, a change which would not be detected with the present apparatus. For this reason no attempt was made to remove the small quantities of ethane present.

§ 3. THEORY

3.1. *Single Relaxation Mechanism*

Kneser (1933) and Rutgers (1933) calculated expressions for the velocity and absorption of sound in an ideal relaxing diatomic gas, neglecting the effects of viscosity and heat conduction. If it is assumed that binary collisions alone are responsible for the transfer of energy between translational and vibrational motion, the relaxation time τ is related to the pressure by the equation $\tau = K/p$, in which case the velocity and absorption equations take the form:

$$V^2 = \frac{RT}{M} \frac{C_{p0}C_{v0} + 4\pi^2(f/p)^2K^2C_{p\infty}C_{v\infty}}{C_{v0}^2 + 4\pi^2(f/p)^2K^2C_{v\infty}^2} \qquad \ldots\ldots (1)$$

and

$$\alpha_\lambda = \frac{\pi RC'2\pi(f/p)K}{C_{p0}C_{v0} + 4\pi^2(f/p)^2K^2C_{p\infty}C_{v\infty}}, \qquad \ldots\ldots (2)$$

where T is the absolute temperature (°K), M the gramme molecular weight, R the gas constant for one gramme molecule (erg), f the sound frequency $(c/s) = \omega/2\pi$, p the gas pressure (atm), K the relaxation time at 1 atm, C_{v0} the molar specific heat at constant volume (erg) $(\omega\tau \ll 1)$, $C_{v\infty}$ the molar specific heat at constant volume (erg) $(\omega\tau \gg 1)$, C_{p0} the molar specific heat at constant pressure (erg) $(\omega\tau \ll 1)$, $C_{p\infty}$ the molar specific heat at constant pressure (erg) $(\omega\tau \gg 1)$, and C' the vibrational specific heat (erg).

$$V_0^2 = \frac{C_{p0}}{C_{v0}}\frac{RT}{M} = \text{sound velocity}^2\ (\text{cm/sec})^2 \quad (\omega\tau \ll 1),$$

$$V_\infty^2 = \frac{C_{p\infty}}{C_{v\infty}}\frac{RT}{M} = \text{sound velocity}^2\ (\text{cm/sec})^2 \quad (\omega\tau \gg 1),$$

$$C_{v0} = C_{v\infty} + C', \quad C_{p0} = C_{p\infty} + C', \quad C_p = C_v + R.$$

The values of K can be obtained from velocity measurement by using the equation

$$4\pi^2\left(\frac{f}{p}\right)_i^2 K^2 = \frac{C_{v0}^2}{C_{v\infty}^2}, \qquad \ldots\ldots (3)$$

where $(f/p)_i$ is the value of f/p at the point of inflection of Eqn (1).

K can be determined from absorption measurements by using the equation

$$4\pi^2\left(\frac{f}{p}\right)_M^2 K^2 = \frac{C_{p0}C_{v0}}{C_{p\infty}C_{v\infty}} \qquad \ldots\ldots (4)$$

where $(f/p)_M$ is the value f/p at which α_λ is a maximum.

The equation

$$(\alpha_\lambda)_M = \frac{\pi RC'}{2[C_{p0}C_{v0}C_{p\infty}C_{v\infty}]^{1/2}} \qquad \ldots\ldots (5)$$

where $(\alpha_\lambda)_M$ is the maximum value of the absorption, can be used to evaluate C'.

The above equations are based on the assumption that a single relaxation time can adequately describe the behaviour of the gas. It has been shown by Landau and Teller (1936) that for a diatomic molecule in which anharmonic effects are not appreciable (a situation which applies at 300°K in most gases) there is only a single relaxation time governing energy exchange between translational and vibrational motion. In this case the rate constant k_{10} for $1 \rightarrow 0$

transitions (i.e. from first excited state to ground state) is related to the relaxation time by the equation

$$\frac{1}{\tau}=k_{10}\left[1-\exp\left(-\frac{h\nu}{kT}\right)\right], \qquad \ldots\ldots(6)$$

where ν is the fundamental vibrational frequency (c/s).

If transitions occur only during collisions and N is the total number of collisions per molecule per second, then the average number of collisions needed for de-excitation, Z, will be N/k_{10} and the probability of de-excitation per collision $P_{10}=1/Z$.

3.2. *Multiple Relaxation*

Most polyatomic molecules have several vibrational degrees of freedom appreciably excited at temperatures around 300°K and this gives rise to the possibility of a multiple relaxation process with several relaxation times.

The actual process of de-excitation can occur in a variety of different ways, the two extreme examples of which can be described as 'parallel' and 'series' mechanisms. In the first of these each mode exchanges energy independently with translation and there are as many relaxation times as there are modes. In the second case only one mode (that of lowest frequency) exchanges energy with translation, while the other modes exchange energy internally with this one. In complex molecules there are numerous possibilities which can be described as intermediate between series and parallel.

The theory of multiple relaxation has been developed by Schäfer (1940) who considered two relaxation times and extended by Herzfeld and Litovitz (1959) to cover the case of many relaxation times. A more general treatment has been given by Tanczos (1956) who has derived equations for sound velocity and absorption in the case where all possible transitions (i.e. simple transitions involving energy changes in one mode only and complex transitions involving simultaneous energy changes in two modes) are considered, subject to the condition that transitions can occur only during collisions.

Tanczos's results can be expressed in the form

$$\left(\frac{V}{V_0}\right)^2=1+\frac{R}{C_{p0}(C_{v0}-\sum_{1}C_1')}\sum_{1}\frac{C_1''\omega^2\tau_1''^2}{1+\omega^2\tau_1''^2} \qquad \ldots\ldots(7)$$

and

$$2\alpha\left(\frac{V}{\omega}\right)\left(\frac{V}{V_0}\right)^2=\frac{R}{C_{p0}(C_{v0}-\sum_{1}C_1')}\sum_{1}\frac{C_1''\omega\tau_1''}{1+\omega^2\tau_1''^2}. \qquad \ldots\ldots(8)$$

The C_1'' and τ_1'' are 'apparent' specific heats and relaxation times which can be related to the actual specific heats C_1' and relaxation times τ_1 of the molecule. The C_1'' always satisfy the equation

$$\sum_{1}C_1''=\sum_{1}C_1'. \qquad \ldots\ldots(9)$$

The relationships between the C_1'', τ_1'' and C_1' and τ_1 depend on the mechanism of the relaxation process and can be derived from calculations of the various transition probabilities for the molecule. Tanczos (1956) describes how this may be done but the calculation is complex and has so far been carried out for only a few molecules (Tanczos (1956) for chlorinated methanes, Dickens and Linnet (1957) for sulphur dioxide).

3.3. *Calculation of P_{10}*

Herzfeld and Litovitz (1959) have derived an expression for P_{10} which is applicable to simple transitions involving a change of one in the quantum number of one mode only.

$$P_{10}=\frac{1}{1{\cdot}017}\left(\frac{r_c}{r_0}\right)^2\frac{1}{Y(2,2)}\frac{1}{Z_0}F(M)\left(\frac{\theta'}{\theta}\right)\left(\frac{2\pi}{3}\right)^{1/2}\left(\frac{\theta'}{T}\right)^{1/6}\exp\left[-\frac{3}{2}\left(\frac{\theta'}{T}\right)^{1/3}+\frac{\theta}{2T}+\frac{\epsilon}{kT}\right], \qquad \ldots\ldots(10)$$

where r_0, ϵ are Lennard-Jones force constants, $\theta=h\nu/k$, $\theta'=16\pi^2\tilde{m}\nu^2/\beta^2k$, $\tilde{m}$ is the reduced mass of the colliding molecules, Z_0 a geometrical factor, r_0 the equilibrium distance for a molecule approaching with a relative velocity V_m, V_m the velocity most likely to cause a transition $(=(4\pi^2kT\nu/\beta\tilde{m})^{2/3})$, $F(M)$ a function of the masses of the molecules and $Y(2, 2)$ the reduced collision cross section.

Equation (10) contains two terms, $\exp(\theta/2T)$ and $\exp(\epsilon/kT)$, which were absent in the earlier derivations of Landau and Teller (1936) and Cottrell and Ream (1955) but the former term was present in the derivation of Schwartz and Herzfeld (1954). These two terms are important in calculating P_{10} and, as pointed out by Milward, McCoubrey and Ubbelohde (1961), their absence in the previous derivations has led to much confusion in the interpretation of relaxation time measurements.

§ 4. RESULTS

Sound velocity and absorption in ethylene were measured at temperatures of -10, 5, 25, 45, 65 and 80°c. At each temperature about eighty pairs of measurements were made covering the range of f/p ratios from 0·24 to 10 Mc/s atm. The results at 25 and 80°c only are presented in graphical form and the relaxation times and specific heat values calculated from the results at all the temperatures are set out in tabular form.

4.1. *Absorption Results*

To obtain a value for the sound absorption due to relaxation alone it is necessary to subtract the viscothermal absorption from the measured value. The viscothermal absorption was calculated using the 'Stokes–Kirchhoff' equation (see, for example, Truesdell 1953),

$$(\alpha_\lambda)_{v+}=\frac{8\pi^2}{3}\left(\frac{f}{p}\right)\frac{1}{\gamma}\left[\eta+\frac{3}{4}(\gamma-1)\frac{\chi}{c_{p0}}\right], \qquad \ldots\ldots(11)$$

where $(\alpha_\lambda)_{v+}$ is the sound absorption per wavelength (nepers), η the viscosity (poise), $c_{p0}=C_{p0}/M$, $\gamma=C_{p0}/C_{v0}$, χ the thermal conductivity (erg deg^{-1} sec^{-1} cm^{-2}).

Values for the viscosity and thermal conductivity were obtained from *International Critical Tables*, (1927), Callear and Robb (1955), *Handbook of Chemical and Physical Constants* (1955), Lambert *et al.* (1955), Kaye and Laby (1956) and Chapman and Cowling (1958).

Figures 1 and 2 show the corrected results of the absorption measurements at 25° and 80°c respectively plotted in the form $\alpha_\lambda(V/V_0)^2$ against log (f/p). In each case a single relaxation curve (Eqn (2)) and a double relaxation curve (Eqn (8)) have been fitted to the measured points.

The values of C_1'', C_2'', K_1'' and K_2'' giving best fit double relaxation curves to the measured absorption at each of the temperatures used are set out in Table 1. The last row of this table gives comparative values of C'/R calculated from spectroscopic data (Sheppard and Simpson 1952).

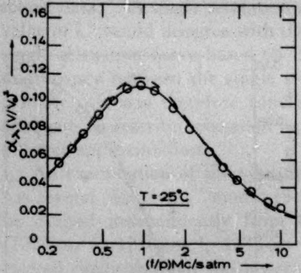

Fig. 1. Ethylene 25°c: sound absorption as a function of frequency/pressure ratio. (Circles, experimental points; full line, calculated double relaxation curve; broken line, calculated single relaxation curve.) Every fifth measured point only is shown.

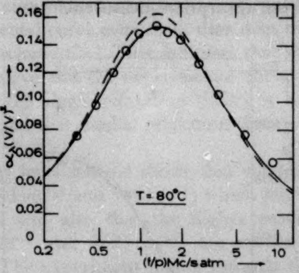

Fig. 2. Ethylene 80°c: sound absorption as a function of frequency/pressure ratio. (Circles, experimental points; full line, calculated double relaxation curve; broken line, calculated single relaxation curve.) Every fifth measured point only is shown.

Table 1

Temperature (°c)	5	25	45	65	80

4.2. *Velocity Measurements*

The measured velocities were 'idealized' by correcting them to zero pressure using the equation

$$\left(\frac{V_{\mathrm{m}}}{V}\right)^2 = \left[1 + \frac{2p}{RT}\left\{B + \frac{T}{C_{\mathrm{V0}}}\frac{dB}{dT} + \frac{1}{2}\frac{T^2R^2}{C_{\mathrm{p0}}C_{\mathrm{V0}}}\frac{d^2B}{dT^2}\right\}\right], \quad \ldots\ldots (12)$$

where B is the second virial coefficient, V_{m} the measured sound velocity and V the idealized sound velocity.

Values for the second virial coefficient and its derivatives were taken from Hirschfelder, Curtiss and Bird (1954).

Figures 3 and 4 show the idealized sound velocities, plotted against log (f/p). The velocities are plotted in the form $(V/V_0)^2 - 1$, where V_0 is the limiting value of the velocity at low f/p ratios. The figures also show calculated single relaxation dispersion curves fitted to the measured points. The double relaxation curves in Figs 3 and 4 were calculated from the specific heats and relaxation times obtained from the absorption curves at the same temperatures.

The relaxation times (assuming single relaxation) at the various temperatures are set out in Table 2; in this table the values of K_1 are relaxation times at one atmosphere pressure from velocity measurements and the values of K_m are those from absorption measurements.

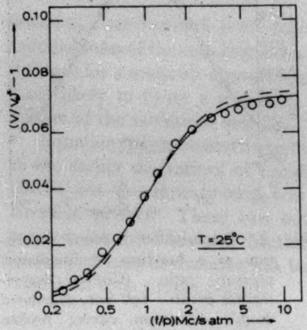

Fig. 3. Ethylene 25°c: sound velocity as a function of frequency/pressure ratio. (Circles, experimental points; full line, calculated double relaxation curve; broken line, calculated single relaxation curve.) Every fifth measured point only is shown.

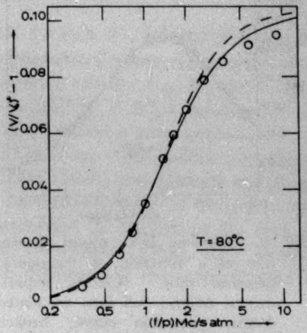

Fig. 4. Ethylene 80°c: sound velocity as a function of frequency/pressure ratio. (Circles, experimental points; full line, calculated double relaxation curve; broken line, calculated single relaxation curve.) Every fifth measured point only is shown.

§ 5. DISCUSSION

The present measurements have been considered from two points of view. Firstly, to establish the number of relaxation times necessary to describe the energy exchange mechanism. Secondly, to investigate the temperature dependence of P_{10} of the lowest mode (810 cm^{-1}), assuming that the relaxation time found by fitting single relaxation curves to the results was that of the lowest mode. Using the Herzfeld and Litovitz (1959) expression for P_{10}, a value has been found for the force parameter β, describing the intermolecular force acting in transition-producing encounters.

5.1. *Multiple Relaxation*

Figures 1 and 2 show that at 25° and 80°c double relaxation curves provide a closer approximation to the measured points than do the single relaxation curves. The same effect was found at the other temperatures. The total specific heat values C' from the double relaxation curves are in good agreement with the spectroscopic values. As a check against the possibility of an error in the spectroscopic C' the empirical formula for C_{p0} as a function of temperature derived by Din (1956) from the best thermodynamic measurements was used to calculate C'. At all the temperatures of the measurements reported here this formula gave a larger C', and hence a larger value of $(\alpha_\lambda)_M$ (Eqn (5)), than did the spectroscopic data. A single relaxation absoption curve based on this thermodynamic value of C' would disagree with the experimental curve even more than does the single relaxation curve based on the spectroscopic C'. This indicates that the discrepancy between the single relaxation curve and the experimental curve is genuine. It was therefore concluded that the single relaxation theory is not adequate to describe relaxation in ethylene and that double relaxation theory is a better approximation.

An examination of the vibrational energy level scheme shows that ethylene has several 'low-lying' modes (810 cm^{-1}, 943 cm^{-1} and 949 cm^{-1}) which might be excited independently from translation and also that the higher modes (1027 cm^{-1}, 1236 cm^{-1}, 1342 cm^{-1}, 1444 cm^{-1} and 1623 cm^{-1}) are probably excited easily through the lower modes. The experiment points towards the existence of two distinguishable relaxation times but it would be difficult to assign them to particular transitions without a theoretical analysis similar to that of Tanczos (1956).

5.2. *Temperature Dependence of P_{10}*

Making the approximation that the average relaxation time found by fitting single relaxation curves to the experimental points is that of the lowest mode, it is possible to estimate the intermolecular force operating in transition-producing encounters.

Equation (6) was used to calculate k_{10} as a function of temperature from the data in Table 2.

The number of collisions per molecule per second at 1 atm was calculated using the Sutherland molecular model,

$$N = 2\sigma^2 n \left(\frac{4\pi kT}{m}\right)^{1/2} \left(1 + \frac{S}{T}\right), \qquad \ldots\ldots(13)$$

where m is the molecular mass, n the molecular density (molecules/cm^3) and S the Sutherland constant for ethylene ($=226^\circ$K).

The Sutherland molecular radius σ was calculated from the experimental viscosity at 0°C using the equation

$$\eta = \frac{5}{16\sigma^2}\left(\frac{kmT}{\pi}\right)\left(1 + \frac{S}{T}\right)^{-1}. \qquad \ldots\ldots(14)$$

Hence $P_{10} = k_{10}/N$ was found as a function of temperature.

A graph of $\ln P_{10} - \ln (1/T)^{1/6} - \theta/2T - \epsilon/kT$ against $(1/T)^{1/3}$ was plotted and from the slope β was found to be $6{\cdot}71 \times 10^8$ cm^{-1} (Fig. 5).

The Lennard-Jones constants for ethylene (calculated from viscosity data) were taken from Hirschfelder, Curtiss and Bird (1954) and a comparative value of β was found by fitting the Lennard-Jones potential to the exponential repulsion by the method given by Herzfeld and Litovitz (1959); this gave

$$\beta = 4{\cdot}72 \times 10^8 \text{ cm}^{-1}.$$

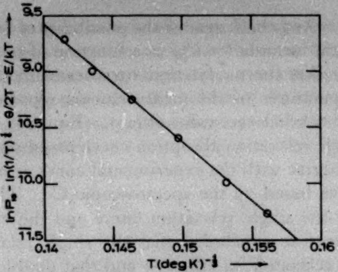

Fig. 5. Graph of $\ln P_{10} - \ln (1/T)^{1/\beta} - \theta/2T - \epsilon/kT$ as a function of $(1/T)^{1/\beta}$.

The two values of β agree to within 40%. If the terms $\exp(\theta/2T)$ and $\exp(\epsilon/kT)$ are omitted from the expression for P_{10} then the relaxation time measurements give $\beta = 17{\cdot}4 \times 10^8\ \text{cm}^{-1}$ which is 4 times greater than the Lennard-Jones value.

§ 6. CONCLUSIONS

Sound absorption and velocity have been measured in ethylene at a series of temperatures between −10 and 80°c. The results suggest that there are two experimentally distinguishable relaxation times governing energy exchange between translational and vibrational motion. The experiment does not permit the relaxation times to be assigned to specific transitions. The value of the exponent in the exponential repulsion potential between colliding molecules found from the temperature dependence of the relaxation time agrees well with the value calculated from the Lennard-Jones potential.

The Scattering of Waves by Dislocations

By F. R. N. NABARRO† and J. M. ZIMAN‡

† University of the Witwatersrand, Johannesburg
‡ Cavendish Laboratory, Cambridge

MS. received 24th July 1961

Abstract. An exact solution is given for scattering by the potential ρ^{-1} in two dimensions. This is compared with the results of the first and second Born approximations for the same potential in an analysis similar to that of Dalitz for the Coulomb potential r^{-1} in three dimensions. Seeger and Bross have shown that, in the scattering of conduction electrons by an edge dislocation, the second-order terms diverge logarithmically with increase of the radius of the cylinder in which the potential of the dislocation is assumed to act. Similar logarithmic terms appear in the second Born approximations for the potentials r^{-1} and ρ^{-1}, and, following Dalitz, reasons are given for believing that they represent a phase shift produced by the refraction of the incident and scattered waves, and that they do not contribute to the scattered amplitude. The cross sections for scattering by a dislocation are probably never much greater than those given by the first Born approximation, and may even be smaller. It is not possible to deduce the large values suggested by some experimental observations.

---

§ 1. Introduction

THE scattering of waves by a straight dislocation line is usually treated in the first Born approximation. The scattering potential is given in cylindrical polar coordinates by $\rho^{-1}\sin\phi$ for an edge dislocation, and there are second-order terms of the form ρ^{-2} for both edge and screw dislocations. It is known that the first Born approximation is only accidentally valid for scattering by the Coulomb potential r^{-1} in three dimensions, and its validity in the case of scattering by a dislocation is in doubt. Both for the scattering of conduction electrons and for the scattering of phonons there are experimental results which are most easily interpreted on the assumption that the true scattering cross section is considerably greater than that estimated by the use of the first Born approximation. Seeger and Bross (1960) have shown that the second-order terms in the wave function of electrons scattered by the potential

$$V=\frac{\hbar^2}{2m}\left(\beta k_{\mathrm{F}}\frac{\sin\phi}{\rho}+\frac{\kappa}{\rho^2}\right), \qquad \ldots\ldots(1)$$

in a cylinder of radius R, are large, of order $\ln k_{\mathrm{F}}R$, although the first-order terms converge for large R. Here m is the mass of the electron, k_{F}, is the wave number at the Fermi surface, assumed spherical, and β and κ measure the strengths of the deformation potentials of the dilatations arising from the linear and the quadratic terms in the elastic equations for a dislocation.

It is not clear whether these terms in $\ln k_F R$ contribute to the scattered amplitude or whether, as Dalitz (1951) showed to be the case for the corresponding term in the Born approximation for scattering by a Coulomb potential, they merely represent a phase shift.

No exact solution has been available for this problem or for a closely related problem which might clarify the physical principles involved. We give here an exact solution for the potential ρ^{-1}. We then summarize Dalitz's discussion of the solution for the potential r^{-1}, develop the first and second Born approximations for the potential ρ^{-1}, and show that the second Born approximation for this potential includes a term of order $\ln kR$ which is to be interpreted as a phase shift. Guided by these two cases for which exact solutions are available, we discuss Seeger and Bross's analysis for the potential (1), and conclude that the terms in $\ln k_F R$ are also to be interpreted as phase shifts which do not contribute to the scattered amplitude.

§ 2. SCATTERING BY THE TWO-DIMENSIONAL POTENTIAL ρ^{-1}

The analysis closely follows Gordon's (1928) analysis for the Coulomb potential r^{-1}, and is therefore given only in outline.

We begin with the wave equation

$$\nabla^2\psi + k^2\psi - 2k^2\alpha\rho^{-1}\psi = 0, \qquad \ldots\ldots(2)$$

and look for solutions in which the coordinate z parallel to the axis of the scattering line does not appear. We introduce new coordinates (x, η) defined by

$$x = x, \quad y = [\eta(2x+\eta)]^{1/2}, \qquad \ldots\ldots(3)$$

so that

$$\eta = \rho - x = 2\rho \sin^2 \tfrac{1}{2}\theta, \qquad \ldots\ldots(4)$$

where θ is the angle of scattering.

The wave equation (2) now becomes

$$\frac{\partial^2\psi}{\partial x^2} - \frac{2\eta}{x+\eta}\frac{\partial^2\psi}{\partial x\,\partial\eta} + \frac{2\eta}{x+\eta}\frac{\partial^2\psi}{\partial\eta^2} + \frac{1}{x+\eta}\frac{\partial\psi}{\partial\eta} + \left(1 - \frac{2\alpha}{x+\eta}\right)k^2\psi = 0. \qquad \ldots\ldots(5)$$

Putting $\psi = \exp(ikx) f(\eta)$, we find

$$\eta\frac{d^2 f}{d\eta^2} + (\tfrac{1}{2} - ik\eta)\frac{df}{d\eta} - k^2\alpha f = 0. \qquad \ldots\ldots(6)$$

The solution of this equation which is appropriate to the present physical problem is given by the confluent hypergeometic function

$$f(\eta) = F(-ik\alpha, \tfrac{1}{2}, ik\eta). \qquad \ldots\ldots(7)$$

When η is large, this has the asymptotic form

$$F(-ik\alpha, \tfrac{1}{2}, ik\eta) \sim \frac{\Gamma(\frac{1}{2})(-ik\eta)^{ik\alpha}}{\Gamma(\frac{1}{2}+ik\alpha)}\left[1 + \frac{\Gamma(\frac{1}{2}+ik\alpha)}{\Gamma(-ik\alpha)}(-ik\eta)^{-1/2-2ik\alpha}\,\mathrm{e}^{ik\eta}\right]. \qquad \ldots\ldots(8)$$

The complete solution is

$$\psi = \mathrm{e}^{ikx} F$$

$$\sim \frac{\Gamma(\frac{1}{2})\exp[ik\alpha \ln ik(x-\rho)]}{\Gamma(\frac{1}{2}+ik\alpha)}\left\{\mathrm{e}^{ikx} + \frac{\Gamma(\frac{1}{2}+ik\alpha)}{\Gamma(-ik\alpha)}\frac{\exp[-2ik\alpha\ln k(\rho-x)}{[ik(\rho-x)]^{1/2}}\,\mathrm{e}^{ik\rho}\right\}. \qquad \ldots\ldots(9)$$

The factor outside the braces is the product of a constant term and a variable phase factor of modulus unity. The factor in braces is the sum of the unperturbed incident plane wave exp (ikx) and of a diverging wave exp $(ik\rho)$, the amplitude of the latter being the modulus of

$$\frac{\Gamma(\frac{1}{2}+ik\alpha)}{\Gamma(-ik\alpha)}\frac{1}{(2k\rho\sin^2\frac{1}{2}\theta)^{1/2}}. \qquad \ldots\ldots(10)$$

It is easily shown that

$$\left|\frac{\Gamma(\frac{1}{2}+ik\alpha)}{\Gamma(-ik\alpha)}\right| = (k\alpha\tanh\pi k\alpha)^{1/2},$$

so that the scattered intensity $I(\theta)$ is given by

$$I(\theta)=\frac{\alpha\tanh\pi k\alpha}{2\rho\sin^2\frac{1}{2}\theta}. \qquad \ldots\ldots(11)$$

When $k\alpha$ is small this leads to the first Born approximation

$$I(\theta)=\frac{\pi k\alpha^2}{2\rho\sin^2\frac{1}{2}\theta}, \qquad \ldots\ldots(12)$$

which is always greater than the exact value (11).

§ 3. THE COULOMB POTENTIAL r^{-1} IN THREE DIMENSIONS

Before we treat scattering by the potential ρ^{-1} in two dimensions by the first and second Born approximations, we shall discuss Dalitz's analysis of the Born approximations to scattering by the potential r^{-1} in three dimensions. Dalitz found that large matrix elements occurred in the higher Born approximations, and showed that they do not contribute to the scattered intensity, but represent a large change in phase from that corresponding to the first Born approximation. We shall summarize Dalitz's argument and provide some additional support for it.

Dalitz made a detailed study of the scattering by a Coulomb potential of a particle obeying the Schrödinger equation. He took the screened potential

$$V=Ze^2r^{-1}\,e^{-r/R}. \qquad \ldots\ldots(13)$$

In addition to confirming the well-known results that in the limit $R\rightarrow\infty$ the differential cross sections calculated by classical mechanics, by the first Born approximation and by an exact solution of the Schrödinger equation, all agree, he calculated the first, second and third Born approximations. He showed that the second approximation involved terms of order $\ln kR$ and the third approximation terms of order $(\ln kR)^2$. Let the first three terms be denoted by B_1, B_2 and B_3, write $i\gamma=B_2/B_1$, and consider the expansion of the expression $B_1\exp i\gamma$ in the form

$$B_1(1+i\gamma-\tfrac{1}{2}\gamma^2+\ldots)=B_1+B_2-\tfrac{1}{2}B_1\gamma^2+\ldots \qquad \ldots\ldots(14)$$

Then Dalitz's result is that the term in B_3 which diverges as $R\rightarrow\infty$ is given correctly by the third term of (14), with B_1 equal to the exact scattering amplitude and γ given by

$$\gamma=-\frac{2Ze^2m}{\hbar^2k}\ln(2kR\sin\tfrac{1}{2}\theta). \qquad \ldots\ldots(15)$$

This suggests that the terms which diverge as $R \to \infty$ represent a phase change of the scattered wave. We shall support this interpretation by showing that the phase shift (15) is asymptotically just that predicted for a particle travelling along the classical orbit. When the particle is far from the scattering centre only its radial motion is important in determining the phase, and its wave equation is approximately

$$\frac{d^2\psi}{dr^2} = \left(-k^2 + \frac{2Ze^2m}{\hbar^2 r}\,\mathrm{e}^{-r/R}\right)\psi \simeq -k^2\left(1 - \frac{Ze^2m}{\hbar^2k^2r}\,\mathrm{e}^{-r/R}\right)^2\psi. \qquad \ldots\ldots(16)$$

The potential acts once to produce a scattered wave at some distance $r_0 \ll R$ from the centre, and then causes the scattered wave to propagate in a refracting medium in which the wave number is reduced from k to $k-(Ze^2m/\hbar^2kr)\,\mathrm{e}^{-r/R}$. This introduces a phase advance of

$$-\frac{Ze^2m}{\hbar^2k}\int_{r_0}^{\infty}\mathrm{e}^{-r/R}\frac{dr}{r} \sim \frac{Ze^2m}{\hbar^2k}\ln\frac{R}{\gamma_0 r_0}, \qquad \ldots\ldots(17)$$

where γ_0 is Euler's constant. The incoming wave suffers an equal phase shift, confirming our interpretation that the logarithmic term in (15) represents the refraction of the incoming and the outgoing waves. This interpretation of the divergent term as a phase shift by refraction is strengthened by the observation that this term arises from intermediate states with wave numbers $\mathbf{k}''$ which lie very close to $\mathbf{k}$ or to $\mathbf{k}'$, the wave numbers of the incident and the scattered waves.

§ 4. THE FIRST AND SECOND BORN APPROXIMATIONS FOR THE TWO-DIMENSIONAL POTENTIAL ρ^{-1}

In treating the Born approximations to the solution of (2) we shall use a notation based on that of Seeger and Bross. We represent the projection of the wave vector $\mathbf{k}$ on the z plane by $\tilde{\mathbf{k}}$. We modify the long-range scattering potential $2k^2\alpha\rho^{-1}$ to a cut-off potential $2k^2\alpha\rho^{-1}\,\mathrm{e}^{-\rho/R}$, and introduce the function

$$T(\tilde{\mathbf{k}}, \tilde{\mathbf{k}}') = (2\pi)^{-2}\int_0^{\infty}\int_0^{2\pi} 2k^2\alpha\rho^{-1}\,\mathrm{e}^{-\rho/R}\,\mathrm{e}^{ik\rho\cos\psi}\,\rho\,d\psi\,d\rho. \qquad \ldots\ldots(18)$$

Here K and Φ are defined by

$$\begin{aligned} K\cos\Phi &= \tilde{k}\cos\phi - \tilde{k}'\cos\phi' \\ K\sin\Phi &= \tilde{k}\sin\phi - \tilde{k}'\sin\phi', \end{aligned} \qquad \ldots\ldots(19)$$

and $(\tilde{k}, \phi)$ and $(\tilde{k}', \phi')$ are the polar coordinates of the projections of $\mathbf{k}$ and $\mathbf{k}'$ on the z plane.

The matrix element for scattering from the state $\mathbf{k}$ to the state $\mathbf{k}'$ by the potential $2k^2\alpha\rho^{-1}\,\mathrm{e}^{-\rho/R}$ can be expanded in an ascending power series of the form

$$\delta(k-k')\,\delta(\bar{k}-\bar{k}')(T_1+T_2+\ldots), \qquad \ldots\ldots(20)$$

where

$$T_1 = T(\tilde{\mathbf{k}}, \tilde{\mathbf{k}}') \qquad \ldots\ldots(21)$$

and

$$T_2 = \int T(\tilde{\mathbf{k}}, \tilde{\mathbf{k}}'')\,T(\tilde{\mathbf{k}}'', \tilde{\mathbf{k}}')\left[(\tilde{k}^2-\tilde{k}''^2)^{-1} - \pi i\,\delta(\tilde{k}^2-\tilde{k}''^2)\right]d_2\tilde{\mathbf{k}}''. \qquad \ldots\ldots(22)$$

Seeger and Bross omit the term in $\delta(\bar{k}^2-\bar{k}''^2)$, which makes no contribution to the divergent term in the solution of their problem, but contributes the whole of the divergent term in the case of the symmetrical potentials r^{-1} and ρ^{-1}.

We find that

$$T_1=\pi^{-1}k^2\alpha\int_0^\infty J_0(K\rho)\,e^{-\rho/R}\,d\rho=\frac{k^2\alpha R}{\pi(1+K^2R^2)^{1/2}}. \qquad \ldots\ldots(23)$$

This converges as $R\rightarrow\infty$ to $T_1=k^2\alpha/\pi K$. Since T_1 is multiplied by $\delta(\bar{k}-\bar{k}')$, we may write

$$K=2\bar{k}\sin\tfrac{1}{2}\theta \qquad \ldots\ldots(24)$$

and

$$T_1=k^2\alpha/2\pi\bar{k}\sin\tfrac{1}{2}\theta. \qquad \ldots\ldots(25)$$

If the wave is incident normal to the z axis, which is the case considered in § 2, we have $\bar{k}=k$, and $T=k\alpha/2\pi\sin\frac{1}{2}\theta$. Following Seeger and Bross, we write the amplitude of the scattered wave as

$$\pi^2\left(\frac{2}{\pi k\rho}\right)^{1/2}T_1=\left(\frac{\pi k}{2\rho}\right)^{1/2}\frac{\alpha}{\sin\frac{1}{2}\theta}, \qquad \ldots\ldots(26)$$

and again obtain the intensity (12).

As in the problems considered by Dalitz and by Seeger and Bross, we find that the integral (21) converges for large $\bar{k}''$, and that possible divergencies arise only as $\mathbf{k}''\rightarrow\mathbf{k}$ and as $\mathbf{k}''\rightarrow\mathbf{k}'$. In all of these problems the asymptotic form of the integral for large R may be found by evaluating the contribution to the integral from the neighbourhood of these two singularities. In this way we readily find that when $\bar{k}'=\bar{k}$,

$$T_2=\frac{ik^2\alpha^2}{\pi\sin\frac{1}{2}\theta}\ln kR. \qquad \ldots\ldots(27)$$

This represents a phase shift

$$\gamma=T_2/iT_1=2k\alpha\ln kR. \qquad \ldots\ldots(28)$$

In the quasi-classical approach which we have used to derive (17) the plane orbits for the potentials r^{-1} and ρ^{-1} are identical, and the ratio of the phase shifts appearing in (28) and (17) is the same as the ratio of the perturbing terms appearing in (2) and (16).

We have thus shown that the exact solutions for the potentials r^{-1} and ρ^{-1} show no divergences as the screening radius R is allowed to tend to infinity, that in each case the second Born approximation contains divergent terms proportional to $\ln kR$, and that in each case this divergent term represents the phase shift due to refraction along the classical orbit.

§ 5. SCATTERING BY AN EDGE DISLOCATION

We now discuss the analysis by Seeger and Bross of the scattering by an edge dislocation, using the potential (1).

The first Born approximation involves the matrix elements $\langle\phi'|V|\phi\rangle$ for scattering from the direction ϕ to the direction ϕ'. The terms in β are given by integrals which oscillate for large values of ρ and, except when $\phi'=\phi$, they are easily made to converge by using a convergence factor or by cutting off the integration at some large radius R. The matrix element for scattering through small angles diverges like $(\phi-\phi')^{-1}$. The terms in κ converge for large ρ, but an inner cut-off radius ρ_i has to be introduced, within which the assumptions underlying (1) are not valid.

In the next higher approximation, terms arise which are proportional to β^2, $\beta\kappa$ and κ^2. The terms in κ^2 may be neglected, but Seeger and Bross show that the terms in β^2 and $\beta\kappa$ include components which are proportional to $\ln k_F R$ and, in practical cases, are considerably larger than the terms linear in β or κ. Of these two terms, that in $\beta\kappa$ predominates. Different methods are used to treat these two second-order terms. That in β^2 is obtained by second-order perturbation theory, while that in $\beta\kappa$ is obtained by applying first-order perturbation theory to the exact solution by phase shift analysis of the two-dimensional Schrödinger equation for the central potential κ. Seeger and Bross assume that the squares of these large second-order matrix elements provide a better estimate of the intensity of the scattering of electrons by a dislocation than do the squares of the first-order elements, and thus a better estimate of the electrical resistivity of a metal containing dislocations. Their method leads, in particular, to the result that if a crystal of large size R contains a single dislocation, this dislocation will make a contribution to the electrical resistance comparable to that of a saw cut of width $(\ln k_F R)^2$ atomic spacings.

We shall now examine these calculations from the standpoint of §§ 3 and 4. We first consider the term in β^2. Here Seeger and Bross introduce a sharp cut-off radius R, and find a first-order term S_1, analogous to the T_1 of (21) and given by $S_1=S(\breve{\mathbf{k}}, \breve{\mathbf{k}}')$, where

$$S(\breve{\mathbf{k}}, \breve{\mathbf{k}}')=\frac{i}{2\pi}\beta k_F \frac{\sin\Phi}{K}[1-J_0(KR)]. \qquad \ldots\ldots(29)$$

The second-order term S_2 is analogous to T_2 of (22) and contains a logarithmically divergent term

$$-\frac{1}{8\pi}\frac{\beta^2 k_F{}^2}{\breve{k}^2}[1+\cos(\phi-\phi')]\ln\frac{k_F R}{\gamma_0}. \qquad \ldots\ldots(30)$$

We now have to decide whether the terms S_2 and S_1 in this analysis can properly be compared with the terms which we have labelled B_2 and B_1 in Dalitz's analysis, so that the large term S_2 represents a large phase shift but not a change of amplitude. We note first that S_2/S_1 is purely imaginary, as is required by this interpretation. We also observe from the analysis of Seeger and Bross that this logarithmic term arises from two regions in the $\breve{\mathbf{k}}''$ plane, namely those regions which are very close to $\breve{\mathbf{k}}$ and those which are very close to $\breve{\mathbf{k}}'$.

Moreover, the asymptotic form of (30) is exactly that required by our interpretation. We may calculate the phase shift along the classical orbit by the same method as we calculated the phase shifts (17) and (28). In the present problem the wave incident along ϕ is travelling along the line $-\phi$, and its phase shift in the β potential is asymptotically

$$\gamma_1=-\frac{\hbar^2\beta k_F\sin(-\phi)}{2m}\frac{m}{\hbar^2\breve{k}}\ln k_F R. \qquad \ldots\ldots(31)$$

For the outgoing wave we have

$$\gamma_2 = -\frac{\hbar^2 \beta k_F \sin\phi'}{2m}\frac{m}{\hbar^2 \bar{k}}\ln k_F R,$$

giving a total phase shift of

$$\gamma = -(\beta k_F/2\bar{k})(\sin\phi' - \sin\phi)\ln k_F R. \qquad \ldots\ldots(32)$$

It is easily verified that this value of γ satisfies the relation $i\gamma = S_2/S_1$ required by our interpretation.

The comparison with the results of classical dynamics is less encouraging than it is in the Coulomb case. Since the forces are not central, there is no easy way of finding the classical orbits explicitly. In the first-order perturbation the total change of momentum along the path is zero. (This was first observed by Hunter and Nabarro (1953), although their sketch of the classical orbits is incorrect. The orbits of electrons in the neighbourhood of a negative edge dislocation are represented roughly by the conventional drawing of the lattice planes in the neighbourhood of a positive edge dislocation.) An angular deflection occurs only in second-order perturbation, and this singular scattering potential therefore gives in classical mechanics, as in quantum mechanics, differential cross sections proportional to β^2 when β is small. This is true in general for non-singular scattering potentials in three dimensions, but non-singular potentials in two dimensions lead to classical differential cross sections which are linear in the scattering potential. For the present potential the impulse on a particle with initial impact parameter p which is derived from classical second-order perturbation theory is proportional to p^{-2}, so that the differential cross section for scattering through a small angle θ is proportional to $\theta^{-3/2}$, whereas in the quantum mechanical case it is proportional to θ^{-2}.

We now consider the term in $\beta\kappa$ which appears in the second approximation to scattering by the potential (1).

Seeger and Bross obtain a matrix element proportional to $\beta\kappa$ by applying the β potential as a first-order perturbation to the exact quantum mechanical solution for a particle moving in the κ potential. We enquire firstly whether this is a correct use of perturbation theory, and secondly whether the resulting large matrix element represents a change in the scattered amplitude or only in the phase of the scattered wave. The first question is delicate, for the perturbation procedure consists in neglecting terms of order β^2 while calculating those of order $\beta\kappa$. The results shows that the term in $\beta\kappa$ which is obtained is indeed, in practical cases, larger than that in β^2. Nevertheless this term arises from regions where ρ is large, and in these regions the β potential is larger than the κ potential. In considering the second question, we see that the waves scattered by κ will be expected to show a change of phase as a result of refraction by the β potential analogous to that calculated in §§ 3 and 4. It is easy to see why phase changes of the order of (32) occur in the β^2 term and in the $\beta\kappa$ term, but not in the β term. For if β acts once, it may either scatter through a finite angle or refract. The β term cannot include the refraction of the scattered ray. The phase shift appears to this order only in the undeviated ray, and perturbation theory breaks down just at this angle of scattering.

§ 6. CONCLUSIONS

Our method of argument is to draw an analogy with a hypothesis. There are arguments in favour of the validity of Dalitz's original hypothesis, and in favour of the validity of our analogy, and there seem to be no compelling arguments against either. We conclude (i) that the problem of the scattering matrix for the potential (1) is still open, (ii) that Seeger and Bross's divergent term in β^2 can be entirely accounted for as a phase shift, and (iii) that a phase shift exists which introduces terms of the same order as their term in $\beta\kappa$. If the present interpretation is correct, (iv) the first Born approximation, supplemented by a correction such as that of Harrison (1958) for scattering by the core of the dislocation, gives the best available estimate of the electrical resistivity produced by undissociated dislocations in a metal. This estimate can hardly be reconciled with the experimental observations on aluminium, although these are still very uncertain.

ACKNOWLEDGMENTS

We are grateful to Professor Seeger for allowing us to see the paper by Seeger and Bross before publication, and for a stimulating discussion which lent support to conclusion (i) above.

Grain Boundary Damping
I: Pure Iron

By G. M. LEAK
Department of Metallurgy, University of Manchester

MS. received 21*st April* 1961

Abstract. Internal friction measurements have been carried out on specimens of high purity iron from which carbon and nitrogen have been removed. A relaxation peak, observed at about 500°c for a frequency of vibration about 1c/s, is associated with the presence of grain boundaries in the specimens. The activation energy Q associated with this damping process is 46 kcal mol^{-1}. The damping appears to be governed by a term, frequency × (grain size)^2 exp (Q/RT). The variation of peak damping and background damping is similar to that observed in other pure metals.

---

§ 1. Introduction

MECHANICAL and physical properties of metals are markedly affected by the presence of grain boundaries. It is not generally possible, however, to investigate boundary phenomena directly. For example, attempts have been made to extract boundary material for analysis but such techniques entail working on a scale of, at least, microns and have not been very successful in the past. Metallographic evidence suggests that grain boundary thickness must be orders of magnitude smaller. Some success has been obtained by the use of radioactive isotopes, for example, in studying segregation of impurities to boundaries (Thomas and Chalmers 1955). The resolution of the technique is not entirely satisfactory for the solution of many problems. Recent work (Brammar, Honeycombe and Ward 1958, Plateau, Henry and Crussard 1958) using electron microscopy to study surfaces of intergranular fractures has been successful. This technique also has its limitations, particularly in the types of problem which can be tackled. Internal friction measurements (Kê 1947 a) give a relaxation peak which is associated with the presence of grain boundaries in the specimen. Very little effort has been devoted to this method, which might, under suitable conditions prove to be a valuable tool for the investigation of grain boundary phenomena. It has one important advantage, that no significant disturbance of the grain boundary material need occur during the experiment. The purpose of this paper is to present results which have been obtained using the internal friction technique to study grain boundaries in pure iron. It represents the initial stages of a programme intended to study the effects of interstitial and substitutional impurity elements in iron.

§ 2. Background Information

Kê observed a damping peak for polycrystalline specimens that was absent in specimens of single crystals (Kê 1947 a, b, 1948, 1949). He suggested that this was caused by sliding at grain boundaries. By analogy with flow in other materials, this was called grain boundary viscosity.

Assuming a flat boundary of thickness d, and of linear dimension similar to the grain diameter D, Kê showed that the coefficient of viscosity was given by

$$\eta = dG\tau/D$$

where G is the unrelaxed shear modulus for the material and τ the time for which stress relaxation is allowed to take place. This expression was modified by Smith (1950) without significantly affecting the model of grain boundary sliding to give

$$\eta = 6dG\tau/D. \qquad \ldots\ldots(1)$$

The temperature dependence of η is given by

$$\eta = \eta_0 \exp(Q/RT)$$

where Q is an activation energy. Thus

$$\tau = \frac{D\eta_0}{6dG}\exp(Q/RT). \qquad \ldots\ldots(2)$$

In a damping experiment, the internal friction δ is given by

$$\frac{\delta}{\pi} = \Delta\frac{\omega\tau}{1+\omega^2\tau^2} \qquad \ldots\ldots(3)$$

where Δ, the relaxation strength of the process, is a constant, ω the frequency of vibration and τ the relaxation time for the mechanism giving rise to the damping. It is assumed that the two values for τ are identical. δ is consequently a function only of $\omega\tau$, that is,

$$\delta = f\left\{\frac{\omega D\eta_0}{6dG}\exp\left(\frac{Q}{RT}\right)\right\}. \qquad \ldots\ldots(4)$$

This point is important for Kê's interpretation of the mechanism. At the peak value of δ, where $\omega\tau$ is unity and the peak temperature is T_p, then plots of $\ln\omega$ against $1/T_p$ for constant grain size D and of $\ln D$ against $1/T_p$ for constant frequency of vibration ω, should both give straight lines of slope Q/R. (It has been assumed that d, G and η_0 are independent of temperature in the region of the damping peak maximum.) Kê's work in fact showed that a variation of grain size was equivalent to a variation of frequency in its effect on peak temperature. Probable atomic mechanisms to account for this damping have been put forward by Mott (1948) and by Kê (1949). Mott considered the boundary as a transition region consisting of islands of good lattice fit between the adjacent grains, separated by regions of bad fit. Slip in the boundary is represented by disordering of atoms around each of the islands. The rate of slip v is then given by

$$v = \frac{\nu a^2 n\sigma w}{kT}\exp\left(\frac{nL}{kT_m}\right)\exp\left(-\frac{nL}{kT}\right) \qquad \ldots\ldots(5)$$

where ν is the frequency of atomic vibration, a the lattice constant, w the area of boundary per atom, σ the shear stress. n atoms are disordered around each island, L is the latent heat of fusion per atom and T_m is the melting point. Kê's results interpreted in this way give n equal to 14, when nL/kT is made equal to the measured activation energy for grain boundary damping. The constant outside the exponent did not give good agreement with experiment. This model, however, can account for the influence of impurities; if they migrate to boundaries the effective value for nL will be altered.

Kê also assumed that the boundary consisted of regions of good lattice fit but that the slip process involved forcing atoms past one another in a disordered group between the islands of good fit. Then

$$v = \frac{q\gamma\nu\sigma}{kT} \exp\left(\frac{-Q}{kT}\right) \qquad \ldots\ldots(6)$$

where q is the density of disordered groups of atoms, γ the shear strain from the rearrangement of atoms and Q the activation energy for the process. Q would automatically be the same as the activation energy for volume self-diffusion and steady-state creep since his model implied no difference between the type and concentration of imperfections in the boundary and in the grain. Neither of these mechanisms suggests any relationship between the activation energies for grain boundary damping and grain boundary diffusion.

Kê observed grain boundary peaks in several metals of varying purity without systematically studying impurity elements. There was close agreement between the activation energies for grain boundary damping, volume self-diffusion and steady-state creep.

Copper has been studied by several workers. Köster, Bangert and Lang (1955) showed a correlation between the height of the grain boundary damping peak (after subtraction of the background damping) and the grain size, although they did not test the validity of Eqn (4). A similar correlation was obtained between the background damping and grain size. (The background damping was measured at an arbitrary high temperature, remote from the grain boundary peak). The activation energy for the grain boundary peak damping was 32 kcal mol^{-1}. Rotherham and Pearson's (1956) value was $33 \pm 3{\cdot}3$ kcal mol^{-1}. Weinig and Machlin (1957) used very high purity copper and found the activation energy to be 40 ± 2 kcal mol^{-1}, whilst less pure copper (OFHC quality) gave a value of 33 ± 2 kcal mol^{-1}. Values quoted in these papers for the activation energy for volume self-diffusion of copper are about 50 kcal mol^{-1}.

Silver specimens (Pearson and Rotherham 1956) gave an activation energy of $22 \pm 2{\cdot}2$ kcal mol^{-1} compared with that for volume self-diffusion of 45·9 kcal mol^{-1} (Le Claire 1949). Boundary damping has also been observed in zirconium (Bratina and Winegard 1956), titanium (Pratt, Bratina and Chalmers 1954) and molybdenum (Maringer and Schwope 1954).

§ 3. TECHNIQUE AND SPECIMEN PREPARATION

High purity iron was used. This was made by vacuum-melting specially pure Swedish iron following the technique described by Hopkins, Jenkins and Stone (1951). A typical analysis (in wt %) was as follows:

C	N	Si	S	Al	O_2
0·002	0·001	0·003	0·006	0·001	0·002

The material was forged and rolled down to a diameter of about 6 mm. At this stage the material was given a prolonged anneal in flowing moist hydrogen followed by similar treatment in dry hydrogen. This reduced the carbon and nitrogen to less than 0·0005%, i.e. to below the limits of chemical analysis. The final wire drawing treatment was a reduction of about 90% to a diameter of about

2 mm. This was found essential to produce specimens with a suitable range of grain sizes after recrystallization. The recrystallization anneal, carried out in vacuum, was for 3 hours at 750°C. Grain growth was allowed to occur at 850°C using times up to 3 hours. This gave a series of specimens with grain sizes of 10·6, 14·7, 19·2 and 29·7 grains per linear mm measured transversely.

Grain size determinations were made on the actual specimens used for internal friction experiments. The figures given represent averages for a number of metallographic sections.

Internal friction analyses at this stage showed no carbon or nitrogen interstitial diffusion peaks. This implies that the content of these impurities would be less than 0·0005 wt%.

A torsion pendulum was used with specimens about 20–25 cm long. The equipment was designed to maintain a vacuum of about 1 μ Hg with a temperature variation over the specimen of less than $\pm 1\frac{1}{2}$°C at about 500°C. Logarithmic decrement was measured from the decay of free vibrations and plotted against temperature of the specimen. This internal friction technique has been described in detail elsewhere (Thomas and Leak 1956).

The grain boundary peaks occurred at temperatures in the neighbourhood of 500°C. Maximum damping was high, even up to a logarithmic decrement of 0·1. Nevertheless it was always possible to locate the peak temperature to within about ±3°C. Vibration frequencies in the range 0·3 to 10 c/s were used, damping being recorded visually in the range 0·3 to 2 c/s and photographically for higher frequencies. Frequencies were recorded during experiments. Owing to the high damping it was not possible to measure the frequencies accurately at the temperature of the peak. Consequently frequencies quoted are those measured accurately at room temperature. This does not introduce an appreciable error in the determination of activation energy.

§ 4. RESULTS AND DISCUSSION

A number of curves of internal friction plotted against temperature were taken for each specimen at different frequencies. Within the accuracy of measurement of the peak temperature, the curves for constant frequency were reproducible.

Results are plotted in Fig. 1 in the form of log frequency against inverse temperature.

A typical curve of damping against temperature is shown in Fig. 2. It is worth noting the following characteristics which are different from those reported by Kê (1949) for an iron specimen: (i) the background damping rises more rapidly; (ii) the peak height, after subtraction of the background is lower and the maximum damping observed is higher; (iii) agreement with a theoretical curve, calculated from Eqn (4), is worse. The second point is unlikely to be associated with the technique of measurement or with the equipment since low temperature damping is similar to that reported by Kê and by other workers using the torsion pendulum.

The curves of Fig. 1 form a family of parallel straight lines, each line corresponding to a specific grain size. This is expected if the stress relaxation obeys an Arrhenius equation. The slope of the lines gives the value Q/R from which Q is found to be 46 kcal mol^{-1}. The experimental error for any specific point is

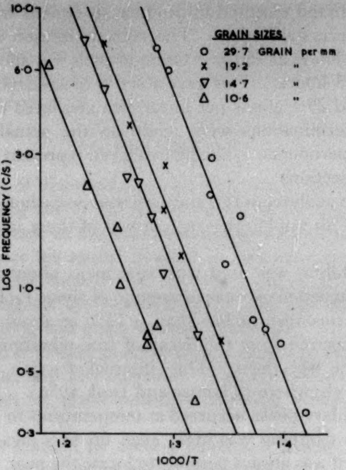

Fig. 1. Variation of peak temperature with frequency of vibration for specimens of various grain sizes.

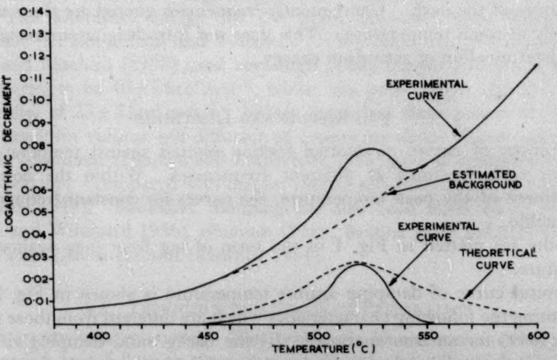

Fig. 2. Typical damping plotted against temperature curves.

high; the estimated error in Q, determined from Fig. 1 is $\pm 3\,\mathrm{kcal\,mol^{-1}}$. The best fit line was obtained by the least squares method, which gave this uncertainty.

The most probable value for the activation energy for self-diffusion in alpha iron is between 62 and $67\,\mathrm{kcal\,mol^{-1}}$ (Borg and Birchenall 1960). The value of Q for grain boundary damping reported by Kê (1947 b, 1948), for iron, is about $85\,\mathrm{kcal\,mol^{-1}}$. Kê assumed this equal to the current value for the self-diffusion activation energy of $78\,\mathrm{kcal\,mol^{-1}}$. It is possible, however, that the pure iron used by Kê (1947 b, 1948, 1949) contained a small amount of carbon which could markedly alter measured activation energies. Furthermore, if the damping process were that of atoms sliding past each other then agreement could be expected between the activation energies for grain boundary damping and grain boundary self-diffusion. Leymonie, Lacombe and Libanti (1958) using radioactive tracer techniques, give a value of Q for grain boundary self-diffusion equal to 45 kcal mol^{-1}. This agrees closely with the present value for the activation energy for grain boundary damping.

The alternative calculation from Eqn (4) is to consider measurements made at constant frequency for specimens of differing grain diameters. For a frequency of 1 c/s the results give a mean value for Q of 21 ± 5 kcal mol^{-1}. The inaccuracy is a consequence of the narrow range of grain sizes.

Although a variation of grain size does radically alter the temperature of the grain boundary peak, the equivalence of ω and D proposed by Kê is not substantiated. Eqn (4) would give approximately correct values for Q if the term D were replaced by D^2. Köster, Bangert and Lang's (1955) results for copper also can be interpreted as requiring a D^2 term. Starr *et al.* (1953) found a relationship requiring a term $D^{1\cdot 86}$ for aluminium specimens. It is possible that an explanation arises from the formation of a sub-grain structure, when the sub-grain diameter might replace the value for D. However, the present specimens contain no carbon and are in a condition where the sub-structure would be difficult to observe. X-ray back reflection photographs show only recrystallized grains, but no measurable sub-structure.

Some comparisons with other consequences of the theories for this relaxation process can be made.

If we accept the model proposed by Mott the number of atoms which are assumed to take part in boundary sliding will be equal to 13 for a latent heat of melting of 3·63 kcal (g atom)$^{-1}$. Mott gave n equal to 14 from his interpretation of Kê's measurements on aluminium.

A coefficient of viscosity for the boundary material can be calculated from Eqn (1). For example, taking the figures grain diameter $3\cdot 3 \times 10^{-3}$ cm, frequency of vibration 6·01 c/s, and a peak temperature of 498°c, then the relaxation time is $2\cdot 65 \times 10^{-2}$ sec. The viscosity of molten iron is about 4×10^{-2} poise. Assuming the validity of Andrade's equation and taking Q as 46 kcal mol^{-1} then we find that the viscosity at 498°c would be 10^6 poise. The shear modulus for iron is 7×10^{11} dyn cm^{-1} with τ equal to $2\cdot 65 \times 10^{-2}$ sec, then the grain boundary thickness is 3×10^{-8} cm. This is similar to the value calculated by Kê.

Comparison of the experimental curve, Fig. 2, with a curve calculated from Eqn (3) gives poor agreement. This is partly due to the difficulty of estimating a true background damping and partly to the inaccuracies in measuring high damping, and must also be related to the fact that it is not strictly valid to use Eqn (3) in regions where the damping is very high.

After subtraction of the background damping estimated graphically from a series of curves such as Fig. 2, the variation of peak height with grain size can be obtained, Fig. 3. The curves give low peak heights, the accuracy is thus poor and Fig. 3 should be considered only indicative of the trend of results. There is no systematic variation of peak height with frequency of measurement and peak temperature. Fig. 3 could be extended to show zero damping at a large grain diameter, and is then similar to that reported for copper by Köster, Bangert and

Lang (1955). It is not clear how to incorporate this variation of damping with grain size into the theory of the mechanism of damping. Köster *et al.* (1955) observed that the background damping at some arbitrary temperature, above the grain boundary damping peak, changed with grain size in a similar way to the change of grain boundary damping. Fig. 4 shows the changes observed in background damping for iron specimens, taken at 600°c. It has been suggested (Zener 1948) that this damping is the result of deformation at grain corners; certainly it varies with grain diameter and must in some way be associated with the boundaries.

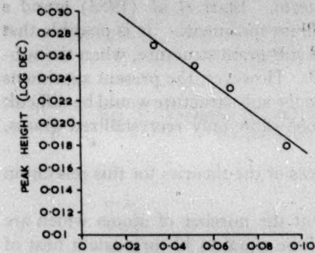

Fig. 3. Variation of intensity of internal friction (peak height) with grain size of specimens.

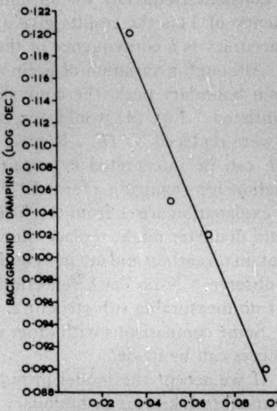

Fig. 4. Variation of background damping with grain size of specimens (measured arbitrarily at 600°c).

Although the experimental results do not give good agreement with Eqn (3), the results in Fig. 1 imply that one relaxation time does predominate. This will be given by

$$\tau = \tau_0 \exp (Q/RT).$$

Taking Q equal to 46 kcal mol^{-1}, we can calculate the values for τ_0:

Grain size (mm^{-1})	10·6	14·7	19·2	29·7
τ_0 (sec) $\times 10^{14}$	4·23	1·74	0·93	0·31.

There is a trend towards a lower value for τ_0 as the grain size decreases; the significance of this trend cannot be assessed without further data. The original work by Kê gave a value about 10^{-21}sec which is not reasonable for a process involving a single atom jump. The present mean value of 10^{-14} sec nevertheless is a reasonable one for such a unit process. This might suggest an alternative mechanism for the grain boundary damping. Movement of grain boundaries, for example, during growth in recrystallized materials, has an activation energy comparable with that of grain boundary diffusion; it appears to increase as the impurity content increases. It is possible that grain boundary damping is caused by migration of the grain boundaries, reversibly, into adjoining grains. Boundaries, in the form of dislocation networks, move reversibly under the action of an applied stress (Washburn and Parker 1952). Thus, qualitatively at least, boundary migration could lead to anelastic phenomena. Boundaries will, in general, be irregular and migrations will occur in which one atom or only a few atoms are involved. This mechanism will involve a τ_0 which is comparable with that for single atom jumps and will yield an activation energy corresponding to that for grain boundary diffusion.

The variation of τ_0, or the frequency factor, with grain size might be dependent on the configurational entropy associated with the atoms taking part in the boundary migration. How such an explanation could be pursued is not clear. The variation of damping with grain size will be dependent on the magnitude of the total grain boundary migration. It should be possible to estimate this dependence.

Clearly, many more experimental results are required to determine the atom movements involved in this contribution to damping. A more accurate determination is required of the shape of the damping curve at the high levels of damping in these experiments.

§ 5. CONCLUSIONS

The results show how the damping peak varies with grain size in the specimens. It is reasonably established that the peak is associated with the presence of grain boundaries in the specimens. The damping appears to be governed by a term frequency (grain size)^2 exp (Q/RT).

The value for the activation energy for grain boundary damping in iron is 46 kcal mol^{-1}. This is in disagreement with values reported by previous workers and disagrees with the activation energy for volume self-diffusion and steady-state creep. It is in very good agreement with the activation energy for grain boundary self-diffusion.

It is not possible, from the results on pure iron, to differentiate between the mechanisms which might account for the damping. It is possible that the damping is associated with grain boundary migration in the form of sub-microscopic grain growth.

The variation of peak damping and background damping, with grain size, has been demonstrated.

On the model of Kê it is possible to estimate the coefficient of viscosity for the grain boundary material. When extrapolated to the melting point of iron this gives reasonable agreement with the observed viscosity of molten iron, if a grain boundary thickness of about two atom diameters is assumed. With Mott's model of grain boundary sliding, it appears that the same number of atoms takes part in grain boundary melting in iron and in aluminium.

ACKNOWLEDGMENTS

Much of the experimental work was carried out by Mr. B. Sweeney and Mr. J. H. E. Fox. Analyses were carried out by Mr. K. Speight. The project received considerable help from early discussions with Dr. W. Thomas.

MS. received 21st April 1961, *in revised form* 10*th July* 1961

Abstract. Internal friction measurements of the grain boundary relaxation peak have been carried out on alloys of high purity iron containing carbon or nitrogen. The influence of these impurities on peak height, peak temperature and on the activation energy for the mechanism giving rise to the damping has been determined. The results differ from those reported on the influence of substitutional impurities. The explanation of these effects is discussed qualitatively in terms of the boundary sliding and boundary migration mechanisms.

---

§ 1. INTRODUCTION

INTERNAL friction measurements show a maximum in the curve of damping against temperature (Leak 1961, to be referred to as Part I) which is associated with the presence of grain boundaries in the specimen. An activation energy can be associated with the process giving rise to the damping. For pure iron this is equal to 46 kcal mol^{-1}. The height for the maximum, after subtraction of the background damping, is dependent upon grain size in a manner shown graphically in Part I. The activation energy is very close to that estimated for grain boundary self-diffusion in alpha iron (Leymonie, Lacombe and Libanti 1958). The coefficient of viscosity for the boundary material has been estimated from Kê's (1947) model of the process. Suitable extrapolation to the temperature of the melting point in iron gives reasonable agreement with the values for viscosity of molten iron, assuming that the grain boundary is two to three atoms wide.

The two principal atomic models for the grain boundary damping process are those proposed by Kê (1949) and by Mott (1948). An advantage of the latter is that account could be taken of the effect of impurities on, for example, the activation energy for the process. This report, based on alloys of high purity iron containing carbon or nitrogen separately shows that interstitial impurities influence the grain boundary damping peak observed with the pure base metal.

Previously published work on the effect of impurities on the grain boundary relaxation peak has referred exclusively to substitutional impurity elements. Weinig and Machlin (1957) investigated alloys of copper containing 0·03 to 1 atomic % of nickel, silicon, aluminium or silver. Addition of the substitutional impurity reduced the height of the original grain boundary peak found with pure copper, called the 'solvent' peak. Simultaneously a new peak, the 'solute' peak, appeared at a much higher temperature and increased in peak height as the amount of the impurity was increased. Small amounts of impurity bring about these changes; for example the original Cu peak disappeared after the addition of about 0·1 at.% Al or Si. As the solute content increased, the background damping, in the neighbourhood of the solute peak, decreased. The activation energy associated with the solvent peak increased as the solute content increased, e.g. from about 40 kcal mol^{-1} for pure Cu to 81 kcal mol^{-1} for Cu 0·1% Al or 0·1% Si. The activation energy of the solute peak decreased, e.g. from 67 kcal mol^{-1} for 0·1% Al to 50 kcal mol^{-1} for 0·8% Al or 55 kcal mol^{-1} for 1% Si. An incidental observation was that there was no significant change in the magnitude of the solute peak as the grain size changed from 0·045 mm to 0·1 mm diameter.

Pearson and Rotherham (Pearson and Rotherham 1956, Rotherham and Pearson 1956) using alloys based on copper and silver as solvents found the activation energy of the solute peaks increased with alloying content, for example to about 44 kcal mol^{-1} (from 33 kcal mol^{-1} for pure Cu, presumably of different purity from that quoted by Weinig and Machlin). Their alloys generally contained more than 1% of alloying element. The temperature of the 'solute' peak decreased as the amount of solute increased. Weinig and Machlin (1957) observed the opposite effect, both works reported results for Cu–Si alloys. The activation energy for Cu–Si alloys determined by Weinig and Machlin dropped from 82 to 55 kcal mol^{-1} as the Si content increased from 0·03 at. % to 1·0 at. %; Rotherham and Pearson's figures are 49 kcal mol^{-1} at 0·9 at. % and 46 kcal mol^{-1} at 8 at. %.

Starr *et al.* (1953) using stress–relaxation methods investigated aluminium-based solid solutions and measured activation energies of 38 kcal mol^{-1}, i.e. unchanged from that of pure aluminium. Only with additions of Mg was the activation energy increased to 54 kcal mol^{-1} for 1·6 at. % Mg.

This brief summary shows the main characteristics of substitutional impurities giving solute and solvent damping peaks. The discussion of the present results will include some comparison of the effects of interstitial and substitutional impurities.

§ 2. SPECIMEN PREPARATION

The basic material used was the high purity iron wire described in Part I. Nitrogen and carbon were removed by prolonged heat treatment in flowing moist hydrogen followed by similar treatment with dry hydrogen (wire diameter about 6 mm).

The wire was reduced in diameter to about 2 mm and given similar recrystallization and grain growth treatments to those described in Part I. Nitrogen was introduced into the specimens by annealing them for 24 hours in a closed system containing known amounts of hydrogen and ammonia at 580°c. Specimens were homogenized by annealing under vacuum at temperatures between 580 and 650°c. The criteria for homogeneity were (*a*) that chemical analyses should remain constant and (*b*) that internal friction determination of the Snoek peak should remain constant. This method for introduction of nitrogen did not contaminate the specimens with carbon, above the level of analysis, approximately 0·0005 wt %. Carbon was introduced by heating specimens at 700°c in flowing hydrogen saturated with heptane at room temperature. The treatment lasted between 30–60 minutes according to the level of carbon required in the specimen, and it was followed by an homogenizing anneal, in vacuum, for 70 hours at 700°c (after removal of the surface deposit of carbon). Experiments showed that the carbon had been introduced uniformly and that the nitrogen content of the specimens was less than 0·001 wt %.

Specimens were wires 20–25 cm long and diameter about 2 mm. A brief survey of the internal friction technique and the references to more complete descriptions are given in Part I.

§ 3. RESULTS

Damping measurements were taken for series of specimens of different grain size and different nitrogen or carbon contents. The specimens were quenched from the temperature of maximum solubility in the α phase, i.e. 580°c for iron–nitrogen specimens and 720°c for iron–carbon specimens. This treatment was adopted in order to give some standard treatment prior to the internal friction experiment. Table 1 gives details of the series of specimens which were prepared. In view of the dependence on grain size observed with specimens of pure iron, two series of iron–nitrogen alloys and one series of iron–carbon alloys were prepared with a fixed impurity content but of varying grain size.

The grain boundary damping peaks were observed at temperatures about 500°c. Precipitation of carbide or nitride would occur as the temperature was raised during the internal friction experiment, followed by re-solution as the temperature was raised further. At the peak temperature all the nitrogen would be in solution except for those alloys containing 0·1%. Carbide would be present for all the iron–carbon alloys with the possible exception of those containing only 0·009% carbon.

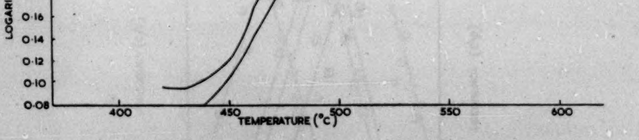

Fig. 1. Typical damping curves for specimens containing carbon.

Figure 1 gives typical damping–temperature curves for the iron–carbon alloys. They are different from those obtained with specimens of pure iron; higher peak damping and higher background damping are observed. Graphically, the peaks agree more closely with the curve calculated theoretically, assuming that the grain boundary stress relaxation takes place with a single relaxation time.

3.1. *Activation Energy*: *Iron–Carbon Alloys*

The activation energy obtained for specimens of pure iron was 46 kcal mol^{-1} (Part I); grain size variation did not affect the estimation of activation energy Q. Furthermore, it was shown that the damping–temperature relationship was governed by a function which included the term D^2, where D is the grain diameter. These two aspects were investigated for the iron–carbon alloys containing 0·089% carbon. Fig. 2 shows the results in the form log (frequency) against peak temperature. These temperatures refer to the peaks after the rising background

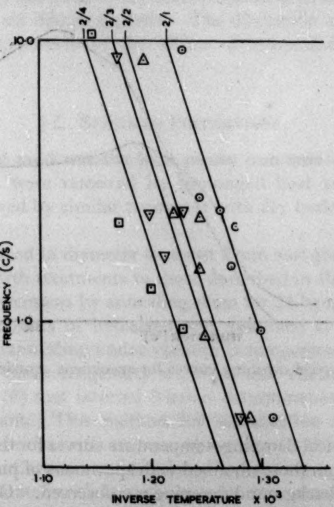

Fig. 2. Damping peak temperatures for iron–carbon specimens plotted as inverse temperature against log (frequency). All specimens containing 0·089% carbon.

damping has been deducted graphically. The two important features are that (*a*) within the limits of scatter of the result there is no significant change of activation energy with grain size, (*b*) the activation energy, measured from the slopes of the lines in Fig. 2, gives $60{\cdot}5 \pm 3{\cdot}5$ kcal mol^{-1} for iron containing 0·089% carbon.

Although there is considerable scatter in these results, the curves in Fig. 2 have been drawn by the method of least squares as parallel straight lines of best fit for each series of specimens. Assuming a constant frequency of vibration, then the activation energy for the process giving rise to the damping should be given by

$$Q = R\frac{(\ln D_1 - \ln D_2)}{1/T_2 - 1/T_1} \qquad \ldots\ldots(1)$$

if there is a simple dependence on D. If, as was found for the pure iron specimens, the dependence is on D^n then the right-hand side of Eqn 2 must be multiplied by n. It is assumed that the relaxation time τ for the process of damping is given by

$$\tau = \tau_0 \exp(Q/RT). \qquad \ldots\ldots(2)$$

The results of this calculation give values varying between 32 and 52 kcal mol^{-1}. The scatter is too great to decide upon a value for n. All that can be concluded is that n lies between 1 and 2, by comparison with the value for Q of 60·5 obtained from frequency variations.

To determine the variation of activation energy with carbon content, series of specimens were carburized to different levels. Results are given in Fig. 3. The

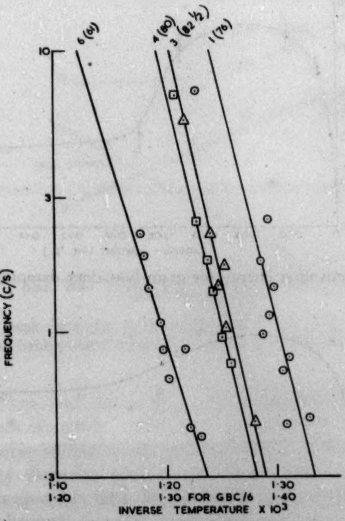

Fig. 3. Damping peak temperatures for iron–carbon specimens plotted as inverse temperature against log (frequency). Each series contains a different level of carbon. The abscissa scale zero is shifted for series GBC/6 to give more clarity.

calculated energies are given in Table 2 together with the value already reported for high purity iron (Part I). The lines in Fig. 3 have been fitted by the method of least squares.

Table 2

Carbon content (%)	0	0·009	0·022	0·07	0·089	0·16
Grain diameter (mm)	—	0·015	0·0313	0·0313	—	0·0054
Activation energy (kcal mol⁻¹)	46 ± 3	76 ± 2	83 ± 4	80 ± 3	60·5 ± 3·5	61 ± 6

These results are shown graphically in Fig. 4 together with probable errors. Although the number of points on this graph is limited, the marked rise in activation energy with small additions of carbon is definite. Similarly the constancy of activation energy as the carbon content is increased above 0·08% is reasonably certain. The peak temperatures for these specimens are approximately at 500°c, where the carbon solubility is about 0·006% (Wert and Keefer 1957). Fig. 5 shows the variation of peak temperature with carbon content for a constant frequency of vibration and grain diameter. The maximum solubility of carbon in α-iron is about 0·02% at 720°c. The results indicate that the equilibrium solubility of carbon in α-iron grain boundaries must be different from that in the more perfect lattice inside the grains.

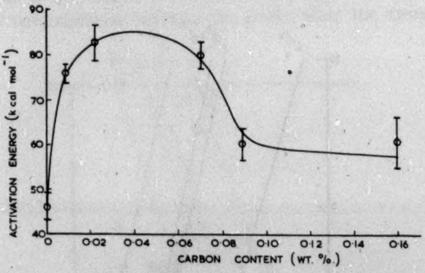

Fig. 4. Variation of activation energy for grain boundary damping with carbon content.

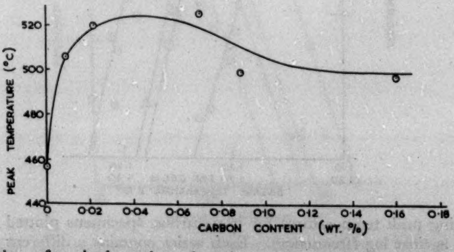

Fig. 5. Variation of grain boundary damping peak temperatures with carbon content.

3.2. *Peak Damping: Iron–Carbon Alloys*

It was reported in Part I that the height of the grain boundary damping peak and also the background damping decreased linearly with increasing grain diameter for the high purity iron. Marked differences have been observed with iron containing carbon. Despite the scatter in results it is possible to report the various trends.

Within the range of frequencies considered in this report there does not appear to be any significant variation of peak damping, peak height or background damping with frequency.

The variation of damping with grain size, for a series of specimens containing a constant amount of carbon, is given in Table 3.

Table 3. Specimens containing 0·089% Carbon

Grain diameter (mm)	0·0334	0·0908	0·1163	0·1725
Peak damping	0·280	0·273	0·285	0·311
Peak height	0·128	0·095	0·078	0·067
Background damping at 600°c	0·223	0·247	0·262	0·278

These results are shown graphically in Fig. 6; the peak damping increases slightly as the grain diameter increases whilst the background damping rises steadily and to a greater extent. (At 600°c the peak damping does not contribute significantly to background damping.) The peak height drops almost linearly with increasing grain diameter. The point corresponding to a grain diameter of 0·1725 mm is probably subject to the greatest error. It has been established that the grain boundary damping peak is no longer detected when the grain size becomes closely comparable with the specimen cross section, although the exact relationship is not known.

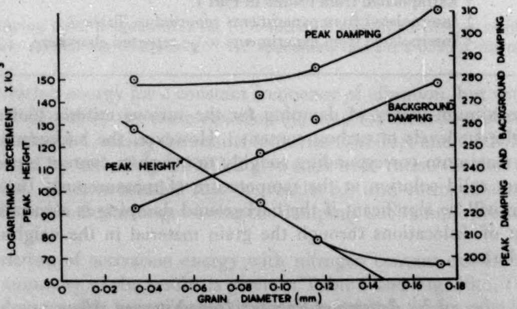

Fig. 6. Variation of peak damping, peak height and background damping with grain size. The background damping is taken arbitrarily at 600°c.

Corresponding average values of damping for specimens of varying carbon content are given in Table 4 and Fig. 7.

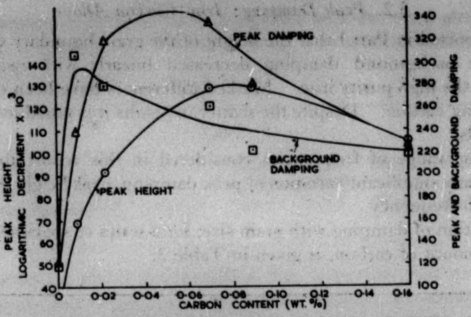

Fig. 7. Variation of peak damping, peak height and background damping with carbon content. The background and damping is taken arbitrarily at 600°c.

Table 4

Carbon content (wt %)	†0	0·009	0·022	0·07	‡0·089	§0·16
Grain diameter (mm)	0·031	0·031	0·031	0·031	0·031	0·031
Peak damping	0·120	0·240	0·320	0·336	0·280	0·230
Peak height	0·028	0·069	0·092	0·129	0·129	0·105
Background damping	0·119	0·308	0·280	0·261	0·221	0·220

† Extrapolated from results in Part I.
‡ Interpolated from experiments reported in Table 3.
§ Interpolated from experiments to be reported elsewhere.

The maximum values of damping for the various criteria plotted occur at widely different levels of carbon content. However, the background damping reaches a maximum corresponding roughly to a carbon content equal to that in equilibrium solid solution at the temperature of measurement (600°c). This conclusion will be significant if the background damping is associated with the movement of dislocations through the grain material in the neighbourhood of the boundaries.

3.3. *Activation Energy*: *Iron–Nitrogen Alloys*

One series of iron–nitrogen alloys was studied to determine any variation of activation energy with grain size. These alloys contained 0·0375% nitrogen. The experimental results are given in Fig. 8.

The experimental curves of damping against temperature for iron–nitrogen alloys were not as well defined as those for iron–carbon alloys. There is no apparent reason for this. Scatter in the results was similar to that for the iron–carbon series. However, Fig. 8 shows that there is no significant variation of activation energy (slope of the curves) with varying grain size of the specimens. All the curves have been drawn as parallel straight lines, within the uncertainty of least squares fitting, giving an activation energy of 68·5 kcal mol^{-1}. The probable error in this figure is ± 3 kcal mol^{-1}.

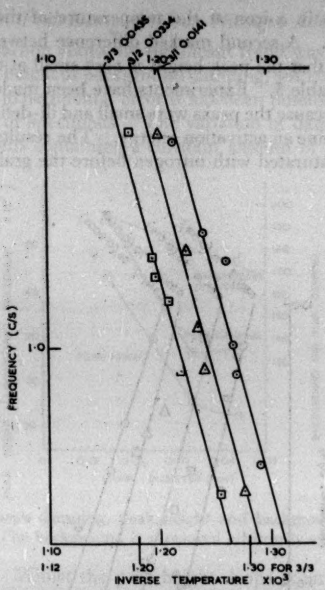

Fig. 8. Damping peak temperatures for iron–nitrogen specimens plotted as inverse temperature against log (frequency). All specimens contain 0·0375% nitrogen.

The activation energy for a constant frequency of vibration, but with varying grain size calculated by the same equation (1) used for the iron–carbon alloys is equal to 75 kcal mol^{-1}, taking the results for series GBN/3/1 and GBN/3/3. The results obtained by including GBN/3/2 give such wide variations that they must be discounted. It is concluded that the results for iron–nitrogen alloys do not require a D^2 term in the factor governing the damping, but a simple proportionality with D.

The variation of activation energy with nitrogen content can be seen from Fig. 9. A summary of the results is given in Table 5 and Fig. 10. The graphs have been drawn using least squares fitting and probable errors calculated from them.

Table 5

Nitrogen content (%)	0	0·0056	0·016	0·018	0·026	0·0375
Grain diameter (mm)	—	0·0225	0·0345	0·0333	0·0165	—
Activation energy (kcal mol^{-1})	46 ± 3	56 ± 2·5	66 ± 5	75·5 ± 6	70 ± 5	68·5 ± 3

The same trend is observed as that found with the iron–carbon alloys; the activation energy rises to a maximum then falls to a steady value. The maximum is not so well defined as for the iron–carbon alloys, but it occurs at a nitrogen content of about 0·02%. This is much less than the equilibrium value of the solubility of nitrogen in α-iron at the temperature of the damping peaks, i.e. about 0·1% at 520°c. A second marked difference between iron–nitrogen and iron–carbon alloys is that the peak height is very small at the maximum level of nitrogen quoted in Table 5. Experiments have been made on alloys containing 0·1% nitrogen, but because the peaks were small and ill-defined, it was impossible to use them to determine an activation energy. The results imply that the grain boundaries become saturated with nitrogen before the grain interiors.

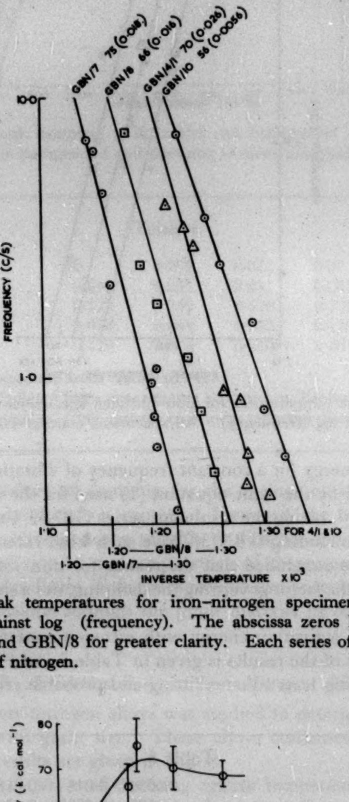

Fig. 9. Damping peak temperatures for iron–nitrogen specimens plotted as inverse temperature against log (frequency). The abscissa zeros have been shifted for series GBN/7 and GBN/8 for greater clarity. Each series of specimens contains a different level of nitrogen.

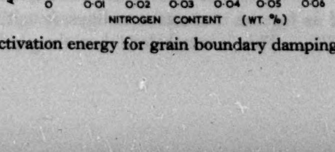

Fig. 10. Variation of activation energy for grain boundary damping with nitrogen content.

3.4. *Peak Damping: Iron–Nitrogen Alloys*

As with the iron–carbon alloys, no significant trend was observed in variation of peak damping, peak height or background damping, with frequency of vibration. Within the margin of experimental error it has been possible to estimate average values for each series of specimens. The variation of damping with grain size, for a series of specimens containing a constant amount of nitrogen, is shown in Table 6 and Fig. 11. Whilst the peak height drops at an approximately linear rate with increasing grain diameter as was observed with the iron–carbon alloys, both background and peak damping also drop. The whole level of damping is generally lower than with the iron–carbon alloys.

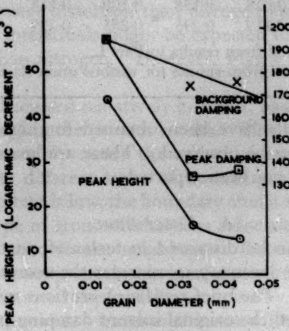

Fig. 11. Variation of peak damping, peak height and background damping with grain size. The background is measured arbitrarily at 600°c.

Table 6. Specimens containing 0·0375% Nitrogen

Grain diameter (mm)	0·0143	0·0332	0·0435

† Extrapolated from results in Part I.
‡ Interpolated from results for various grain sizes.

Some anomalous results have been obtained for higher levels of nitrogen where peaks can sometimes be observed. These are low and inconsistent, and for this latter reason have not been reported.

§4. DISCUSSION

The present results can be discussed in terms of existing theories of grain boundary damping. It is necessary to consider the corresponding influence of substitutional impurities. The brief review of previous work showed that substitutional impurities caused the original solvent damping peak to disappear and a new solute peak to appear at a higher temperature. Both peaks could be observed simultaneously. Kê's (1947, 1949) mechanism of grain boundary sliding must consequently imply the existence of two specific types of boundary; the division of boundaries into these two groups must be caused by the presence of solute atoms. Solutes will segregate preferentially to boundaries; their concentration at boundaries will vary according to the misorientation of adjacent grains (McLean 1957). An explanation for the results could then be argued. As solute atoms are added to the alloy, initially some boundaries will be devoid of impurity atoms whilst others will contain varying amounts. This leads to two types of peak. As the solute content is increased all the boundaries will contain some solute atoms and so only one peak will be observed. Increased difficulty in sliding at boundaries in alloys is to be expected; the solute peak will consequently be at a higher temperature. Such an argument would really require a gradual transition in solute peak temperature. This is not observed with substitutional alloys but is observed with interstitial alloys. However, the level of damping in iron–nitrogen alloys was considerably lower than in the iron–carbon alloys. This suggests that less energy was absorbed in the boundaries of iron–nitrogen alloys because a smaller number of interstitial atoms was taking part in the boundary process. The only other explanation would be based on the possibility that less distortion was associated with nitrogen by comparison with carbon atoms. This in turn would imply considerable differences in peak temperatures which were not observed. Theories of boundary segregation cannot yet solve this problem for nitrogen and carbon atoms.

Mott's model of boundary damping gives an expression containing a term $\exp(-nL/kT)$ for the rate of slip at boundaries. n atoms take part in an elementary process of slip at temperature T, L is the latent heat of melting per atom. Whilst this model also cannot satisfactorily explain the existence of solute and solvent peaks it can explain some of the changes observed in activation energy for the damping process as impurity is added. The changes for substitutional impurities are complex but those for interstitial alloys might be more easily explained. Initially interstitial atoms will add to the value of *nL*, increasing the observed activation energy. As more impurity is added a stage will be reached in which the number of iron atoms in the group must be reduced. This could allow a decrease in the value of *nL*. Ultimately the groups of atoms will be saturated with interstitials and the activation energy will become constant. Since carbon introduces greater distortion than nitrogen atoms in the iron lattice, so the general effects of interstitials might be expected to be observed with smaller amounts of carbon than nitrogen. However, Figs 4 and 10 show the opposite trend.

The explanation discussed tentatively in Part I, based on boundary migration, can be extended to explain the present results. The boundary will migrate into an adjacent grain reversibly under the action of an applied stress. It is not necessary to postulate different types of boundary. For substitutional alloys, when the impurity content is low, the boundary atoms will be of two types, solvent and solute. Each type of atom will have its associated energy of activation for jumping from one lattice to the neighbour. Two damping peaks should be observed. As the impurity content is increased all the atom sites favoured for jumping, i.e. all the distorted sites, will be occupied by solute atoms and thus only a solute peak will be observed. Interstitial atoms will occupy distorted interstitial sites in the boundaries. The energy barrier to be overcome by an iron atom in jumping to a neighbouring lattice will now be greater than for the pure metal; extra distortion energy must be supplied. Two peaks will not be observed, merely an increased activation energy for the original solvent peak. This should be identical with the activation energy for iron diffusion in the boundaries of the interstitial alloys. Data for comparison purposes are not available; appropriate measurements are now being made. It is surprising, however, that the measured activation energy for boundary damping in the alloys can rise to a value greater than that for volume self-diffusion.

Unfortunately, calculations of the relaxation time constants τ_0 do not clarify the situation. Eqn (2) is assumed to be valid. Results, calculated for data at 1 c/s, are given in Table 8.

Table 8

Carbon content (wt %)	0·009	0·022	0·07	0·089	0·16
Relaxation constant τ_0 (sec)	5×10^{-23}	3×10^{-24}	3×10^{-23}	10^{-18}	10^{-18}
Nitrogen content (wt %)	0·0056	0·016	0·018	0·026	0·0375
Relaxation constant τ_0 (sec)	3×10^{-17}	10^{-19}	10^{-22}	10^{-20}	5×10^{-20}

The corresponding frequency factors reach maxima at impurity contents similar to those at which the activation energies reach maximum values. None of these frequency factors corresponds to the value to be expected if single atom jumps controlled the damping. This may not be unreasonable when it is realized that impurity atoms segregating to the boundaries alter, considerably, the environment of the iron atoms.

The gradual drop of peak height with increasing solute concentration would be expected as more energy is required to move atoms to the adjacent lattice.

The gradual decrease with increasing grain size is difficult to understand quantitatively. Kê originally suggested that damping should be independent of grain size; this is not substantiated by the present results. Qualitatively as the amount of boundary material present increases so will the amount of energy absorbed, during boundary migration increase.

If the background damping is associated with dislocation movements, for example, in the neighbourhood of the boundaries, then it might be expected to be higher for iron–carbon alloys than for iron–nitrogen alloys. The solubility of carbon is much lower than that of nitrogen; precipitation of iron carbides would take place at temperatures of 500–550°c. This would restrict dislocation movement, but might lead to a greater dislocation density than for the iron–nitrogen alloys.

There are no data in the literature to compare estimations of the viscosity of the iron–carbon and iron–nitrogen alloys from damping measurements with those of experimental viscosity determinations in molten iron. Small changes in the assumptions of boundary thickness could accommodate the sparse viscosity measurements available.

The results presented can be summarized as follows:

(i) Interstitial impurities raise the temperature of the grain boundary relaxation peak.

(ii) They alter the activation energy of the damping process which increases to a maximum then decreases to a steady value.

(iii) The peak height is initially increased, after which it decreases to zero as the impurity content is increased.

(iv) The background damping and peak damping follow trends similar to each other.

(v) The explanations put forward by Kê and by Mott cannot adequately explain the damping phenomena in alloys.

(vi) It is suggested that the mechanism of damping is that of reversible boundary migration on an atomic scale. The observed effects can then be explained at least qualitatively.

(vii) It is essential to obtain more data on boundary diffusion in order to test this explanation.

ACKNOWLEDGMENTS

Much of the experimental work has been carried out by Mr. J. H. E. Fox. The analyses have been done by Mr. K. Speight.

Microwave Measurement of Attachment in Oxygen–Nitrogen Mixtures

BY J. J. LENNON AND M. J. MULCAHY†
Department of Electrical Engineering, The University of Liverpool

MS. received 30*th June* 1961

Abstract. A microwave cavity method has been used to measure the electron loss rate following a pulsed discharge in oxygen–nitrogen mixtures. Preliminary results indicate that, when suitable pressures of oxygen and nitrogen are chosen, the main mechanism of electron removal in the later afterglow is a three-body attachment process. The three-body coefficient $K = 2{\cdot}4 \times 10^{-30}\,\mathrm{cm}^6\,\mathrm{sec}^{-1}$ is in good agreement with the drift tube measurements, for thermal electrons, of Chanin, Phelps and Biondi.

Up to recent times, experimental difficulties prevented the measurement of attachment rates in electronegative gases at electron energies less than about 1 ev. The advent of microwave and refined drift tube techniques has enabled attachment of electrons at thermal energies (0·04 ev) to oxygen molecules to be studied. Microwave measurements in pure oxygen have indicated a two-body attachment process with a very low cross section (Biondi 1951, Holt 1959, Sexton, Mulcahy and Lennon 1959 a) ($10^{-22}\,\mathrm{cm}^2$) whilst the drift tube studies of Hurst and Bortner (1959) and Chanin, Phelps and Biondi (1959) have shown that for average electron energies less than 1 ev the process is a three-body one involving the formation of an excited O_2^- ion which is subsequently stabilized by collision with a neutral molecule. The purpose of this note is to give new preliminary results of attachment measurements in oxygen–nitrogen mixtures, using a microwave method.

A resonant microwave cavity method was used which was similar in principle to that used originally by Biondi and Brown (1951) and has already been fully described (Sexton, Mulcahy and Lennon 1959 b). The gas sample being investigated is contained inside the resonant cavity and is ionized by a magnetron pulse. Subsequent deionization is measured by observing the change in resonant frequency of the cavity as a function of time. The detuning of the cavity, caused by the large admittance of the ionized gas, can be related to the average electron density.

As shown by Chanin, Phelps and Biondi (1959) the time rate of change of electron density, for a three-body attachment loss, can be written as

$$\frac{dn_e}{dt} = -\nu_a n_e = -Kn^2 n_e$$

where ν_a is the attachment frequency, K is the three-body coefficient and n is the density of captor molecules.

For a binary gas mixture of, say, oxygen and nitrogen this equation can be written as

$$\frac{dn_e}{dt} = -(K_{O_2} n_{O_2}^2 + K_{N_2} n_{N_2} n_{O_2}) n_e$$
$$= -K' n_{O_2} n_{N_2} n_e$$

---

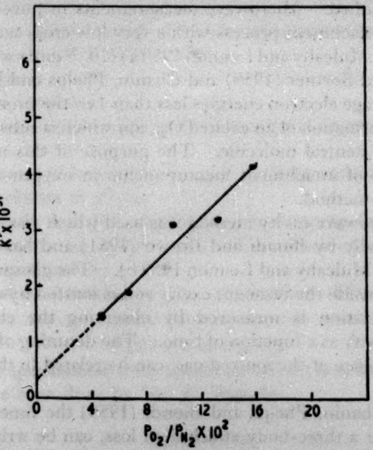
† Now at Associated Electrical Industries (Manchester) Ltd., Trafford Park, Manchester.

where K' is an overall three-body coefficient for the mixture and

$$K' = K_{O_2}\frac{n_{O_2}}{n_{N_2}} + K_{N_2}.$$

Thus K' can be calculated from a knowledge of the partial pressures of oxygen and nitrogen and a measurement of dn_e/dt. A three-body attachment process is indicated by a straight line plot of K' against n_{O_2}/n_{N_2}. The slope of this straight line gives K_{O_2} and the intercept on the K' axis gives K_{N_2} which is an indication of the efficiency of nitrogen as a stabilizing agent as compared with oxygen itself.

In an endeavour to resolve the difficulties encountered in interpreting the microwave results in pure oxygen, various mixtures of oxygen and the rare gases have been studied in this Department. While these results give indirect evidence of three-body attachment, it is impossible to extract a coefficient for the process from them. Data on oxygen–helium mixtures have been submitted elsewhere (Mulcahy, Sexton and Lennon†). The present measurements indicate that when suitable pressures of oxygen and nitrogen are chosen, the main mechanism of electron removal in the later afterglow is a three-body attachment process.



Three-body coefficient plotted against oxygen concentration for oxygen–nitrogen mixtures. $P_{N_2} \simeq 10$ mm Hg; $P_{O_2} \simeq 0{\cdot}5$–2 mm Hg; $K_{O_2} = 2{\cdot}4 \times 10^{-30}$ cm^6 sec^{-1}; $K_{N_2} = 3{\cdot}5 \times 10^{-32}$ cm^6 sec^{-1}.

The Figure shows a plot of K' against the ratio of oxygen to nitrogen pressure. The nitrogen pressure was kept fixed at approximately 10 mm Hg and the oxygen pressure varied from 0·5 to 2 mm Hg. The slope of this line gives a value for K_{O_2} of $2{\cdot}4 \times 10^{-30}$ cm^6 sec^{-1} and the extrapolated intercept shows that $K_{N_2} = 3{\cdot}5 \times 10^{-32}$ cm^6 sec^{-1}. This indicates that a nitrogen molecule is about 70 times less efficient than an oxygen molecule in stabilizing the newly formed excited negative ion. These figures compare favourably with Chanin's values of $2{\cdot}8 \times 10^{-30}\,\mathrm{cm}^6\,\mathrm{sec}^{-1}$ for K_{O_2} (electron energy 0·04 ev) and a factor of about 50 times smaller than oxygen for K_{N_2}.

---

† Mulcahy, M. J., Sexton, M. C., and Lennon, J. J., Paper submitted to the *Fifth International Conference on Ionization Phenomena in Gases*, held in Munich, August 1961.

For oxygen pressures above 2 mm Hg the value of K' was found to decrease with increase of oxygen partial pressure. This effect could not be pursued to any great extent as the electron loss rate was too fast to permit of accurate measurement for oxygen pressures greater than about 2·7 mm Hg.

The decrease in K' is felt to be due to the onset of collisional detachment by vibrationally excited oxygen molecules as suggested by Nicholls and Hopwood (Craggs 1957) to explain the microwave results in pure oxygen. As the oxygen pressure is reduced below 0·5 mm Hg the calculated value of K' increases rapidly with decrease of oxygen concentration. It is felt that this effect is spurious and may well be due to the loss rate of electrons in mixtures with low oxygen concentrations being comparable with that in pure nitrogen at the same pressure. A similar effect was observed by Hasted, Chantry and Wharmby (1961, private communication) who seem to have confined their measurements to this low oxygen pressure range.

Preliminary results with higher nitrogen pressures indicate a somewhat lower value of K_{O_2}. These results will be reported more fully at a later date.

The Correction of Signals Distorted by Linear Apparatus†

By C. P. FLYNN

Department of Physics, University of Illinois, Urbana, Illinois

MS. received 28th October 1960, in revised form 5th June 1961

Abstract. In a previous paper by Flynn and Seymour a technique was developed whereby a type of distortion produced by linear apparatus could be corrected rapidly and efficiently to obtain a 'true' output signal. The distortion considered was not the most general linear distortion, and several cases of practical importance were therefore excluded.

In the present paper, the general linear distortion is examined and equations are developed which permit the rapid correction of distorted output signals into those to be anticipated from the use of ideal apparatus. The procedure is illustrated by means of an example. The accuracy of the corrected signals is then discussed, and it is shown that in some apparatus, as for instance, the magnetic resonance spectrometer, predictable optimum conditions occur under which the form of the true output signal may best be determined.

§ 1. INTRODUCTION

THE desire to obtain more precise data from apparatus output signals has led, particularly in the field of communication engineering, to a continued interest in the relationship between the input and output signals of linear apparatus, both in the presence and absence of apparatus noise. In optics also, much ingenuity has been shown both in the design of components in order to minimize image distortion, and in the development of new techniques whereby inherent distortions may be partially inhibited, as in the case of the 'apodization' of optical instruments (see Dossier and Jacquinot 1950). Nevertheless, it is not possible to produce instruments having infinite resolving power, and rather than deal with the modification of particular apparatus to minimize distortion, our concern will be with the interpretation of the output signal in the inevitable presence of the sources of limited resolution.

In a previous paper (Flynn and Seymour 1960, to be referred to as I) on the correction of output signals, the earlier work of Shull (1946), Stokes (1948) and Tournarie (1957) was considered, and an alternative scheme was presented whereby a simple type of linear distortion could be numerically inverted with a minimum of labour. The present paper contains the extension of this treatment to the general linear distortion, in which case the reponse of the apparatus is a function of the coordinates of the input signal. It will be appreciated that this

† Supported in part by the U.S. Atomic Energy Commission.

distortion is more complex than that normally encountered in communication apparatus, since the demand of reproducibility in apparatus whose independent variable is time precludes the possibility of the more general distortion occurring. Rather, the present treatment becomes necessary in apparatus having variables other than time, in which event the resolution frequency depends on the position of the input signal.

The application of information theory to transmission systems has resulted in a much wider understanding of the capacity of systems to convey detailed signals from a source to an interpreting device (Shannon 1948, see also Blanc-Lapierre 1953). The theory has been extended by several workers in treatments of optical apparatus (Blanc-Lapierre 1953, Blanc-Lapierre, Perrot and Peri 1955, Toraldo di Francia 1955, Linfoot 1958), and in each case the degrading effect of noise on the quantity of information contained in the output signal has been stressed. It has also been pointed out that in assessing the quality of the output signal in the presence of noise, it is necessary to be pragmatic to the extent of inquiring as to the precise nature of the information required and the manner in which it may be obtained from the output signal, before deciding the appropriate conditions under which an experiment may be performed (see Linfoot 1958). In the present investigation, we are interested in the shape of the input signal, which may only be obtained from the output data by means of a linear processing scheme such as that described in the following pages; our aim in performing an experiment must therefore be to minimize the discrepancy between the input signal and the corrected output signal. In §§ 6 and 7, the standard deviation between the two signals over the interesting section of the output signal is used as a measure of this discrepancy, and in this way simple relationships are obtained which inform the experimentalist as to the apparatus conditions under which the particular structure of interest may best be examined.

Following the notation developed in I, we write $f(x_0)$ for the output signal of a linear apparatus, where x_0 is so chosen as to preserve the order and weight of the output data. This output signal is stimulated by the application to the apparatus of an 'input signal' $g(x_0)$ which may also be considered as a function of x_0. By virtue of the assumed linearity of the apparatus, the relation between input and output signal of the apparatus may be written

$$f(x_0)=\zeta g(x_0) \qquad \ldots\ldots(1.1)$$

where ζ is some linear operator. It will be demonstrated that ζ is a function of the differential operator d/dx_0 and of x_0, and that a practical method exists for inverting Eqn (1.1) to yield the apparatus input function

$$g(x_0)=\zeta^{-1}f(x_0). \qquad \ldots\ldots(1.2)$$

The functions $f(x_0)$ and $g(x_0)$ will be assumed to be smooth curves capable of Taylor expansion over a sufficiently wide range of x_0 round any point x. It is true that occasionally an output signal is presented as a set of amplitudes at discrete intervals of x_0, but it is rare for the input function to be of this form. Thus, the output function will bear more resemblance to the input if modified initially to a smooth curve, and it will be adequate if this case only is considered.

§ 2. THE CORRECTION OPERATOR

As pointed out in I, the relation between $f(x_0)$ and $g(x_0)$ need not wholly be concerned with limiting the resolving power of the apparatus, but may also result in displacements, differentiations, etc., of the input signal. It is convenient to extract from the operator ζ that part which causes the limited resolution only. This may be performed by simulating an apparatus identical with our real apparatus except for the removal of the source of limited resolving power; that is to say, an apparatus whose response to a δ function input signal is the δ function or one of its derivatives, together with an appropriate constant of proportionality. If we take the response of this apparatus to be

$$f(x_0)=\xi g(x_0) \qquad \ldots\ldots(2.1)$$

and write for our real apparatus

$$f(x_0)=(\zeta\xi^{-1})\xi g(x_0)=\eta\xi g(x_0) \qquad \ldots\ldots(2.2)$$

where $\eta=(\zeta\xi^{-1})$, then it is evident that we may reduce the distorted output signal to that to be anticipated from the use of an idealized instrument, by means of the correction operator η^{-1} and the relation

$$\eta^{-1}f(x_0)=\xi g(x_0). \qquad \ldots\ldots(2.3)$$

It is clear that as the resolving power of the instrument is increased, η^{-1} tends to unity and the modification of $f(x_0)$ produced by the correction operator tends to zero. In practical correction, this property of η^{-1} is invaluable, since the distortion is normally quite small, and a rapidly convergent expansion of correction terms may therefore be used to obtain an infinitely resolved output signal from the distorted one.

§ 3. THE GENERAL LINEAR APPARATUS

If we supply a δ-function input signal to a real apparatus at $x_0=x$:

$$g(x_0-x)=\delta(x_0-x), \qquad \ldots\ldots(3.1)$$

then we may anticipate some sort of output signal

$$f(x_0-x)=h(x_0-x|x) \qquad \ldots\ldots(3.2)$$

in the neighbourhood of $x_0=x$, tending to zero fairly rapidly as $|x_0-x|$ increases. It will be noted that in general, the function $h(x_0-x|x)$ is a function both of the displacement from the position of the input δ-function, and of the position x itself.

By taking account of the linearity of the apparatus, it is evident that in the presence of an input signal $g(x_0)$, the apparatus response will be given by the relation

$$f(x_0)=\int_{-\infty}^{\infty} g(x_0-x)h(x|x_0-x)\,dx. \qquad \ldots\ldots(3.3)$$

By Taylor expansion of the function $g(x_0-x)h(x|x_0-x)$ round the point x_0, it is found that

$$f(x_0)=\int_{-\infty}^{\infty}\sum_{n=0}^{\infty}\frac{(-1)^n}{n!}x^n\frac{d^n}{dx_0^{\,n}}\left\{g(x_0)h(x|x_0)\right\}dx \qquad \ldots\ldots(3.4)$$

$$=\left\{\sum_{n=0}^{\infty}\sum_{m=n}^{\infty}\frac{(-1)^m}{(m-n)!\,n!}M_m^{\,m-n}(h|x_0)\frac{d^n}{dx_0^{\,n}}\right\}g(x_0), \qquad \ldots\ldots(3.5)$$

where

$$M_p^{\,q}(h|x_0)=\frac{d^q}{dx_0^{\,q}}\int_{-\infty}^{\infty}h(x|x_0)x^p\,dx \qquad \ldots\ldots(3.6)$$

is the qth rate of change, with respect to the position x_0, of the pth moment of the apparatus response to a δ-function input signal at x_0. It is now evident from comparison of Eqns (1.1) and (3.5) that the response operator of the real apparatus may be written

$$\zeta=\left\{\sum_{n=0}^{\infty}\sum_{m=n}^{\infty}\frac{(-1)^m}{(m-n)!\,n!}M_m{}^{m-n}(h|x_0)\frac{d^n}{dx_0{}^n}\right\}. \qquad \ldots\ldots(3.7)$$

The idealized apparatus operator ξ appears when a factor independent of the $M_p{}^q(h|x_0)$ can be removed from ζ. In the great majority of cases, this factor is simply a constant, but in a few cases, a power of d/dx_0 is common to all terms in ζ as a consequence of the zero value of the first few moments of $h(x|x_0)$. Infrequently, examples may be found, as for instance in the case of a time constant circuit where a more complicated factor occurs, corresponding to a displacement operator.

Let us suppose that the first p moments of $h(x|x_0)$ vanish identically: clearly $\xi=\dfrac{d^p}{dx_0{}^p}$, leaving

$$\eta=\left\{\sum_{n=0}^{\infty}\sum_{m=n}^{\infty}\frac{(-1)^{m+p}}{(m-n)!\,(n+p)!}M_{m+p}{}^{m-n}(h|x_0)\frac{d^n}{dx_0{}^n}\right\}. \qquad \ldots\ldots(3.8)$$

Hence by placing

$$M_n(h|x_0)=\sum_{m=n}^{\infty}\frac{(-1)^{m+p}}{(m-n)!\,(n+p)!}M_{m+p}{}^{m-n}(h|x_0), \qquad \ldots\ldots(3.9)$$

and

$$\mu_n(h|x_0)=M_n(h|x_0)/M_0(h|x_0), \qquad \ldots\ldots(3.10)$$

$$f(x_0)=\eta\xi g(x_0)=\left\{M_0(h|x_0)\sum_{n=0}^{\infty}\mu_n(h|x_0)\frac{d^n}{dx_0{}^n}\right\}\xi g(x_0). \qquad \ldots.(3.11)$$

Equation (3.11) will be used in §4 as the basis of a technique for correcting the general linear distortion. Before continuing, however, it is useful to note the relationship between the general form (3.8) of the distortion operator and the form found in the particular case studied in I.

Consider the curve

$$\psi(x_0|x_1)=\xi^{-1}h(x_0|x_1). \qquad \ldots\ldots(3.12)$$

Assuming that $\xi=d^p/dx_0{}^p$, we may relate the moments $M_r{}^s(\psi|x_1)$ of the curve $\psi(x_0|x_1)$ to the moments $M_r{}^s(h|x_1)$:

$$M_{r+p}{}^s(h|x_1)=(-1)^p\frac{r!}{(r+p)!}M_r{}^s(\psi|x_1). \qquad \ldots\ldots(3.13)$$

Hence, substituting for $M_{m+p}{}^{m-n}(h|x_0)$ in Eqn (3.8),

$$\eta=\left\{\sum_{n=0}^{\infty}\sum_{m=n}^{\infty}\frac{(-1)^m(m+p)!}{(m-n)!\,(n+p)!\,m!}M_m{}^{m-n}(\psi|x_0)\frac{d^n}{dx_0{}^n}\right\}. \ldots\ldots(3.14)$$

In the event of $h(x|x_0)$ being independent of x_0, i.e. $h(x|x_0)=h(x)$; $\psi(x|x_0)=\psi(x)$, it may be seen that

$$\eta=\left\{\sum_{n=0}^{\infty}\frac{(-1)^n}{n!}M_n{}^0(\psi)\frac{d^n}{dx_0{}^n}\right\}, \qquad \ldots\ldots(3.15)$$

which is effectively the result derived in I.

§ 4. THE CORRECTION EQUATION

Following the procedure adopted in I, Eqn (3.11) may be inverted to give an equation for $\xi g(x_0)$ in terms of $f(x_0)$ and its horizontal difference at a differencing interval ω. The conventional symbols δ and μ will be used for the differencing operators since there is little chance of confusion between μ and $\mu_n(h|x_0)$.

To be of value, the various terms in $f(x_0)$ in the expression for $\xi g(x_0)$ need to be sorted into an approximate order of decreasing size so that the correction procedure may easily be terminated when a sufficient accuracy is achieved. In order to achieve this, it is useful to make the following reasonable assumptions as to the form of $h(x|x_0)$:

(i) The total distortion is small, in which case

$$\left.\begin{aligned} 1 \gg \frac{\mu_2(h|x_0)}{\omega^2} \gg \frac{\mu_4(h|x_0)}{\omega^4}, \\ \mu_1(h|x_0) \gg \frac{\mu_3(h|x_0)}{\omega^2}, \text{ etc.} \end{aligned}\right\} \qquad \ldots\ldots(4.1)$$

(ii) The variation of the $\mu_n(h|x_0)$ over a distance ω is small compared with $\mu_n(h|x_0)$.

(iii) $h(x|x_0)$ is essentially even or odd according to whether p is even or odd. In this event, $\mu_n(h|x_0)$ is small for n odd.

These assumptions are easily justified; the first by the demonstration in §§ 6 and 7 that the maximum information concerning the input signal may be determined only when the distortion is small, and the second and third assumptions are simply observations concerning the output characteristics of many forms of linear apparatus.

Using assumptions (i) to (iii) in order to find the most important terms, the correction equation is found to be

$$\begin{aligned} \xi g(x_0) = \Big[1 - \mu_1(h|x_0)\frac{\mu\delta^1}{\omega} - \Big\{\mu_2(h|x_0) - \mu_1{}^2(h|x_0)\Big\}\frac{\delta^2}{\omega^2} \\ - \Big\{\mu_3(h|x_0) - \frac{\omega^2}{6}\mu_1(h|x_0) - \mu_1(h|x_0)\mu_2(h|x_0)\Big\}\frac{\mu\delta^3}{\omega^3} \\ - \Big\{\mu_4(h|x_0) - \frac{\omega^2}{12}\mu_2(h|x_0) - \mu_2{}^2(h|x_0)\Big\}\frac{\delta^4}{\omega^4} - \ldots\ldots \Big]\mathsf{f}(x_0), \end{aligned} \qquad \ldots\ldots(4.2)$$

where $$\mathsf{f}(x_0) = f(x_0)/M_0(h|x_0). \qquad \ldots\ldots(4.3)$$

It is instructive to compare the general correction Eqn (4.2) with the particular form deduced in I for the case of $M_p{}^q(h|x_0)$ not dependent on x_0. In the present notation, the latter equation is

$$\xi g(x_0) = \Big[1 - \mu_2(h)\frac{\delta^2}{\omega^2} - \mu_3(h)\frac{\delta^3}{\omega^3} - \Big\{\mu_4(h) - \frac{w^2}{12}\mu_2(h) - \mu_2{}^2(h)\Big\}\frac{\delta^4}{\omega^4}\Big]\mathsf{f}(x_0) \qquad \ldots\ldots(4.4)$$

where the $\mu_n(h)$ are simply proportional to the normalized moments of $h(x_0)$, i.e.

$$\mu_n(h) = (-1)^{n+p}M_n(h)/(n+p)!\,M_0(h). \qquad \ldots\ldots(4.5)$$

In the general case, $\mu_1(h|x_0)$ may not be assumed zero, and additional terms are thereby introduced into the correction in passing from (4.4) to (4.2). Further, the $\mu_n(h|x_0)$ are sums of a series of terms in $M_p{}^q(h|x_0)$ rather than being of the simpler form (4.5). However, these complications are not very serious, since the terms in $\mu_1(h|x_0)$ are usually small, corresponding to a reasonably symmetrical response function, and the series for $\mu_n(h|x_0)$ converge very rapidly in most cases so that only one or possibly two terms are significant in the correction.

The principal difference introduced by the more general form (4.2) is the dependence of the $\mu_n(h|x_0)$ on x_0. In the numerical correction procedure, the differences of $f(x_0)$ must then be multiplied by the coefficients appropriate to the point x_0 at which the differences are taken, rather than by a factor whose value is independent of x_0, as in the case of the more simple distortions.

§ 5. A PRACTICAL EXAMPLE

From the general form of Eqns (3.6), (3.9), (3.10), (4.2) and (4.3), the computation of a corrected output signal may appear a formidable proposition. By means of an example in which a fairly complicated distortion is corrected, it will be shown that this is not the case, and that the correction may be accomplished with efficiency and accuracy.

The apparatus response to an infinitely resolved input $\delta(x_0)$ will be represented by

$$h(x|x_0)=(\beta^2/\pi)^{1/2}(1+x_0/3)\exp\{-\beta^2x^2\} \qquad \ldots\ldots(5.1)$$

so that in the range $-3<x_0<3$, the magnitude $M_0(h|x_0)$ of the response varies from 0 to 2, and also, each element of the input is spread into a Gaussian shape with dispersion $(2\beta^2)^{-1/2}$. The distortion represented by (5.1) is therefore a rather exaggerated example of the variation of sensitivity which occurs in many practical instruments. For instance, the wavelength sensitivity of photographic plates and photocell, and the variations of flux with energy in a particle spectrometer lead to this type of distortion. Again, the sensitivity variation may be due to an inherent, though undesired, property of the experiment itself, as are the effects of transition probabilities on bands observed by soft x-ray techniques.

The apparatus input function will be taken as

$$g(x_0)=(\alpha^2/\pi)^{1/2}\exp\{-\alpha^2x_0^2\} \qquad \ldots\ldots(5.2)$$

and the apparatus response to this input,

$$f(x_0)=\int_{-\infty}^{\infty} g(x_0-x)h(x|x_0-x),$$

may be found in the form

$$f(x_0)=(\gamma^2/\pi)^{1/2}(1+\gamma^2x_0/3\alpha^2)\exp\{-\gamma^2x_0^2\} \qquad \ldots\ldots(5.3)$$

where

$$\gamma^2=\alpha^2\beta^2/(\alpha^2+\beta^2). \qquad \ldots\ldots(5.4)$$

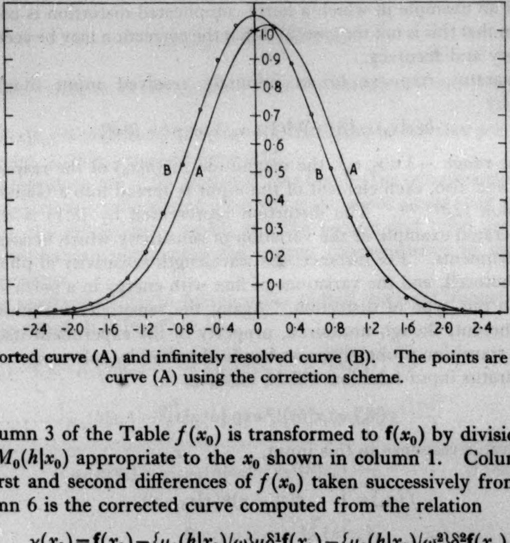
α and β are chosen to be 1 and 3 respectively, in order both that $g(x_0)$ is spread over a wide range of apparatus response and that a fairly severe distortion occurs owing to the width $(\beta)^{-1}$ of the curve $h(x|x_0)$. Using these values, $f(x_0)$ is shown as curve A in the figure and tabulated at intervals of $\omega=0{\cdot}2$ in the second column of the Table. $g(x_0)$, the output to be anticipated from an idealized experiment, is shown marked B in the figure. The difference between curves A and B shows the magnitude of the distortion to be large, as could be anticipated from the description of the distortion function.

The moments for use in the correction scheme are found from (5.1) (in practice, they would be experimentally observed or theoretically predicted quantities):

$$\left.\begin{aligned} M_0{}^0(h|x_0) &= (1+x_0/3), \\ M_1{}^n(h|x_0) &= 0 \quad \text{for all } n, \\ M_2{}^0(h|x_0) &= (1/18)(1+x_0/3), \\ M_2{}^1(h|x_0) &= 1/54 \end{aligned}\right\} \qquad \ldots\ldots(5.5)$$

etc. Using only the moments written above, the values of the $\mu_n(h|x_0)$ are found to be

$$\mu_1(h|x_0)/\omega = -15/108(3-x_0); \quad \mu_2(h|x_0)/\omega^2 = 25/36. \qquad \ldots\ldots(5.6)$$



Plot of distorted curve (A) and infinitely resolved curve (B). The points are derived from curve (A) using the correction scheme.

In column 3 of the Table $f(x_0)$ is transformed to $\mathbf{f}(x_0)$ by division using the value of $M_0(h|x_0)$ appropriate to the x_0 shown in column 1. Columns 4 and 5 are the first and second differences of $f(x_0)$ taken successively from column 3, and column 6 is the corrected curve computed from the relation

$$\chi(x_0) = \mathbf{f}(x_0) - \{\mu_1(h|x_0)/\omega\}\mu\delta^1\mathbf{f}(x_0) - \{\mu_2(h|x_0)/\omega^2\}\delta^2\mathbf{f}(x_0) \qquad \ldots\ldots(5.7)$$

Care must be taken to use the correct sign for the difference 1, and to note that the appropriate values of $\mu\delta^1\mathbf{f}(x_0)$ are the *means of two successive entries* in column 4.

The calculated ideal output signal $\chi(x_0)$ is shown as the points lying almost exactly on the theoretical curve (in fact, the standard deviation of the points is less than 0·3% of the peak height of $g(x_0)$). In view of the large distortion and the brevity of computation, this agreement must be considered very satisfactory. The inclusion of higher order terms in (5.7) would refine the calculation, but is hardly necessary in this case.

It is usual for an apparatus to be used in the measurement of many different input signals. In this event, it is not necessary in practice to recompute the

Numerical Correction of $f(x_0)$ to find $\chi(x_0)$

moments of the distortion function for each correction: initially the moments may be tabulated, and any number of signals then corrected using the accumulated data. The process correcting an individual curve is then simply the manipulation involved in the Table, needing perhaps an hour of computation on a hand machine. It will be noted also that the scheme is well adapted for programming into a digital computer if available.

§ 6. The Effect of Noise on Output Information†

The fact that a signal has been subjected to a transformation does not necessarily imply that information contained in the signal has been dissipated, since the application of the inverse transformation reproduces the original signal. As far as convolutions are concerned, the inverse transformation may always be found provided that all the moments of the response function do not vanish round some point. This may be seen by considering the Fourier transforms of the constituent curves, together with the theorem of resultants. For practical purposes, therefore, the input function is completely defined by the output signal together with the apparatus response operator.

The misconception that a loss in resolution does imply a loss of information about the input signal no doubt arises from experience in cases where the output signal contains noise (random errors). In this event, as will be demonstrated below, a dissipation of information does occur in the presence of any noise which is independent of the apparatus distortion: i.e. more information may be derived from an undistorted signal with this type of noise than is possible from its distorted counterpart having an identical noise content. On the other hand, in the presence of noise which does suffer the apparatus distortion, the signal and noise are indistinguishable to the apparatus, and the application of the inverse operation simply reproduces the input signal plus noise with no loss of information due to the distortion.

The loss of the information may be understood in general terms as follows. The result of the distortion is that the output signal is broader and lower than the input, with the consequence that the percentage uncertainty introduced into the two signals by a standard noise content is greater in the case of the output signal. In reproducing the input signal from the output, not only is this larger percentage error reflected into the input signal, but also some additional enhancement of the noise occurs since, in passing from input to output signals reversibly, the noise should be flattened in precisely the manner found in the case of the true signal. As an example of this type of loss of information, one could cite the example of the nuclear resonance apparatus in which the noise from the input coil does not suffer the modulation distortion evident in the output resonance signal. More generally, this applies to all spectrographs having both finite resolving power and an intrinsic detector noise.

It is of interest to determine the degree to which the input formation is degraded by a noise content of this type since, in this way, conditions are found under which the input signal may best be determined. The relative random errors contained in the corrected and observed curves will therefore be discussed, subject to the assumption that only the first-order correction term is used, as will be the case when the distortion is small. As usual, the output signal is written $f(x_0)$ and the corrected output $\xi g(x_0) = \chi(x_0)$. Writing $M_2(\psi)/2\omega^2 = \mu_2$, and reading $\Delta\ \ (x_0)$ as 'the error in $f(x_0)$', we have

---

† The writer would like to thank Professor N. T. Hamilton, of the University of Illinois, and also the referees, for some helpful comments on this section.

$$\chi(x_0) + \Delta\chi(x_0) = (1 + \mu_2\delta^2)\{f(x_0) + \Delta f(x_0)\}. \qquad \ldots\ldots (6.1)$$

Hence from the first-order correction relation

$$\chi(x_0) = f(x_0) - \mu_2\delta^2 f(x_0) \qquad \ldots\ldots (6.2)$$

it follows that

$$\Delta\chi(x_0) = \Delta f(x_0) - \mu_2\delta^2\Delta f(x_0). \qquad \ldots\ldots (6.3)$$

If three consecutive differencing ordinates x_1, x_2 and x_3 have respective errors in $f(x_0)$ of σ_1, σ_2 and σ_3, then at the central point it may be shown from (6.3) that

$$\Delta\chi(x_0) = -\mu_2\left\{\sigma_1 - 2\left(1 + \frac{1}{2\mu_2}\right)\sigma_2 + \sigma_3\right\} \qquad \ldots\ldots (6.4)$$

Introducing a mean square value σ_0^2 for each of σ_1, σ_2 and σ_3, it follows that the root mean square error in the corrected curve is given by

$$\sigma = \sigma_0\{1 + 4\mu_2 + 6\mu_2^2\}^{1/2}. \qquad \ldots\ldots (6.5)$$

Eqn (6.5) shows that the relative error in the corrected signal increases monotonically as μ_2 and the distortion increase. It is therefore evident that given a distorted curve, the value of the differencing interval ω chosen for the correction procedure should be as large as is consistent with the structure on the curve to be analysed. In this event, the value of μ_2, and consequently also the value of the random error in the corrected signal, will be reduced to a minimum.

§ 7. The Optimum Apparatus Conditions

In many types of linear apparatus the fractional random error in the output signal bears an inverse relation to the distortion. For example, increasing the aperture of an optical apparatus may decrease the resolving power but cause a simultaneous increase in intensity of the output signal. A similar set of circumstances occurs on increasing the modulation amplitude of a magnetic resonance spectrometer. Thus, a decrease in fractional random error occurs which may offset the increase in random error described by Eqn (6.5). The possibility exists, therefore, that conditions may be found under which the form of the input function is best determined.

Before deriving these conditions, it may be advisable to consider the form they can take. The only unit of length with which the moments of the distortion function $f(x)$ can be compared is the differencing interval ω, which, in view of Eqn (6.5) must be chosen as large as possible. The differencing interval, however, is limited by the structure on the curve to be represented, and must not be so large that the chosen points do not give an adequate representation of the curve. Thus the optimum differencing interval relates the moments of the distortion function to the structure of the signals to be corrected.

In the particular case of the magnetic resonance spectrometer, the idealized apparatus operator is proportional to the modulation amplitude and therefore to

$\mu_2^{1/2}$. Similarly in the case of an optical slit the intensity shows the same dependence on $\mu_2^{1/2}$. In both cases, we may therefore simulate the relative error in the corrected output signal by

$$\sigma/\sigma_0 = \mu_2^{-1/2}\{1 + 4\mu_2 + 6\mu_2^2\}^{1/2}, \qquad \ldots\ldots(7.1)$$

rather than by Eqn (6.5) alone.

Equation (7.1) shows that the corrected signal has a minimum in its fractional error when $\sqrt{6}\mu_2 = 1$. In terms of the modulation amplitude a, this leads to the condition $a \simeq 1{\cdot}8\omega$ (see I).

This expression for the optimum modulation amplitude has been used in observing the shape of the copper nuclear resonances at temperatures up to 1300°K, under which conditions the available signal-to-noise ratio is rather poor (Flynn and Seymour 1961). In practice, it was judged that six or seven differencing intervals in the peak-to-peak derivative width of the resonances were needed to give an adequate description of the shapes. The predicted optimum condition of the modulation proved admirable, since the modulation peak-to-peak amplitude was then some two-thirds of the width of the resonance and the signal amplitude therefore approached its maximum value. On the other hand, the maximum first-order correction to the shape was only about 5% of the peak integrated signal amplitude, and the second-order correction was often negligible. Consequently, the additional noise effectively introduced into the corrected signal by the distortion was small, while the relative true noise on the signal was maintained small also. It is therefore considered that equations of the type (7.1) do in fact predict closely the experimental conditions under which the shape of an output signal may best be determined.

§ 8. SUMMARY

A method has been presented whereby signals subjected to a general linear distortion may be corrected to give a more precise measure of the input signal. This technique is particularly efficient in the practical case of small distortion.

The effect of noise on the output signal has been discussed and an analysis has been given of the dissipation of information concerning the input signal, resulting from the presence at the output of noise which does not suffer the apparatus distortion. This led to the prediction of optimum apparatus conditions in the presence of such noise. Noise which undergoes the same distortion as the signal does not give rise to these conditions; the noise is indistinguishable from the signal, and the quantity of input information, including noise, is not affected by the distortion.

In conclusion, it may be remarked that many experimenters are reluctant to subject output data to linear processing either by the use of adequate compensating apparatus or by means of numerical methods. This might appear unreasonable since applying the inverse transformation to a transformed system seems an admirable method of restoring the *status quo*. However, assumptions concerning linearity and reproducibility of apparatus are invoked whatever the method of correction used. The greatest care must therefore be exercised to avoid the production of artificial structure on a signal by the use of linear processing techniques in inappropriate circumstances. It is clear then, that the matter is best left to the skill and discretion of the individual experimentalist.

ACKNOWLEDGMENT

Part of this work was performed at the University of Leeds under the supervision of Dr. E. F. W. Seymour. The writer wishes to thank Dr. Seymour for his helpful criticisms.

OBITUARY NOTICES

Professor W. T. Astbury

William Thomas Astbury, Sc.D., F.Inst.P., F.R.S., who died at the age of 63 on 4th June 1961, was the eldest son of a large family in the potteries district of Staffordshire There was no advantage of a scholastic or professional background in his origins, yet he rose to a position of world-wide fame in his field. After very successful years at Longton High School he proceeded to Cambridge, gaining his education by winning scholarships His University degree was in Physics and he graduated in 1921.

He worked with Sir William Bragg from 1921–1928, mostly at the Davy Faraday Laboratory of the Royal Institution. A wonderful new subject, x-ray crystallography, was just beginning. There were the numerous tasks of managing the early fickle x-ray tubes, there was much equipment to devise, even photometers to invent, and any of these jobs could have occupied years. But Astbury wanted results to exercise his mind and he became very quick at settling on sufficient apparatus that would work just neatly and effectively. He soon published papers on tartaric acid and on acetyl acetones among the host of crystals waiting to be done. And with Yardley he had simplified, in the well-known space group tables, the important facts about symmetry in crystals so that these could be readily used by the increasing band of x-ray crystallographers.

With all the choice available to him Astbury chose the most difficult field of all to work in. To others it would seem a great gamble to tackle the structure of fibrous proteins as he did in 1928 when he became lecturer in Textile Physics in the Department of Textile Industries at Leeds University. However, Astbury would scarcely notice the odds against him, so great was his energy and his faith in himself. More important still was the mystery of the unknown. This continued to drive him on; his leading spirit and his success encouraged others to start working in this field.

In the early 1930s Astbury published his great detailed papers on the structure of hair, wool and related fibres, of especial note being that with H. J. Woods entitled ‘The molecular structure and elastic properties of hair keratin’[†]. These described the α–β transformation of fibrous proteins and explained this as a reversible intramolecular chain folding. The many original experiments and arguments gave a very clear picture of chains unfolding on stretching to reach a limit about twice their natural length. There were many other original papers on feather keratin, protein denaturation, muscle proteins and muscle itself, nucleic acids, alginic acid; also the two very important Proctor Memorial Lectures on collagen. His work on keratin had been to him a first step in molecular biology—it had revealed the possibility of explaining biological phenomena in molecular terms. Most of these other studies he regarded as adventures to survey and open up the field. He was in great demand to introduce and to give the concluding remarks at scientific meetings both abroad and at home. A notable part of his teaching was done in this way, and he achieved great simplicity of explanation and attractiveness of style.

Over the years many efforts were made to provide a model to explain the α–β transformation, the structure of collagen, the structure of nucleic acids, but he did not win the race he started in finding acceptable models. He was an outstandingly keen and proud worker and with characteristic cheerfulness and enthusiasm he took up the implications of the planar amide group and applied these to considerations on wool keratin, collagen, cross-β structure and feather keratin.

Astbury had great gifts and he used them well. He was a very eminent man without the slightest shade of grey eminence. He was abundantly friendly and cheerful with the most infectious enthusiasm. He became Professor of Biomolecular Structure at Leeds in 1945, though he would have preferred the name of Biophysics or Molecular Biology for the field of his studies. He died most actively engaged in this work, and the force of his pioneering efforts will last long after his death. K. M. RUDALL.

† Astbury, W. T., and Woods, H. J., 1933, *Phil. Trans.* A, **232,** 333.

Guy Barr

Dr. Guy Barr's lifetime researches of 42 years at the National Physical Laboratory will probably best be remembered by the use in science and industry of his standard methods of measuring the viscosity coefficient of Newtonian liquids. At the outbreak of the first world war, Dr. Barr was a Senior Assistant at the N.P.L., the staff of which he joined in 1908, having graduated with first class honours in physics and mathematics at Cambridge University in 1907; he later obtained the D.Sc.(London) degree in 1917.

His work began under Dr. W. Rosenhain, F.R.S., mainly on metallurgical analyses, then on physical–chemical problems arising in aeronautics. He published numerous reports in *Reports and Memoranda of the Advisory Committee for Aeronautics*, 1910–1926.

This work on the development of tests for the hydrogen permeability of balloon fabrics and for the strength and tautness of aircraft fabrics was continued for the Fabrics Co-ordinating Research Committee leading to reports on the waterproofness of 'porous' fabrics and on the deterioration of fabrics during weathering. Parallel researches on the formulation of aeronautical dopes and observations of the deteriorating action of sunlight on doped fabric were made at the Royal Aircraft Establishment under the guidance of Dr. J. E. Ramsbottom when the writer became acquainted with Dr. Barr and his valuable national work. At Farnborough both Dr. F. Aston of isotope fame and Dr. Lindemann, later Lord Cherwell, shared in these wartime researches and it was Dr. Aston who taught us younger chemists to blow Dr. Barr's U-tube viscometers in glass. At that time we were aware of the rheological properties of aircraft dopes, the viscosity being dependent on the rate of shear and so on the design of the viscometer. Dr. Guy Barr using an X-ray method and the writer a sphere suspended over a light pulley demonstrated that the fall of a sphere in pigmented dopes and similar systems was not in accord with Stokes' law. Barr's work on the viscosity of aeroplane dopes led to the development of U-tube viscometers the design of which has been adopted by the British Standards Institution and since 1929 the calibration of such viscometers and of Redwood viscometers (Institute of Petroleum) has been carried out in the N.P.L. Metallurgy division. Barr's

Monograph of Viscometry (Oxford University Press) was printed in 1931 and became a recognized handbook on the subject.

Prior to and during the 1939 war years, Dr. Barr developed methods for measuring the rate of transmission of moisture through wrapping films and proofed cardboard, and tests were made on containers for mortar bombs and other ammunition to assist the Ministry of Supply in the development of improved types. Further work for the same department was done on the best method of sealing lids on tins to withstand immersion in water when supplies were to be landed on beaches. Shortly before his retirement on 31st May 1950, Dr. Barr assisted the Home Office Gas Cylinder and Containers Committee regarding recommendations for the filling ratios, marking and maintenance of gas cylinders. As a P.S.O. in charge of the Chemistry section of the Metallurgy division he assisted in researches on new methods of preparing pure beryllium in the early days of nuclear energy development and was responsible for developing the spectrographic section in the division.

At the World Petroleum Congress organized by the Institute of Petroleum, held at the Imperial College of Science and Technology in July 1933, the measurement of viscosity was discussed at great length and the agreed recommendations were incorporated in the B.S. 188 method for the determination of the viscosity of liquids in c.g.s. units, under the chairmanship of Dr. Guy Barr.

His scholarly, sound and patient work is well shown in this B.S. 188 standard. All his colleagues will miss him and his friendly and sympathetic manner and his ability in solving problems. He was a keen athlete in his younger days and his activity as a scientist is indicated by the imposing number of his official publications.

E. W. J. MARDLES.

Leslie E. C. Hughes

Leslie E. C. Hughes, Ph.D., B.Sc.(Eng.), M.I.E.E., passed away very suddenly on 10th June at the age of 57 and at a time when he was full of enthusiasm for the new tasks he had set himself. Following graduation, Hughes became a demonstrator and later a lecturer in acoustics and telecommunications at the City and Guilds College, South Kensington, and it was during this period that he wrote his well-known textbook *Engineering Acoustics*.

In 1941 Dr. Hughes entered industry and for the next ten years he was engaged in various aspects of electro-acoustics research. However, his interests were turning towards technical writing and he became editor of many technical reference books.

Dr. Hughes had a lively mind and a great love and knowledge of music which stemmed from his early training under Dr. Jolly at St. George's, Hanover Square, where he was a chorister. He was a keen educationalist and maintained an active interest in his old school, the Quintin, and in Convocation of London University. He was also a member of many societies and was a past president of the Institution of Electronics and the first president of the British Sound Recording Association and had been elected vice-chairman of the newly formed H. G. Wells Society. Only a few days before his untimely death he had been appointed editor of a technical journal.

Members of the Acoustics Group of The Institute of Physics and The Physical Society will particularly miss his lively interventions in discussions. R.W.B.S.

Sir K. S. Krishnan

It is with profound regret that we record the sudden death of Sir K. S. Krishnan, F.R.S., Director, National Physical Laboratory, India, on 14th June 1961. Scientific research in India owes much to his contribution and valuable guidance, particularly during the crucial period of scientific and technological progress of the country, and his death is a national loss.

Kariamanikkam Srinivasa Krishnan was born on December 4, 1898, in the village of Watrap near Srivilliputtur in Madras State. After basic education in Watrap and Srivilliputtur, he studied the Intermediate in American College, Madurai (1914–1916) and joined the Christian College, Madras (1916–1918) for the graduate course. Soon after his obtaining the B.A. degree in Physics he was appointed as a Demonstrator in Chemistry in the same college. But his thirst for higher studies and research led to his joining the Indian Association for the Cultivation of Science, Calcutta in 1923 to work under Professor C. V. Raman. Placed in the proper environment, Krishnan's latent potentialities came to light and soon he shone as an enthusiastic and brilliant investigator and was foremost among Professor Raman's collaborators. Based on the results of his original work, Krishnan was awarded the M.Sc. (1925) and D.Sc. (1932) degrees of the Madras University. He was appointed as a Reader in Physics at the Dacca University in 1928 and in 1933 as Mahendralal Sircar Professor of Physics at the Indian Association for the Cultivation of Science. Subsequently, in 1942, he joined the Allahabad University as the Professor of Physics. When the N.P.L., the first of the chain of new national laboratories of India was opened in 1947, it was but natural that Sir K. S. Krishnan should have been chosen as its first Director, a post which he held until his death.

The research work of Krishnan and his associates extends over diverse branches of physics. During the years 1923–1928 he carried out theoretical and experimental investigations on the scattering of light by liquids and related molecular phenomena in collaboration with Professor C. V. Raman, which culminated in the discovery of the Raman effect. His versatility and deep appreciation of the essential unity underlying several of the physical phenomena and the internal architecture of crystals resulted in Krishnan's becoming interested, while at Dacca, in the magnetic properties of substances. He devised an elegant and ingenious method for the precise determination of the magnetic anisotropy of crystals, and even today the results obtained by him on several paramagnetic and diamagnetic crystals remain the most authoritative in the subject, and valuable correlations were obtained by him and his students connecting the symmetry and configuration of the molecules in crystals, the crystalline field and their magnetic properties. During the period 1933 to 1947 he carried out significant investigations on statistical thermodynamics and quantum theory and at Allahabad he built up an active school of research interested in thermal and electrical properties of metals and alloys. At the N.P.L., besides organizing its multifarious activities, he was concerned with work on the physics of the solid state. His recognition of the interdependence of the different branches of science, both pure and applied, are well illustrated by the problems studied by him and his co-workers during the past decade. In trying to eliminate the difficulties which beset an accurate study of the thermionic properties of metals and semiconductors, he evolved a new technique for a precise determination of not only the thermionic constants but also their temperature coefficients. This method has been successfully applied to the monovalent and the transition metals. A study of the temperature distribution along an electrically heated filament yielded a new experimental method for the measurement of the thermal conductivity, particularly at high temperatures. The electrical conductivity of metals and alloys is a topic which engaged his attention in relation to the above studies and an elegant theoretical explanation has been given by him and his co-workers for the large increase in resistance of a binary alloy due to alloying. A longstanding controversy about the relative merits of the Lorentz and Drude refraction formulae was also resolved in an extremely simple manner and their mathematical equivalence established. Another recent contribution is the subject of vibrations of ionic crystals and the anharmonicity of some of their normal modes.

In recognition of his distinguished researches Krishnan was elected a Fellow of the Royal Society in 1940 and was knighted in 1946. The Government of India honoured him with Padma Bhushan in 1954 and he was the recipient of the Bhatnagar Memorial Award in March 1961. He was elected a Foreign Associate of the National Academy of Sciences, U.S.A., and was a Fellow of the Royal Society of Arts, the Institute of Physics, the Physical Society and the Institute of Metals, London. He was also a Fellow of the Indian Academy of Sciences and the National Institute of Sciences of India. He was the recipient of the honorary D.Sc. degree from various Indian Universities.

Krishnan was President of the section of Physics, Indian Science Congress in 1940 and its general President in 1949. He was Chairman, Scientific Advisory Committee, UNESCO; Vice-President of the International Council of Scientific Unions and of the International Union of Pure and Applied Physics; Chairman, Indian National Committees URSI and IGY and Chairman, Sub-Commission for co-operation with UNESCO. He was Chairman, Board of Research in Nuclear Science, Member, Atomic Energy Commission, the University Grants Commission and the Standing Board of Astronomy. His association with the Council of Scientific and Industrial Research, India, dates back to its inception and he served the Council in various capacities, as member of the Governing Body, Board of Scientific and Industrial Research, Board of Engineering Research, Editorial Board of the Journal of Scientific and Industrial Research and was a member of several Research Committees.

No sketch of Professor Krishnan's career would be complete without a reference to his extensive travels abroad, which gave him many an opportunity to visit important centres of research in Europe and America and to cultivate personal relations with eminent men of science. He first visited Europe when he was invited to take part in the International Conference on photoluminescence held at Warsaw in 1936. He toured widely throughout Europe and delivered a series of lectures at various important centres including the Royal Institution in London and the Cavendish Laboratory at Cambridge and in many of the continental universities. The Liège University honoured him with the award of the University Medal. He again visited Europe in 1939 to attend the International Conference in Magnetism held at Strasbourg under the auspices of the International Institute of Intellectual Co-operaton and of the Service Central de Recherche Scientifique de France. In the summer of 1946 he went to England as one of the Indian delegates to the Empire Scientific Conference organized by the Royal Society. He has since been abroad many times.

Krishnan, who was a physicist of no mean calibre, possessed also other qualities which endeared him to those with whom he came into contact. His love of fundamental research did not blind him either to the need for or to the value of applied physics and technology and he was often able to show up in a striking manner the close relation existing between the two. He had an abiding interest in pure mathematics also and his knowledge of the subject often enabled him to find an elegant solution to physical problems. He was also a learned scholar of Tamil and Sanskrit and one found in him a rare combination of a true scientist, unassuming and simple, and a philosopher with an integrated personality. R. S. KRISHNAN.

Sydney Marsh

Dr. Sydney Marsh died in London on 14th December 1960 at the age of seventy-six. His death has ended a long career of service to education and to science.

As an undergraduate he studied mathematics and physics at the University College, Cardiff, and obtained first class honours in both these subjects. From the University of Wales he proceeded to postgraduate studies in the Universities of Munich and Göttingen where he worked under the supervision of Professor E. Riecke, and for his investigations on the operation of discharge tubes he was awarded the degree of Ph.D. He continued his interest in this field of research after his return home and, with A. E. Evans, published a paper on ‘ Electrode Potential Measurements with Direct and Alternating Current Electrolysis ’, which appeared in the *Proceedings of the Royal Society* in 1922.

For his contribution to physics he was later awarded the degree of D.Sc. in the University of Wales.

He was appointed to the staff of the Battersea Polytechnic in 1909 and after spending two years (1917–19) as head of the Mathematics and Physics Department at the Rutherford Technical College, Newcastle-upon-Tyne, he returned in 1919 as head of the Department of Physics to the Battersea Polytechnic and remained there until his retirement in 1950. He continued his association with the Physics Department at Battersea as a part-time lecturer to the end, and gave his last lecture only two days before his unexpected death.

Marsh was a scholar and a great teacher. It is not too much to say of him that he was one of the most sound, lucid and sympathetic teachers of physics associated with the work of the University of London. He made his department a centre of sound learning and, in the difficult circumstances of busy teaching demands, he encouraged and stimulated research.

His friends and colleagues of the University of London met him most frequently as a member of academic and examining boards upon which he played active and important parts. For many years he acted as a chief examiner for the external special and general honours degrees and his colleagues recognized his sound judgment and sense of fairness in this work. His work on the Joint Matriculation Board was equally recognized on account of his unerring judgment. His own knowledge was wide and deep and in the new branches of physics which are now represented in examination papers he had a rare ability of detecting the superficial and half-understood knowledge from that which was deeper and firmly grasped. He was an excellent examiner ready to reprove when questions proposed seemed to him unsuitable, and ready to temper the wind of too harsh a marking.

He was a devoted member of the Physical Society and of the Physical Society Club.

His death has brought a feeling of great loss to all his friends and colleagues. Those working with him have always recognized the quality of his contribution to the work they had in common and his sudden departure from their midst has emphasized the reliance they had in him and the regard and affection they felt for him.

H. T. FLINT.

Reprinted from *Nature*, 1st July 1961

J. Walter Ryde, F.R.S.

John Walter Ryde died at Marlborough, Wiltshire, on 15th May, after a short illness. He was sixty-three years old. He was born in Brighton on 15th April 1898 the son of Mr. W. W. Ryde, and was educated at St. Paul's School and in France. Plans for him to continue his studies in Germany and then go to the University of Cambridge were interrupted by the First World War. He returned from Berlin to England just before the outbreak of war and entered the City and Guilds Technical College, Finsbury, where he studied under Professor Sylvanus Thompson and Professor Charles R. Darling.

Ryde joined the Royal Engineers voluntarily in 1916, at the age of eighteen, on the completion of his course at City and Guilds, and was trained in anti-aircraft work in Monmouthshire and on the Norfolk coast before being drafted to France during the last few months of the War. He continued to serve in France until his demobilization in 1919.

Ryde joined the Research Laboratories of the General Electric Company, Ltd., as a physicist in 1919, going directly from his war service to the newly established research unit directed by Clifford C. Paterson in the Company's lamp factory at Hammersmith. He was a leading member of the scientific staff of the Laboratories from the start.

In the early days at Hammersmith, and again after the Laboratories had moved to their new premises at Wembley in 1923, the variety of Ryde's research work was indicative of the breadth of interests which was so characteristic of him. They included pure spectroscopy, thermionics and the gaseous electrical discharge. Under his direction the first practical high-pressure mercury vapour lamp was developed—the foundation of a new industry to which he made many subsequent contributions.

His theoretical work on the scattering of light, first applied in the twenties to optical diffusing media in glasses, was extended by him during the Second World War to classic studies of the attenuation and the radar echoes produced by meteorological phenomena at centimetre wavelengths. (A footnote in this paper included the following: " The author (J. W. R.) and Mrs. Ryde were responsible for the theory and calculation of the effects caused by liquid and solid particles, ...") He was an early worker on crystal valves and quickly recognized the potentialities of germanium as a semiconducting material.

Other researches included velocity modulation tubes, luminescent materials and optical projection systems. He contributed much to various research projects undertaken for the United Kingdom Atomic Energy Authority, and he took part in work on the FIDO fog-dispersal system. It was typical of Ryde to design, in his leisure hours, a pocket illumination chart for use by the Services. It showed levels of illumination, by day and by night, at various latitudes, and was used extensively in military operations.

Ryde was elected a Fellow of the Royal Society in 1948. He was appointed chief physicist at the G.E.C. Research Laboratories—recently named the Hirst Research Centre—in 1950 and chief scientist in 1953. During these recent years he had overall responsibility for the programmes of pure scientific research of the Centre, and his particular interests lay in the fields of new materials, crystal growing and solid state physics.

He was a member of the Royal Institution of Great Britain since 1935 and chairman of the Davy Faraday Laboratory of the Institution since 1951. He served on the Board of Managers of the Institution and always took a great interest in its affairs. He was a Fellow of the Institute of Physics and the Physical Society, a Fellow of the Royal Astronomical Society, and a member of the Geological Association, the Wiltshire Archaeological Society and the Athenaeum.

Ryde married, in 1930, Dorothy Ritchie, daughter of the then chief illuminating engineer of the General Electric Co. There is one son.

The Hirst Research Centre has lost a senior man who earned the admiration and respect not only of his colleagues but also of eminent men both in Great Britain and overseas. He lived his life for science, and his leisure activities were very largely extensions of his life's work. Archaeology was a persistent interest—at an early age he learned to read hieroglyphic writing and ancient scripts. He was a profound student of astronomy but, in recent years, microscopy became a dominant hobby. He was particularly interested in diatoms, and his beautifully mounted specimens are evidence of the elegant experimental skill which he retained to the end.

His memory was prodigious and visual. He never forgot the details of work which he had done and could sketch from memory some experimental arrangement or the detailed shape of a specimen long afterwards. Such a memory, supplemented with the many carefully prepared and indexed note-books which he compiled throughout his working life, made Ryde a powerful authority indeed in the world of science.

In all his work he displayed great ability and unfailing perseverance, together with brilliant insight and inspiration. His colleagues will always remember his patient readiness to discuss and assess the problems of the day, and his helpful elucidation of critical experiments, often elegant in their simplicity, which he designed to solve them. O. W. HUMPHREYS.

Arthur Mannering Tyndall

Arthur Mannering Tyndall was a man who devoted his life to the University of Bristol and who played a very important part in guiding its growth from a small college to a great university. He was a physicist who was elected into the fellowship of the Royal Society for his work on the mobility of gaseous ions. No less important was his work in building the Henry Herbert Wills Physical Laboratory, in staffing it and in giving it scientific leadership. He died suddenly at his home on October 29th. His wife, Lilly Tyndall, his son and two daughters survive him.

Arthur Tyndall was born in Bristol on 18th September 1881. He entered the University College, holding the only scholarship offered annually by the City of Bristol for study in that college, and graduated with second class honours in physics in the external London examination in 1903. That year he was appointed assistant lecturer, was promoted to lecturer in 1907, and became lecturer in the University when the university college became a university in 1909. During this time he served under Professor A. P. Chattock, but Chattock retired in 1910 at the age of 50 and Tyndall became acting head of the department. Then, with the outbreak of war, he left the university to run an army radiological department in Hampshire. He was about to go to the Mediterranean when he was summoned back to the university to continue in charge of the physics department, which was in danger of disintegrating without him. It was in 1916 that he first met Henry Herbert Wills, pro-Chancellor and chairman of a special buildings committee, who was planning with the architect the details of the Great Hall of the University. His first contact with him was a letter to Wills as chairman of the General Purposes Committee about a site for a battery of accumulators. Out of this arose a friendship, and with it Harry Wills's ambition to build a truly worthy home for physics. Though his intentions were clear earlier, it was in March 1919 that he announced a gift of £100 000 and as much again a year later. In 1922 he died leaving a further considerable sum to the University for buildings and endowment.

In 1919 Tyndall was elected to the Henry Overton Wills Chair of Physics. The formal opening by Lord Rutherford of the new laboratory was in 1927. The staff then was twelve, including Lennard-Jones, Skinner and Sucksmith; there was ample space in the building—a large room for everyone, as there was in 1933 when the present writer succeeded Lennard-Jones as Professor of Theoretical Physics. For undergraduates too there was plenty of room; there were never before the second war more than six honours students in the final year, sometimes only two.

In fact one of my first recollections of Bristol physics before the war was this spaciousness; the other was, of course, the personality of Tyndall. He was a man who lived for the achievements of his colleagues in the department. Nothing gave him greater pleasure than when they achieved a good piece of research, or any outside recognition. Everyone knew this and it coloured the whole place. Anything less like the tyrannical professor of contemporary legend it would be difficult to imagine. Frequently the whole staff joined him in a Sunday walk over the Somerset hills; and if there were any departmental problems, that was how they were resolved. After the war there was of course a sudden and large expansion in the number of students and of staff but he preserved remarkably the intimate, friendly atmosphere of a small department in which everyone knew and took pride in each other's achievements. Among those who worked with Tyndall before and after the war are E. T. S. Appleyard, C. R. Burch, F. C. Frank, H. Fröhlich, R. W. Gurney, W. Heitler, L. C. Jackson, J. E. Lennard-Jones, H. Jones, H. London, A. C. B. Lovell, S. H. Piper, C. F. Powell, H. W. B. Skinner, W. Sucksmith and the present writer, to mention only a few.

Tyndall was so wrapped up in their achievements that he was too modest about his own personal research, but his work was of real distinction. His principal contributions to physics were in the field of the discharge of electricity in gases. As a young man, working in a small laboratory, he had followed with great attention the early experiments on radioactivity, and he used to describe with what excitement in the early 1900's he used to await the next issue of the *Philosophical Magazine* in which, at that time, Rutherford and his colleagues published much of their work. The study of the ionization produced by radium and its products raised the question of the nature of the ions, and methods for determining their mobility were developed by Rutherford, Langevin, Zeleny and others. In Bristol, Chattock had made extensive studies of the ' electric wind ', the small pressure difference established in a gas as a result of a point-discharge. Tyndall took part in some of these experiments; he was led to make independent studies of the nature of the ions, and developed a number of independent methods.

By the early 1920's, measurements of the mobilities of the positive ions had been made in many laboratories, but the results were very discordant. Tyndall realized that this was associated with the presence of traces of impurities in the gas which attached themselves to the original ions, or which led to a change in the constitution of the ions through charge-exchange. In all the earlier apparatus these small traces of impurities could not be excluded, but the great change in vacuum-practice introduced after the first world war gave the possibility of making experiments in much improved conditions, in glass apparatus with metal electrodes which could be baked-out before the introduction of the gas.

Taking advantage of these technical innovations and generators of high-frequency alternating potential based on the use of valves, Tyndall and his colleagues developed a number of elegant methods of determining the mobility of a great variety of positive ions in a number of pure gases. In the course of a few years, a large measure of order was brought into a field which had been the subject of hundreds of investigations over a period of twenty-five years. On this subject he wrote a monograph which was published by the Cambridge University Press.

From 1919–48 he was H. O. Wills Professor of Physics and from 1927–40 Director of the H. H. Wills Physics Laboratory. In 1940–45 and from 1946–47 he was pro vice-chancellor and in 1945 acting vice-chancellor. In 1948 at the age of 67 he retired and was created Emeritus Professor and Honorary Fellow. At that time his portrait, a gift of colleagues, past and present students and friends, was painted by James Gunn and now hangs in the main building of the university. In 1950 he was awarded the C.B.E.; in 1958 the Hon. Ll.D. of his own university.

He took a leading part in the scientific committee work of the country. Elected into the fellowship of the Royal Society in 1933, he served on Council from 1941–42 and was vice-president in 1942. He was president of the Institute of Physics in 1946–48 (his photograph is on the staircase at 47 Belgrave Square), he was on the Council of the Physical Society from 1925–29, he was president of the physics section of the British Association in 1952. He was a manager of the Royal Institution, president in 1953 of the Science Masters' Association, chairman from 1946–49 of the executive committee of the National Physical Laboratory. He was from 1940–45 member and sometime chairman of a

Ministry of Education committee on the award of state bursaries and scholarships. In Bristol from 1948 he was a member and for part of the time vice-chairman of the Management Committee of the Southmead Hospital Group. In fact, from the date of his retirement and indeed before, he gave most generously of his time and ability to medical education and the National Health Service.

From the date of his retirement until the day of his death he was an editor of the *Philosophical Magazine*, and indeed a most active one, most of the papers accepted or rejected passing through his hands.

In his early days he played hockey and gained a number of county caps; he was also an active tennis player. He was keenly interested in music and in drama.

Tyndall will be remembered particularly for two things. He presided over part of that phenomenal growth of English physics in the 1930's, when it burst out of its traditional homes at Cambridge and Manchester and flourished all over the country. The generosity of Harry Wills gave him his opportunity and he knew how to take it. If the H. H. Wills Physical Laboratory has achieved anything in the post-war period, all those who worked there know how much they owe, both to that generosity and to Tyndall's wisdom, kindness and uncompromising standards.

He also worked during his whole life for what has become one of our greatest universities. In his department he believed that no effort was too great, no time should ever be grudged in finding out what everyone thought and in seeing that everyone was heard. If Bristol's growth from small beginnings has been happy, and if the university has been relatively free from the strains and frustrations which are occasionally expressed elsewhere, it may be that Tyndall's example has had much to do with it. N. F. MOTT.

Russell S. Wright

R. S. Wright was probably the last of the instrument makers associated with the manufacture of the old 'gas' X-ray tubes of the pre-First-World-War years. He was for many years the moving spirit in the firm of Newton and Wright which produced surgical X-ray equipment. Another of his loves was the smaller firm of Newton and Co. which had two great distinctions. Firstly, the firm had a continuous existence from the time of Sir Isaac Newton and, secondly, the lantern slides produced by the firm were used to illustrate lectures all over the world.

R. S. Wright was a 'character'. He was Captain of a Boys' Brigade Company for an incredible number of years; he bathed daily, summer and winter, far beyond his youth, in the Highgate Ponds. He regarded his firm as his family, and on retirement took the lay charge of a Presbyterian Church! Every year he was to be found going most carefully round the Physical Society Exhibition. He lived a very full life and enjoyed every minute of it.

A. J. PHILPOT.

REVIEWS OF BOOKS

1960 *Nuclear Data Tables: Part* 3. *Nuclear Reaction Graphs*, edited by J. B. Marion. Pp. xi + 181. (Washington: National Academy of Sciences—National Research Council, 1960). $1.25.

This volume contains the most comprehensive collection of graphs and data yet published in this field. It should prove to be very useful for the planning and analysis of nuclear reaction experiments.

There is a section on the ranges and energy loss of charged particles in matter, but unfortunately there is little information on the ranges of protons in matter above an energy of about 7 Mev. A complete collection of data on gamma-ray detection in NaI(Tl) crystals and some information on neutron source cross sections is included. There is a graph of electron ranges in aluminium, but it is not immediately clear whether the quantity we are looking up is the mean range or the maximum range. Among the many other graphs are some polarization contour maps, energies of elastically scattered particles, and also a silicon diode barrier nomograph.

This is an excellent publication and at a price of 10*s*. this volume represents very good value for money. B. H. ARMITAGE.

Advances in Electronics and Electron Physics. Vol. XIII. 1960. Edited by L. Marton. Pp. x + 454. (New York and London: Academic Press.) $13.50.

One of the chief purposes of the progress review ought to be to keep the non-specialist up-to-date without his having to read the original papers: it ought also to help the specialist by concentrating recent material into a convenient compass and by reminding him of things he might have overlooked. In fact the progress review ought to be one part of the answer to the complaint that it is almost impossible to keep up with the literature in any but the most restricted field. But it ought, too, if a continued publication, to be the sort of volume the informed non-specialist can turn to when he wants to know ‘ what it is all about ’ when a new topic attracts his attention. Perhaps, in addition to all this, the ideal review will help in fertilization by attracting attention to new fields and by supplying the worker in one field with ideas borrowed from another.

All of the articles in this volume fulfil some of these purposes and most of them fulfil them all to some extent. It is an admirable publication, consisting of five substantial articles varied in style almost as much as in content. The writing and presentation are good and clear enough throughout to be comprehensible to the non-specialist, except perhaps for P. A. Lindsay's work on ‘ Velocity distribution in electron streams ’, which is necessarily and properly mathematical. But here the author specifies clearly in the introduction that he will consider electron flow “ in the six dimensions of phase space, consisting of the configuration and momentum spaces joined together ”.

In an article on ‘Inelastic collisions between atomic systems’, J. B. Hasted introduces a new and elegant system of notation particularly suitable for dealing with inelastic collisions, where the complexity of state of the particles is so much greater than the complexity of chemical species. There is a balanced account of developments in experiment and in theory characterized by clear statements of the various questions which arise followed by careful presentation of the information available.

'Field ionization and field ion microscopy' by E. W. Muller makes a strong aesthetic appeal: photographs which actually show atoms sticking up in ordered arrays produce a satisfaction which nothing less direct could provide. Here the introduction is a quite inadequate shop window: surely it should tempt the general reader with some hint that he is to be shown photographs of a tungsten tip at a magnification of 10^6 and that he will be told how they are taken. The account of field evaporation of layers of atoms until site vacancies appeared is particularly fascinating.

Raymond Castaing's account of 'Electron probe microanalysis' deals with a clearly delimited field in a satisfying way, presenting the experimental information, a study of the corrections and limitations, and an account of the applications of the method to scientific research.

The last article in the volume is by P. K. Weimer, on 'Television camera tubes: a research review'. Physicists often want to know how things work, what they can be used for and what their limitations are, without being committed to prolonged study. The present article supplies just this want.

The book is pleasant to handle, the production is excellent and it is to be commended to the general reader as well as to the reader with a specific interest in the topics mentioned in the titles.

W. A. PROWSE.

Plasma Acceleration, edited by S. W. KASH. Pp. vii + 117. (London: Oxford University Press; California: Stanford University Press, 1960.) 34*s*.

This book is based upon the fourth Lockheed Symposium on Magnetohydrodynamics. The earlier volumes of this series dealt with the theory of ionized gas behaviour and the problems of thermonuclear fusion. Here the temperatures discussed are much lower than those required for fusion and the emphasis is on plasma acceleration as a power source for rocket propulsion. Low level thrusts over a long period, e.g. accelerating 10^6 grams at 1 cm sec^{-2} for several days, are sufficient to manoeuvre a rocket in space.

A number of possible plasma accelerators are discussed both theoretically and experimentally and an article on scaling laws describes a procedure for interrelating any two experiments. Several methods of acceleration are available, homopolar devices, electrostatic plasma guns and the use of travelling magnetic fields, but the most promising approach seems to be the hydromagnetic plasma gun of Marshall at Los Alamos. Marshall has achieved plasma velocities of 100 km sec^{-1} with an efficiency of 40% but only for a very short time. A practical system may demand continuous running. An interesting proposal is a d.c. accelerator where plasma is fed into a coaxial nozzle which has a suitable configuration of currents, and electric and magnetic fields. The plasma acceleration arises from the interaction between the currents and the magnetic field. The most efficient acceleration is a gentle one with just sufficient Joule heating to maintain the plasma state, and this is achieved when the back e.m.f. produced by the motion of the plasma across the magnetic field is only slightly less than the applied electric field. The book suggests that although the basic requirements are well understood the development of a successful device will take a long time.

H. J. PAIN.

Théorie des Ondes dans les Plasmas, by J. F. Denisse and J. L. Delcroix. Pp. xii + 167. (Paris: Dunod, 1961.) 16 n fr.

This small book in the Dunod series of monographs gives a fairly exhaustive account of the propagation of waves of small amplitude in a plasma. The spatial and time dependences of physical quantities are assumed to be of the form $A \exp (j\omega t - jkz)$ and a general dispersion relation in the form of a ninth-order determinant is developed. From this, particular modes of oscillation are examined. These include transverse and longitudinal electromagnetic waves and their polarization in the presence of a longitudinal magnetic field. The theory is taken further than the simple cases usually considered in the literature, and many more types of wave are examined here. Inevitably this results in an increased complexity in the formulae, but the authors partly overcome this by confining the more elaborate equations to the appendix and by including many illustrative diagrams to explain the physical processes involved. For example, an explanation of resonances in ordinary and extraordinary transverse electromagnetic waves is made in terms of the gyromagnetic frequencies of the ions and electrons respectively. There is new work presented in three of the chapters, including a classification of the types of wave in terms of the source of energy for propagation, and the coupling of the modes of oscillation by a transverse magnetic field. It is disappointing to find in the section on electrostatic oscillations no derivation of Landau damping but an inadequate interpretation in terms of electron trapping. This book is within the understanding of the average research student, and will be of use to those in this particular field. M. G. HAINES.

Infra-red Physics: *An International Research Journal*, Vol. 1, No. 1, edited by W. K. Weihe, S. Passman, N. Migeotte and T. S. Moss. Pp. vi + 103 + iv. (Oxford, London, New York, Paris: Pergamon Press, March, 1961.) £7 per annum.

This is a new international journal concerned with all aspects of infra-red physics. Whether the introduction of any new journal is justified is always the first question to be asked, and in this case the wide variety of the aspects of the subject as indicated in the first issue certainly suggests that the journal is indeed desirable. The branches of the subject covered by the reports include light sources for optical communication, infra-red photography, infra-red interferometry and a sun-seeker for solar spectroscopy. The printing of the journal, including the reproduction of photographs and diagrams, is of high quality and the editors are to be congratulated on making an excellent start with the new journal. A. JACKSON.

Halbleiterprobleme, edited by F. Sauter. Pp. vii + 343. (Germany: Friedrich Vieweg, 1960.) DM. 48.

The fifth volume of this series, which was up to now edited by W. Schottky, contains an unusual variety of contributions. This feature is, in fact, suggested by the title (for almost anything can be called problems in German), but it might puzzle people here to find articles different in type, as reported below, in one slim volume.

Three of the contributions, occupying about a third of the volume, are of the type of ‘ progress reports ’. All three are excellent and very readable. O. O. Folberth discusses the physical chemistry of $A^{III}B^{V}$ compounds; O. Madelung surveys and analyses the behaviour of semiconductors in strong magnetic fields, and D. Geist reports on masers. Another third of the book, or rather more than a third (137 pages), is occupied by a paper on the theory of tarnishing reactions by K. Hauffe and W. Schottky. This is a new analysis of the phenomenon, based on a review of older work, a paper such as one would, in this country, expect to find in the *Transactions*, and it should not be missed by anyone working in this field.

The rest of the volume consists of the extended version of a lucid discourse given by J. Jaumann on infra-red absorption spectra of solids; an article by H. Krömer on his new ideas about negative effective masses in semiconductors (published in more detail in *Progress in Semiconductors*, Vol. IV); a discussion, by H. Schmidt, of some aspects of band structure, electron lattice interaction and light absorption in semiconductors; and some supplements to reports published in earlier volumes.

The present volume is a witness of a lively and penetrating approach to semiconductor problems. Although, in the first instance, a record of the semiconductor group of the German physical societies, it deserves a place among the books on solid state physics everywhere. W. EHRENBERG.

Problems in Quantum Mechanics, by I. I. GOLDMAN and V. D. KRIVCHENKOV. Pp. viii + 275. (London, New York, Paris, Oxford: Pergamon Press, 1961.) 50*s*.

The problems which are to be found at the back of Abraham and Becker's *Electricity and Magnetism* are prefaced by the phrase " Be ye doers of the word, and not hearers only, deceiving your own selves ". Anyone who has ever studied any branch of the exact sciences will appreciate the aptness of this quotation.

The book under review is an excellent translation from Russian, and consists of over 250 problems complete with their solutions. It is designed as a companion volume to the text book ' Quantum Mechanics ' by Landau and Lifshitz and covers the same ground, with particular emphasis on matrices and angular momentum. There are collections of specific problems on motion in a magnetic field, the atom, the molecule, and the scattering of a particle in a potential.

The book should be of great value both to lecturers and students. Anyone who has worked through it can be confident that he has both understood the concepts, and mastered the basic techniques, in the topics covered. One's only regret is that it does not go further, into relativistic quantum theory and elementary particle physics. Perhaps a further volume will be forthcoming.

P. T. MATTHEWS.

Quantum Mechanics, by J. L. POWELL and B. CRASEMANN. Pp. x + 495. (Reading, Massachusetts: Addison-Wesley, 1961.) 74*s*.

This book is an introduction to quantum mechanics. The early chapters are disappointing in that the approach is historical and somewhat old-fashioned, Schrödinger's equation being obtained by a heuristic argument based mainly on the phenomenon of electron diffraction. The notions of linear differential operators, eigenfunctions and eigenvalues do not appear until Chapter 6 and it is only then after 150 pages that a serious effort is made to explain what the subject is really about. Matrix operators are first introduced in Chapter 9, more than half way through the book. These essentially theoretical chapters are interspersed with fairly standard discussions of one-dimensional motion in simple potentials including the harmonic oscillator, spherically symmetrical systems, phase shift analysis, and (after the chapter on matrices) angular momentum, perturbation theory for bound states and scattering amplitudes, and finally statistics and the exclusion principle.

The best book of this type available during the last ten years has been, by common consent, that of Schiff, and when a new one appears one cannot help asking how it compares. The book as a whole does not stand up to this severe test, but there are some aspects of it which are attractive. A large number of instructive problems are included at the end of each chapter. References to other books on the various topics given at the ends of the chapters are ample and sound. There is a welcome shift towards the use of operator methods, but unfortunately no use is made of the Dirac notation.

It is a book that will be a welcome addition to a college library, but one would probably not advise a student to buy it for himself. P. T. MATTHEWS.

Diffusion and Heat Flow in Liquids, by H. J. V. TYRRELL. Pp. xii + 329. (London: Butterworths, 1961.) 65*s*.

This book is a very useful addition to the literature concerned with irreversible processes. Of particular value are the description and criticism of various experimental techniques, the detailed analysis of optical methods of measuring diffusion coefficients, and the presentation of some practical solutions to the macroscopic differential equations descriptive of the response of a liquid to thermal and mechanical forces. The author has also included a considerable amount of experimental data and has attempted to show how this data can be interpreted.

In my opinion, the treatment of the macroscopic aspects of diffusion and heat flow is excellent, but the microscopic interpretation is too conventional and, above all, too abbreviated to be adequate. For instance, more space is devoted to the well-known activated state models than to the conceptually more satisfying and much more difficult theory of Kirkwood (the ratio of space is about 8:1). To give some examples, no mention is made of the linear prediction theory and acoustic analysis of Fixman; no space is devoted to the question of how one estimates the friction constant of the molecular theory; the rigid sphere model is mentioned but not analysed in physical terms; no mention is made of the Kubo autocorrelation function formulation. While this book is clearly not intended to be a monograph in statistical mechanics, the omissions are very serious.

In general, then, Tyrrell's book will be extremely useful to those investigators concerned with measuring the diffusion coefficient, soret coefficient, etc., of a liquid but it will not help them to understand the results in terms of the current molecular theory. That such understanding is pertinent to the matters discussed is best illustrated by the use of the general statistical theory of transport to develop a quantitative theory of the heat of transport of ionic solutions (Helfand and Kirkwood). Although this work appeared too late to be incorporated into the text, it could not be fitted in unless some of the background material I have indicated was omitted were to be added. STUART A. RICE.

***Progress in Low Temperature Physics*, Vol. III, edited by G. J. GORTER. Pp. xii+495. (Amsterdam: North Holland, 1961.) 96*s*.**

After the second volume appeared in 1957, Professor Gorter wanted to return to ' pondering and reading about questions that fascinate him ' rather than edit another book. Fortunately he was persuaded of the usefulness of the series and he has again collected together review articles by a considerable number of authoritative authors. Like its predecessors, Vol. III is fairly evenly divided between the purely low temperature topics—liquid and solid helium and superconductivity—and others. While some people have been debating whether low temperature physics still exists as a subject in its own right, Professor Gorter has increased the fraction of the book devoted to helium and superconductivity to well over half.

Superconductivity is represented solely by a masterly review of recent developments by Bardeen and Schrieffer. They are at pains to discuss the meaning of the present theory as well as describing its application in the interpretation of the many properties which have now been measured. With nearly two hundred and fifty references, this chapter should become a classic in the field.

Liquid helium four is represented by ' Vortex lines in liquid helium II ' by Vinen, by ' The nature of the λ-transition ' by Buckingham and Fairbank and by ' Helium ions in liquid helium II ' by Careri. Vinen gives a very clear account of recent experiments and of their significance in a field to which he and Hall have made notable contributions. Buckingham and Fairbank have taken the opportunity of describing their recent more accurate measurements of the specific heat near the λ-point, made with Kellers, from which they derive the singular term. The behaviour of other properties is analysed, and an experiment to look for a similar specific heat singularity in a superconductor is mentioned.

The increased availability of helium three is reflected in the articles by Grilly and Hammel on ' Liquid and solid ^{3}He ' and by Taconis on ' ^{3}He cryostats'. While enough was known about the low temperature properties of ^{3}He in 1955 for an article to appear in Vol. I, ^{3}He cryostats were then only just being developed. Nuclear orientation is another subject which has advanced so rapidly that a second article is required, and the developments since the appearance of Vol. II are discussed by Huiskamp and Tolhoek.

The remaining three articles are: ' Electron resonance in metals ' by Azbel' and Lifshits, ' Solid state masers ' by Bloembergen and ' Some solid–gas equilibria at low temperatures ' by Dokoupil. One could not hope for more authoritative authors on electron resonance than two of the Russians who have contributed so much to this subject. In an extremely well produced book, it is unfortunate that the only serious misprints seem to occur in the translated details on some of their figures (z^{-1} for Oe^{-1}, N_0 for Na, and Ll-thik for Li-thick).

Although it may be difficult to write high-brow review articles which will be understandable to physicists not engaged in fields related to one's own, the present series shows what can be achieved in broadening the outlook of anyone working in one large branch of physics and having some acquaintance with the concepts used. Now that Professor Gorter has once shown that he can be forced to surrender under sufficient pressure, let us hope that he will continue to edit this series and to derive satisfaction from reading the contributions which are sent to him for further volumes. R. BERMAN.

Handbuch der Physik, Vol. III, Part 1, *Principles of Classical Mechanics and Field Theory*, edited by S. FLÜGGE. Pp. viii + 902. (Berlin: Springer, 1960.) DM 198.

The first part (225 pages) by J. L. Synge is a complete and elegant account of classical mechanics, including the dynamics of special relativity. The treatment is fairly formal, and obviously not for the beginner, but, as the latest treatise on the oldest and most important branch of applied mathematics, it will stand comparison with its many illustrious predecessors. It is noteworthy for the careful definition of the various abstract ' Spaces ' into which the analysis is extended, and for the thorough geometrical interpretations of the formulae. It seems to fulfil perfectly the role expected of such an article in the *Handbuch*.

The remainder, nearly 700 pages, is called ' The Classical Field Theories ' and is by C. Truesdell and R. Toupin, with an appendix on ' Tensor Fields ' by I. L. Ericksen. This is certainly an unusual work. Not only does it deal with the basic theory of elasticity and hydrodynamics, but also presents an analysis of thermodynamics, and of electromagnetism. These topics are seen entirely from a formal mathematical point of view, as examples of special kinds of tensor fields subject to the fullest rigour of definition and abstraction; every result is proved in the most general form, and only explained in more familiar terms as a trivial special case. Although this abstract mathematical point of view is a perfectly proper and valuable attitude towards physics, it is rather startling to find it carried through with such ruthlessness and erudition over such a wide field. The authors have tried to restate and prove (or, in some cases disprove) every theorem of importance that can be found in the literature, going back more than two centuries for some of their references. They propose quite frankly, to replace some of our crude old-fashioned rules, like Maxwell's equations or the Laws of Thermodynamics, with their own more general principles based upon a more critical study of the mathematical possibilities. In many cases they claim, quite rightly, that the complete account which they give has never been attempted before, so that their work is, in this sense, of the highest originality and interest. I think, myself, that they overrate the importance of mathematical rigour, especially of the algebraic kind, and betray a lack of intuition for the synthetic, geometrical type of proof (how can they write on such a subject at such length with only about one figure per 14 pages of text?) which has always been more fruitful of *new* ideas than the analytical approach. But, as an attempt to reduce all known classical physics to the most abstract and elementary mathematical statements, this book is likely to be extremely valuable as an authority and as a source book, for years to come. The historical notes alone (our old friend Stokes' theorem is really due to Kelvin; or shouldn't it be Thomson, as in 1850 he then was!) are excellent.

It is most unfortunate that such an idiosyncratic work should be published as part of an encyclopaedia. It is too big, and cuts across too many boundaries. The reformulation of Thermodynamics, for example, with entropy as the independent field variable in place of temperature, should have been in Volume III, Part 2. It is a pity that the editor did not, in this case as in others in this series, insist on closer conformity to the general scheme—or else bring all the other contributors into step.

Another reason why Professor Truesdell and his collaborators would have done better to have this work published elsewhere as a separate book is that I calculate that it could then have been sold for about £8, which would have brought it just within the reach of the ordinary individual applied mathematician or theoretical physicist. At the monstrous price of £18 (according to the current rate of exchange) it will be purchased only by libraries, where it will not have the circulation and influence that it deserves. The new edition of the *Handbuch der Physik* has some good things in it, but it is certainly not worth twice as much per word and symbol as ordinary treatises and textbooks. J. M. ZIMAN.

Field Theory for Engineers, by PARRY MOON and DOMINA E. SPENCER. Pp. ix + 530. (Toronto, New York, London, Princeton, New Jersey: Van Nostrand, 1961.) 96*s*.

The purpose of the book is stated by the authors to be the application of boundary value techniques to engineering. The field theory approach is dealt with by the technique of separation of variables, and it is thought that this method is of most use for applications of this kind.

Chemical Crystallography, by C. W. BUNN. Pp. xiii + 509. (Oxford: Clarendon Press, 1961.) 60*s*.

This is the second edition of a book first published in 1945. Its scope is essentially the same as that of the first edition, but there are several additions and alterations: these are chiefly in the latter part of the book which is expanded to cover important recent developments in the various methods of structure determination, especially direct experimental methods involving heavy atoms and the use of anomalous scattering effects to determine the phases of different x-ray beams, and indirect interpretative methods involving the concept of the molecular transform.

The Mathematical Theory of Relativity, by A. S. EDDINGTON. Pp. ix + 270. (Cambridge: University Press, 1961.) 16*s*.

The Mathematical Theory of Electricity and Magnetism, by SIR JAMES JEANS. Pp. vii + 652. (Cambridge: University Press, 1961.) 25*s*.

The Mathematical Theory of Non-uniform Gases, by S. CHAPMAN and T. G. COWLING. Pp. xxiii + 431. (Cambridge: University Press, 1961.) 17*s*. 6*d*.

These three further reprints, at a very reasonable price, of some of the classics of physics are a welcome issue from the Cambridge University Press. They will be most valuable to students in these days of expensive textbooks.

The Collected Works of Irving Langmuir, edited by GUY SUITS (Oxford, London, New York, Paris: Pergamon Press, 1961.) £5 per Vol.

The Collected Works of Irving Langmuir are to be published in twelve volumes. Each volume covers one or more subjects in which Langmuir was interested and contains reprints of papers which he had published in the various scientific journals. Four volumes have been published to date: Volume 3, *Thermionic Phenomena*; Volume 4, *Electrical Discharge*; Volume 5, *Plasma Oscillations*; Volume 6, *Structure of Matter*.

In Volume 12 there is to be a survey of Langmuir's career as a whole; it is of interest that his creative work covered a very wide range of years. Irving Langmuir was the first American industrial scientist to receive a Nobel prize; he was associated with the General Electric Research Laboratory for nearly fifty years.

1961—VOL. 78

SUBJECT INDEX

PAGE

Abrasion in plastically deformable non-metals 979
Absorption edge, optical, of GaAs (L) 615
Absorption of coesite in wavelength region 5–22 microns (L) 1260
Absorption spectrum of BaO found in shock excitation 705
Absorption spectrum of BiF molecule, ultra-violet 610
Absorption spectrum, ultra-violet, of indium vapour, extension of series . . 600
Absorption, ultra-violet and visible, of gaseous ozone 932
Absorption, *see also under* Electron spin resonance
Air showers, electron density spectrum at high densities 103
Alloys, Al–Mn, low temperature specific heat 1489
Alloys, dilute Ag–Mn, Lorenz parameter at liquid helium temperatures . . 1361
Alloys, GaSb–InSb, temperature variation of optical energy gap 354
Alloys, InAs–In_2Se_3 and InSb–In_2Se_3, electrical and optical properties . . 1009
Alloys, Ni–Fe, preparation of continuous single-crystal thin films . . . 33
Alloys of high purity iron, internal friction measurements and grain boundaries . 1529
Alloys, Pt–Co, ordered, domain structure 225
Alloys, U–Nb, electrical and magnetic properties 361
Alloys, U–Zr, electrical and magnetic properties of γ and δ phases . . . 722
Alpha particles, range–energy relations and stopping power for ethyl alcohol and CCl_4
  in liquid and vapour states 766
Alums, ferric, zero-field paramagnetic resonance 812
Anisotropy in electric strength of alkali halide crystals (L) 1261
Anisotropy of electrical conductivity in Bi_2Te_3 838
Anisotropy, magnetic, *see* Magnetic anisotropy
Anisotropy, magnetocrystalline, and coercivity in square-loop ferrite material . . 819
Antiferromagnetic resonance in extreme infra-red (L) 774
Apparatus, linear, correction of signal distortion 1546
Arc discharge, post-arc temperature decay 948
Argon, liquid, electric strength, influence of cathode and anode surfaces . . 448
Argon, thermodynamic properties 1449
Atomic spectra, isotope shift in CdI resonance line 2288 Å 1304
Atoms, impact excitation, schematic model 661
Auger effect in semiconductors, phonon-assisted 204

Band spectra, emission, O_2 Schumann–Runge 1024
Band spectra of BiF and SbF (L) 614
Band spectra, rotational analysis of E–X system of silicon monosulphide . . . 1307
Band spectra, second negative system of oxygen, new bands (L) 1074
Band spectrum, triplet, of CO molecule, Franck–Condon factors and *r*-centroids . 399
Band spectrum of CuAg molecule in visible region 197
Band spectrum, *see also* Absorption spectrum
Band structure, electronic, of model of cubic crystal 1195
Band structure of body-centred cubic transition metals 1321
Berthelot tubes, tensile strength of liquids in 133
Beta decay, Fierz interference term for Gamow–Teller decay of ^{58}Co . . . 1056
Biphenyl negative ion, narrowing and broadening of spectrum 370
Bismuth telluride, anisotropy of electrical conductivity 838
Breakdown, *see under* Ionization
Breakdown, electrical, *see* Electrical breakdown
